INFORMATION FOR CONTRIBUTORS

Suggestions for Contributors

Send manuscripts to Elmer Hutchisson, Case Institute of Technology, Cleveland 6, Ohio. Textual material (abstract, the body of the paper, tabular material, references, and figure captions) must be in English, typewritten (except mathematical expressions) double spaced with wide margins on a durable, white paper, preferably letter size. The original copy, not the carbon, should be submitted. For general style, spellings, abbreviations, and form, consult recent issues of this journal. Authors' institutions are requested to pay a publication charge of $8 per page which entitles them to 100 reprints without further charge.

An **abstract** must accompany each article. It should be adequate as an index and as a summary.

All but the simplest **mathematical expressions** should be carefully printed in by hand. Be sure to distinguish between capital and small letters. Indicate clearly superscripts and subscripts by inverted carets and carets, respectively. Avoid complicated superscripts and subscripts. Avoid repetition of a complicated expression by representing it by a symbol. Identify in the margin Greek letters and unusual symbols. Use fractional exponents instead of root signs. Use the solidus (/) for fractions wherever its use will save vertical space.

References should appear as footnotes, numbered consecutively, and arranged thus:

[1] A. B. Smith, Phy. Rev. 41, 852 (1932).
[2] H. Lamb, *Hydrodynamics* (Cambridge University Press, Teddington, England), sixth edition, pp. 573, 645.

Tables may be typewritten on sheets separate from the running text. Each table must have a caption which will make the data in the table intelligible without reference to the text. Avoid complicated column headings.

Wherever possible **figures** should be planned for the width of a column (3 in.). A convenient reduction ratio is about 2:1 or 3:1. Lettering should be large enough on the original that when reduced it shall not be less than about $\frac{1}{16}$ in. ($\sim$1.5 mm). Line drawings must be in *India ink* on white paper or tracing cloth. Coordinate paper is not desirable but if used must be blue lined and the coordinate lines which are to show must be inked over. Photographs should have maximum black and white contrast.

Identify each original drawing or photograph on the back with the author's name and the figure number. Figures should be numbered consecutively. Captions should be typed on a separate sheet of paper.

A limited number of **alterations** in proof are unavoidable, but the cost of making extensive alterations after the article has been set in type will be charged to the author.

Proof and all correspondence concerning papers in the process of publication should be addressed to the Publication Manager, American Institute of Physics, 57 East 55 Street, New York 22, New York.

INFORMATION FOR SUBSCRIBERS

The JOURNAL OF APPLIED PHYSICS is devoted to physics in its role as the science basic to other natural sciences and to the arts and industries. Previous to 1937 this publication was known as PHYSICS. It aims to be of service not only in physical laboratories, but also in the laboratories of industrial, chemical, geological, geophysical, meteorological, radio, and similar concerns. The JOURNAL OF APPLIED PHYSICS publishes editorials and reviews, as well as technical papers of applied physics.

Subscriptions and orders for back numbers should be addressed to the American Institute of Physics, 57 East 55 Street, New York 22, N. Y.

Thermionic Work Function of the (100) Face of a Tungsten Single Crystal

A. A. Brown,* L. J. Neelands,** and H. E. Farnsworth
Department of Physics, Brown University, Providence, Rhode Island
(Received July 5, 1949)

A slab with one surface cut and etched parallel to (100) crystallographic planes formed the cathode in a low power electron microscope. The electron image of the cathode was formed on a fluorescent screen with a small hole at the center. An electron collector placed behind the hole permitted a measure of the electron current passing through the hole as a function of the temperature of the cathode as measured with an optical pyrometer.

The most probable value of the work function, φ, obtained after 2400 hours of outgassing in a sealed-off, gettered tube is 4.59 ± 0.02 ev. This may be compared with 4.56 ev obtained previously by Nichols for the work function in the [100] direction of a tungsten single crystal wire.

INTRODUCTION

It is now quite well established experimentally that the work function of a metal single crystal is a function of the crystallographic plane which forms the surface boundary, although the amount of reliable experimental data is still very small. Some theoretical treatments[1] have been published but more experimental data are needed to check the validity of any satisfactory theory. Most of the previous measurements have been made photoelectrically or by means of contact potential differences, although Nichols[2] has obtained thermionic values for tungsten characteristic of certain crystal directions from measurements on a single crystal filament. Because these values may differ from those characteristic of the crystallographic planes of the same Miller indices, we have made measurements which are characteristic of the crystal planes. The (100) and (110) faces were chosen since they are the ones which appear most readily as a result of the heat treatment that tungsten filaments receive in use.

PREPARATION OF THE CRYSTAL

The crystal[3] was cut parallel to a specified set of crystal planes with an error of less than 0.05°, using a diamond wheel, and optical arrangement for alignment. The cutting marks left in the crystal surface by this method were removed by hand grinding. The resulting surface was substantially free of voids.

Attempts to remove the disturbed surface layer were made by (1) chemical etching with a number of different reagents and various conditions of temperature and concentration, (2) electrolytic etching, and (3) heat treatment. No single reagent or etching condition was found to expose smooth plane surfaces parallel to only one set of crystallographic planes. A (110) surface was prepared by first obtaining a good electrolytically polished surface,[4,5] and then heating the crystal, by electron bombardment of the back surface, at 2600°K. The resulting single crystal surface was quite smooth except for a few small pits corresponding to the natural voids of the crystal. A (100) surface was similarly prepared and heated to 2600°K for 100 hours. The resulting surface, although as smooth as the prepared (110) surface, was slightly more pitted. However, even in

this case the pits covered only a very small fraction of the total area.

Two slabs with sides parallel to the (100) and (110) crystallographic planes respectively were cut from a large single crystal; these were cut to a size of 8×5×1 and 8×4×1 mm, respectively. One edge of each was beveled at an angle of 45° so that when the two were placed with the beveled edges together there resulted a slab 8 mm square and 1 mm thick with a division line between the (110) and (100) faces across the front. These were then ground and polished as described above.

The advantage of studying the two faces chosen is due to the fact that while the (110) surface appears most readily upon heat treatment,[6,7] the (100) face appears to have the lower work function[2,8] so that small pits showing other faces will not affect appreciably any observed current readings.

APPARATUS

A schematic diagram of the experimental tube is shown in Fig. 1. The crystals formed the cathode, Q, of a low power electron microscope. They were heated by electron bombardment from the filaments at P. The electrons emitted from the front surface were

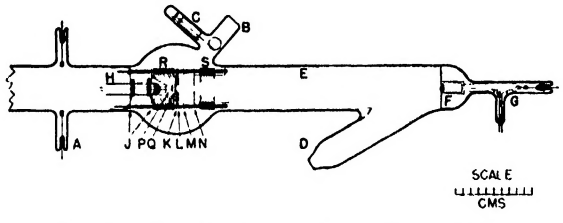

FIG. 1. Schematic diagram of experimental tube.

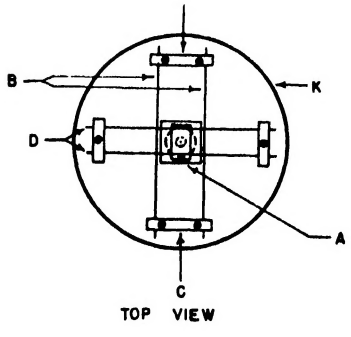

FIG. 2. Diagram of crystal mounting.

focused by means of the electrostatic lenses, L, M, and N, on the fluorescent screen and collector system, F. The temperatures of the crystals were measured by means of an optical pyrometer sighted through the side tube, B. In this tube a magnetically controlled shutter, C, prevented tungsten from depositing on the window at high crystal temperatures when readings were not being taken. The image could be deflected on the screen by a magnetic field and the emission current measured from any portion of either face by means of a Faraday collector placed behind a small aperture in the screen. R and S were guard rings used to prevent the passage of electrons from the bombarding filaments to the collector.

The crystals were attached to the diaphragm, K, by means of 0.5-mm tungsten wires passing through grooves in the backs of the crystals. A piece of 5-mil tungsten wire bent to form a 7-mm square was placed between the crystals and the diaphragm to decrease the heating of the diaphragm. During the later part of the work only one crystal was used. Consequently, the crystal mounting was changed to that shown in Fig. 2. In this mounting the heating of the diaphragm, K, was further decreased by interposing the small tungsten square A between the crystal and the diaphragm. This square was separated from both the crystal and the diaphragm by rectangles formed of 5-mil tungsten wire. The magnification produced by the electrostatic lenses was about ten.

The major part of the glass envelope is shown in Fig. 1. All glass and metal parts were thoroughly cleaned, in boiling dilute sodium hydroxide, in chromic acid, and rinsed in distilled water. The entire assembly was carried out using clean tools and sterile cotton gauze. No part was touched by the hands after being cleaned and a gauze mask was worn to prevent breathing on the parts.

Between the pumps and the experimental tube, and between the diffusion pumps and the fore pump, were traps cooled by dry ice and acetone. The tube, after being evacuated, was baked for two 24-hour periods. Between these bakings the crystals were heated 170 hours at a temperature of 1500°C. Just before the second baking, the trap between the pumps and the experimental tube was warmed to room temperature to remove any condensed vapors. After the second baking the ionization gauge indicated a pressure of 1.5×10^{-8} mm of Hg with the crystals cool and 6×10^{-8} mm of Hg with the crystals at a temperature of 1750°C. After an additional 380 hours of outgassing with the crystals at 1750°C, the first getter was flashed and the tube sealed off. Following this the pressure did not rise above 4×10^{-8} mm of Hg with the crystals at 1750°C and after 1500 hours of outgassing at this temperature it did not rise higher than 1.5×10^{-8} mm of Hg. The flashing of the second getter at this time did not cause any detectable change in the vacuum conditions.

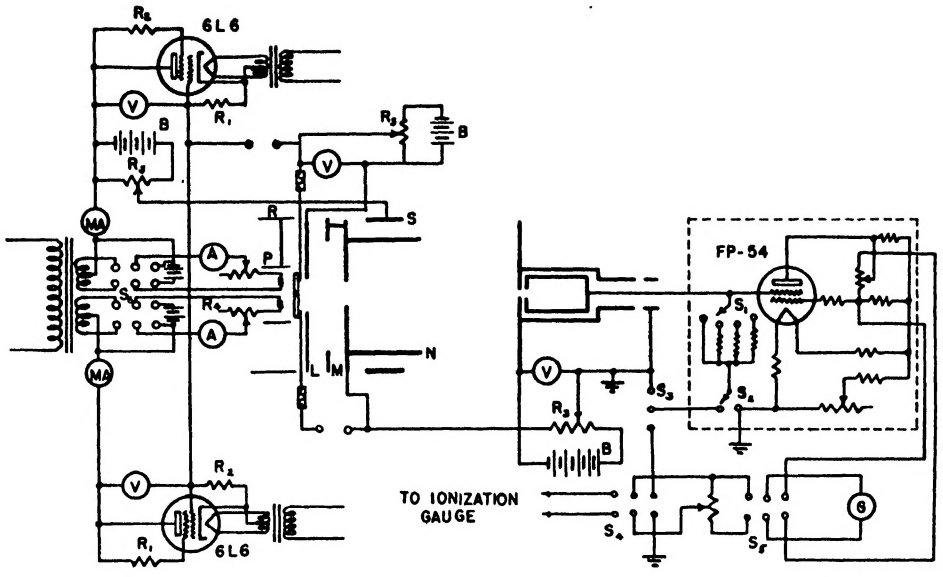

FIG. 3. Wiring diagram of the electrical circuit.

An optical pyrometer of the disappearing filament type was used to measure the temperature of the crystal surfaces. Experience indicated that even at temperatures as high as 2300°C, settings by different operators could be made as close as 2°C. The pyrometer was calibrated against a standard lamp obtained from the Bureau of Standards. The true temperature of the crystals was obtained from the brightness temperature by using the Wien equation and the value of the emissivity of tungsten obtained by Wahlin and Whitney[9] who found it constant and equal to 0.46 in the temperature range from 1200 to 2200°C at a wave-length of 6900A. Another correction was necessary due to reflection at the Pyrex window through which readings were taken. This correction was based on the work of Benford.[10]

A wiring diagram for the complete electrical circuit is shown in Fig. 3. The measuring system consisted of a d.c. amplifier and a galvanometer. This permitted the measurement of currents from 10^{-4} to 10^{-14} ampere.

PROCEDURE AND RESULTS

Measurements were started after 75 hours of heating and continued until the crystal had been degassed 2400 hours. All of the degassing except the first 240 hours was carried out at a temperature of 1750°C. The image was in focus when an accelerating potential of 2500 volts and a focusing potential of −200 volts with respect to the crystal were used. A retarding potential of 230 volts on the collector was sufficient to keep out the secondary electrons.

After the tube had been in operation for some time, evidence was obtained that some of the bombarding electrons were passing between the crystals and into the collector. This made measurements below 1300°C impossible. When a short circuit developed in the tube and made a reassembly necessary, the crystal mounting was redesigned and only one crystal with the (100) face was used. Consequently the measurements on the (110) face are of qualitative significance only, since they were taken before the most favorable conditions were obtained. The discussion which follows pertains only to the later work on the (100) face.

The measurements of the emission current and temperature were fitted to the formula

$$i = AT^2 \exp[-(\varphi/kT)]. \quad (1)$$

The value of φ was determined from the slope of the experimental curve obtained by plotting $\log i/T^2$ against $1/T$. It was not possible to calculate A since it was not ascertained that all of the electrons from the crystal passed through the various apertures.

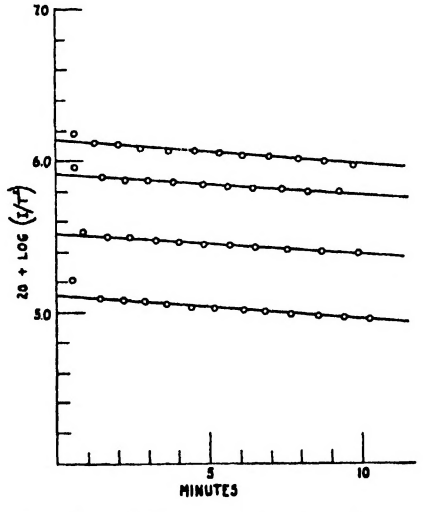

FIG. 4. Plot of $\log(i/T^2)$ against time elapsed after flashing the crystal at 2650°K for 15 seconds.

[9] Wahlin and Whitney, Phys. Rev. **50**, 735 (1936).
[10] F. Benford, J. Opt. Soc. Am. **29**, 162 (1939).

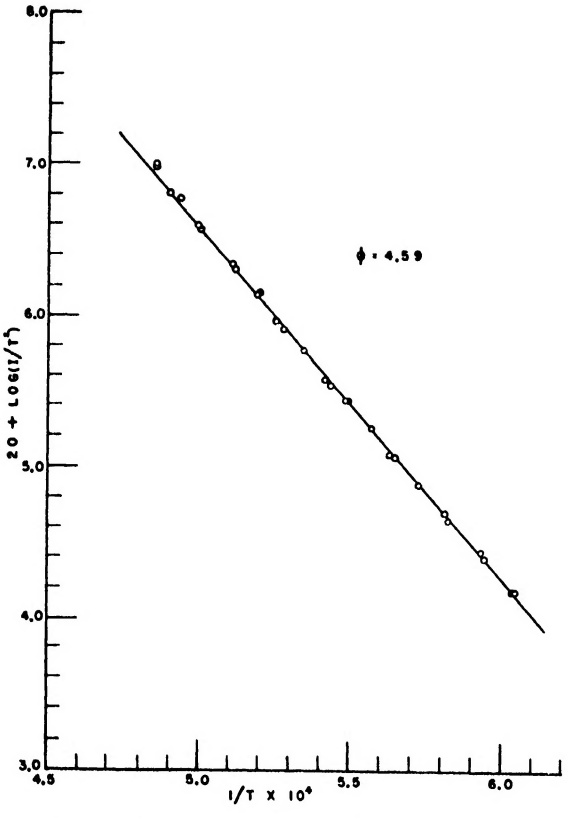

FIG. 5. A typical Richardson graph after 2000 hours of outgassing.

After about 900 hours of heating, the gas pressure as indicated by the ionization gauge did not continue to decrease with outgassing time and the procedure was adopted of flashing the crystal a short time at a temperature of 2650°K to obtain an uncontaminated surface. It was found that a flashing time of 5 sec. or longer resulted in a maximum emission current, and that a flashing time of 30 seconds did not increase the gas pressure over 4×10^{-8} mm of Hg. Consequently a flashing time of 15 seconds was used. Since the crystal surface became contaminated again in less time than was needed to complete a set of measurements, it was necessary to flash the crystal and then follow the emission current as a function of time and extrapolate back to zero time to obtain the values corresponding to the uncontaminated surface. The log i/T^2 was plotted which resulted in a set of straight parallel lines as shown in Fig. 4. The first one or two points are high in each case, since the measurements were made before the crystal had cooled to the desired temperature. This procedure was adopted after about 1000 hours of outgassing. The value of φ was then 4.77 ev. During the next 1000 hours of heating, the value decreased to 4.59 ev. It remained constant at this value until the work was ceased after a total outgassing time of 2400 hours. A typical plot, taken during the last 400 hours, is shown in Fig. 5.

For greatest accuracy, account should have been taken of the effect of the electric field at the crystal surface on the value of the work function. That is, every value of the current should have been corrected to the corresponding zero field value by using the relation

$$i_v = i_0 \exp(SV^{\frac{1}{2}}/T), \tag{2}$$

where i_v is the high field current; i_0 is the zero field current; V is the accelerating potential; and S is a constant which depends on the geometry of the apparatus. Equations (1) and (2) may be combined to give

$$i_v = AT^2 \exp[(\varphi - \Delta\varphi)/kT], \tag{3}$$

where $\Delta\varphi$, the correction due to the field, is given by

$$\Delta\varphi = KSV^{\frac{1}{2}}. \tag{4}$$

The configuration of the electric field in the microscope was such that the field was very low at the crystal surface and it was believed that no correction would be necessary. To confirm this, measurements of φ were made with the accelerating (and focusing) voltage varied by a factor of two. The values checked within the experimental error. It was found impractical to measure S by measuring i_v as a function of the accelerating potential at a constant crystal temperature, since this temperature could not be held constant for the length of time needed to complete a set of measurements.

CONCLUSIONS

The most probable value of φ for the (100) surface, obtained after 2400 hours of outgassing, was found to be 4.59 ± 0.02 ev. This is believed to be characteristic of the uncontaminated crystal surface. This checks well with the value of 4.56 ev obtained by Nichols[11] for the [100] direction. No definite value was obtained for the (110) face but the early results indicate that φ for this face is higher than φ for the (100) face. This is also true of Nichols' results for the [110] direction.

[11] The values of φ first published by Nichols are 0.03 ev to low due to a numerical error. Corrected values are given in Rev. Mod. Phys. **21**, 202 (1949).

Interference of Growing Spherical Precipitate Particles*

C. WERT AND C. ZENER
Institute for the Study of Metals, University of Chicago, Chicago, Illinois
(Received June 27, 1949)

The exact theory of the rate of growth of spherical precipitate particles has previously been developed for the initial stage where the individual precipitate particles do not interfere with one another. In the present paper this theory is carried one stage further to include their mutual interference. It is found that in the particular case of a very dilute solution this interference may be accounted for in a relatively simple manner. The applicability of the theory has been tested by new observations upon the precipitation of carbon from α-iron. Good agreement is found up to 95 percent completion of precipitation.

A. INTRODUCTION AND RESULTS

ONE of the authors (C. W.) has recently studied the rate of precipitation of carbon from freshly quenched α-iron.[1] From the observation that during the initial stage of precipitation the fraction of precipitation completed, W, obeys the equation

$$\tau dW/dt=(\tfrac{3}{2})(t/\tau)^{\frac{1}{2}}, \tag{1}$$

where τ is a constant, he concluded (a) that the growth nuclei were already present when the material was first quenched; (b) that the precipitate particles started as small spheres and remained spherical in shape throughout their growth. During the later stages of precipitation the growth of each precipitate particle is impeded by the general depletion of carbon in the surrounding matrix. An attempt was made to take account of this mutual interference of precipitate particles by the arbitrary introduction into the right side of Eq. (1) of an "interference factor" $(1-W)$. The observations were found to be in fairly good agreement with the resulting equation, namely,

$$\tau dW/dt=\tfrac{3}{2}(1-W)(t/\tau)^{\frac{1}{2}}, \tag{2}$$

which, when integrated, becomes

$$W=1-e^{-(t/\tau)^{\frac{3}{2}}}. \tag{3}$$

In spite of the fair success of this formula, the authors were unsatisfied with its heuristic derivation, and have since placed the theory of interference upon a firmer foundation. This new theory is developed in Section B. Experiments have been made to test the applicability of this theory to the particular system of carbon precipitating from solid solution in α-iron. These experiments are presented in Section C.

The results of the analysis of Section B may be presented in a simple form. Toward this end we rewrite Eq. (1) in the equivalent form

$$\tau dW/dt=\tfrac{3}{2}W^{\frac{1}{3}}. \tag{4}$$

It is then found that in the particular case of a very dilute solution the mutual interference of growing precipitate particles is properly taken into account by multiplying the right side of Eq. (4) by the interference factor $(1-W)$. The governing equation is, therefore, found to be

$$\tau dW/dt=(\tfrac{3}{2})(1-W)W^{\frac{1}{3}}. \tag{5}$$

While the original Eq. (2) can be directly integrated, the authors have been unable to integrate Eq. (5) analytically. However, W is a unique function of t/τ, and this function may be found by numerical integration. The results of such an integration are presented in Figs. 1 and 2. In these same figures a comparison is made with the solution of the original Eq. (2). It is seen that while both methods of taking interference into account lead to essentially the same results during the early stages of precipitation, they lead to markedly different results during the later stages. The very close agreement of the present theory with the observed precipitation is shown in Fig. 3. Tentative reasons for the deviations in the very last stages of precipitation are discussed in Section C.

B. ANALYSIS

The rate of growth of a spherical precipitate particle is completely determined by the gradient in concentra-

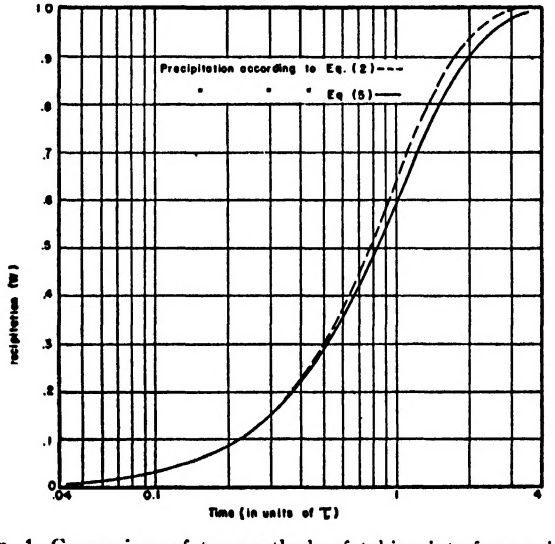

FIG. 1. Comparison of two methods of taking interference into account, standard coordinates being used.

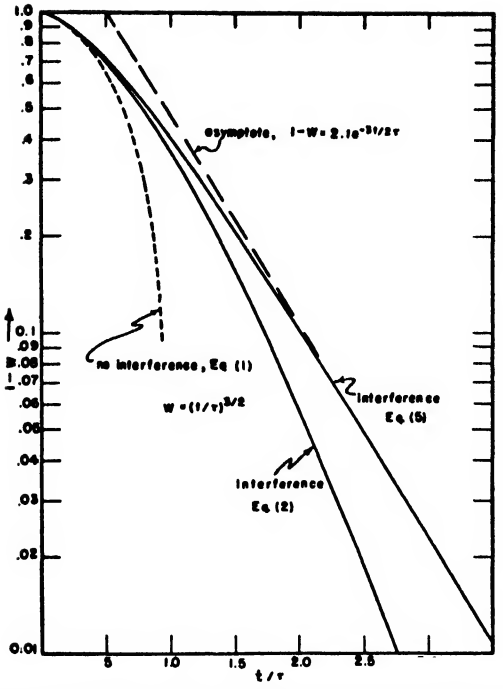

FIG. 2. Comparison of two methods of taking interference into account, coordinates being used which emphasize later stages of precipitation.

tion in the matrix adjacent to the particle. We shall let $n(r, t)$ denote the concentration of solute atoms in terms of number of atoms per unit volume. The value of n in the precipitate will be denoted by n_0, and the boundary value of n in the matrix at the precipitate-matrix interface will be denoted by n_1. The rate of growth is then given by

$$(n_0-n_1)(dV/dt)=4\pi R^2 D(\partial n/\partial r)_{r=R}, \qquad (6)$$

where V and R are the volume and radius of the particle, respectively, and D is the diffusion coefficient of the solute atoms. In the particular case of a very dilute solution the particle grows so slowly that the growth rate itself has a negligible effect[2] upon the gradient $(\partial n/\partial r)_{r=R}$. We may thus assign this gradient the steady-state value it would approach if the radius were to remain constant. The steady-state solution of the diffusion equation in the case of a fixed radius R is

$$n(r)=n_\infty-(n_\infty-n_1)(R/r),$$

and hence we shall equate the concentration gradient at the boundary to

$$(\partial n/\partial r)_{r=R}=(n_\infty-n_1)/R. \qquad (7)$$

This gradient is fortunately quite insensitive to the precise manner in which we specify the boundary conditions far away from the particle. The gradient is, e.g., not appreciably altered if we specify that the concentration be n_∞ at some radius R_∞ very large compared to R, or if we specify that $\partial n/\partial r$ vanish at some radius R_∞ large compared to R. In the later case n_∞ will be the concentration at R_∞, and will gradually decrease with time.

The assumption of a very dilute solution enables us to make one further simplification. In this case the precipitate particles will be relatively far apart, so that essentially each precipitate particle is surrounded by a concentration field which approaches the average concentration $n_\infty(t)$ as we go away from the particle in any direction. In the case of a dilute solution this average concentration is related to the fraction W of the precipitation which has already occurred by the equation

$$\{n_\infty(t)-n_1\}/\{n_\infty(0)-n_1\}=1-W. \qquad (8)$$

If we now let R_0 denote the final radius of the precipitate particles, corresponding to complete precipitation, and observe that

$$W=(R/R_0)^3, \qquad (9)$$

we find that substitution of Eqs. (7) and (8) into Eq. (6) leads to Eq. (5) of Section A, with the time of relaxation τ given by

$$\tau=[\{n_0-n_1\}/\{n_\infty(0)-n_1\}]R_0^2/2D. \qquad (10)$$

This time of relaxation may be expressed in alternative forms through the introduction of the density of precipitate particles, N, i.e., their number per unit volume, which satisfies the relation

$$(4\pi/3)R_0^3N(n_0-n_1)=n_\infty(0)-n_1. \qquad (11)$$

We have implicitly assumed that all the precipitate particles attain the same final radius. In accordance with the empirical observations of one of the authors,[1] it is legitimate, at least in the case of carbon in α-iron, to assume that all the precipitate particles start growing at the same time, namely, at the instant of quenching. It might appear, however, as if fluctuations in the density N would be reflected as fluctuations in the final radii. In order to demonstrate the invalidity of this objection in the case of very dilute solutions we shall eliminate the concentration from Eq. (10) by use of the relation (11), thereby obtaining

$$\tau=3/(8\pi NR_0D).$$

If we now introduce a measure λ of the mean distance apart of the precipitate particles by the definition

$$N=\lambda^{-3},$$

we obtain

$$\tau=(3\pi\lambda/8R_0)(\lambda^2/\pi^2D).$$

The second factor is seen to be the time of relaxation τ_λ for the smoothing out of fluctuations in concentration over a distance λ. Under our assumption of a very dilute solution the first factor is a very large number, and hence τ is very long compared to τ_λ. Thus although those regions in which N is unusually large will suffer an unusually rapid rate of precipitation, the excess

[2] C. Zener, J. App. Phys. **20**, 962 (1949).

rate of depletion of the solute atoms will, to a large extent, be compensated by the long range diffusion of solute atoms from surrounding regions. The average concentration $n_\infty(t)$ will thus remain almost constant in spite of possible fluctuations in N.

In order to have a formula whereby we may calculate N from an empirical value of τ, we eliminate R_0 from Eqs. (10) and (11), therby obtaining

$$N=(\tfrac{3}{4}\pi)2^{-\frac{1}{2}}[(n_0-n_1)/\{n_\infty(0)-n_1\}]^{\frac{1}{2}}(D\tau)^{-\frac{3}{2}}. \quad (12)$$

C. EXPERIMENT

The experiments made to test the validity of the foregoing analysis were carried out in a manner nearly the same as that described in an earlier paper by one of the authors.[1] The apparatus for preparing the specimens and making the internal friction measurements was that used previously. The only real difference between the past and present work is that the earlier work placed emphasis on the initial part of the precipitation process, whereas the present experiments emphasize the latter part of the process.

Precipitation measurements were carried out in the temperature range 85°C to 210°C. These measurements are compared with the theoretical curves in Fig. 3. In this figure the times τ' and τ (which differ only slightly) refer to the time constants of Eqs. (2) and (5) respectively. These constants τ' and τ were so chosen for each temperature that the experimental points coincided with the theoretical curves when the precipitation was about 60 percent complete. In order that simultaneous comparison could be made between experiment and the two theoretical curves, the scale factors for the two equations were so chosen as to make the curves coincide at 60 percent precipitation. It is clear from these plots that the theory deduced in the preceding section fits the experimental facts much better than the treatment expressed by Eq. (2). The experimental points show good agreement with Eq. (5) up to about 90 percent to 95 percent of the total precipitate.

The reason for the discrepancy during the last 5 percent of the precipitation is not known definitely. A possible reason is lack of homogeneity of the initial

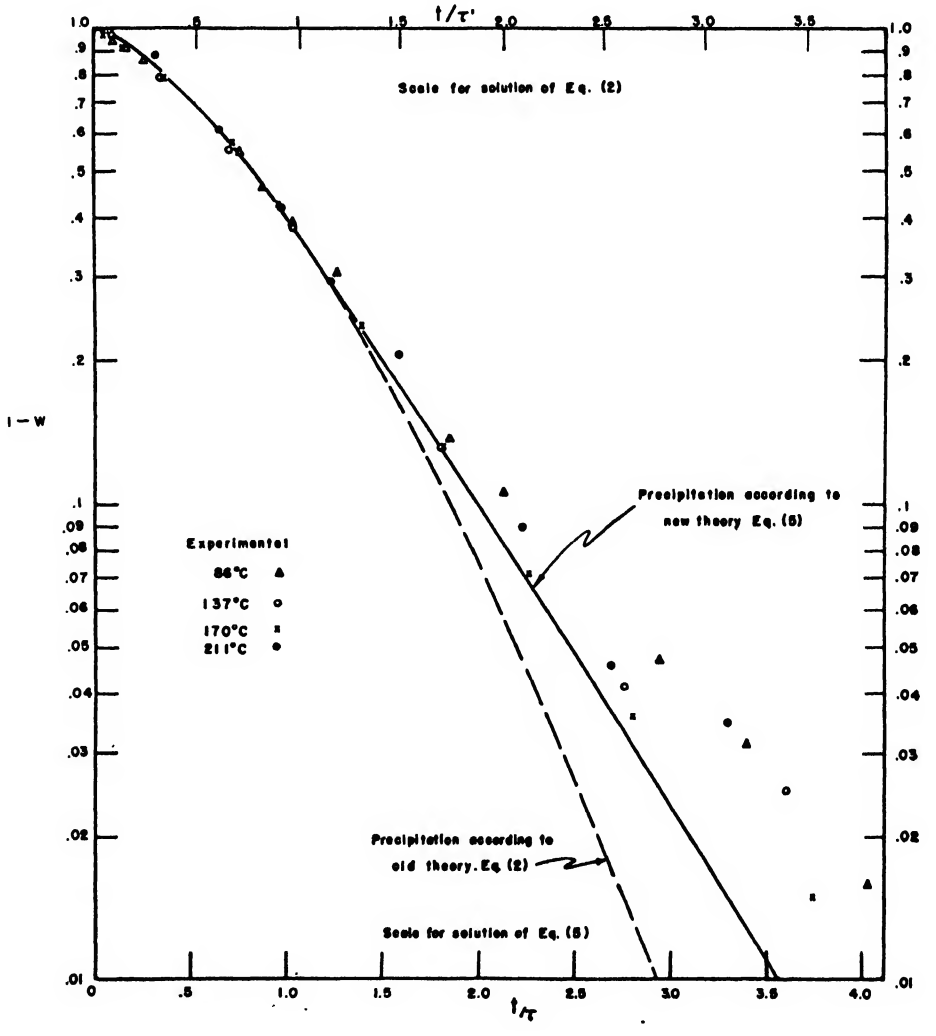

FIG. 3. Comparison of experiments with theory.

TABLE I.

Temp. °C	$n_\infty(0)$ (wt. percent)	τ(sec.)	N/cc
86	0.016	79000	39×10^{12}
137	0.013	3500	26×10^{13}
170	0.018	700	17×10^{13}
211	0.012	190	9×10^{13}

solid solution of carbon, which results in a range of values for τ. It was observed that specimens which were carburized without a long homogenization anneal gave very erratic and nonreproducible data. Further, the data on such specimens deviated from Eq. (4) as early as the 75 percent point of the total precipitation. When such a specimen was homogenized by an anneal of several hours at 720°, much more reproducible data were obtained. All the data shown in Fig. 3 were made on specimens which had been given such an anneal, and still longer anneals gave no improvement in the fit of the data to Eq. (4). However, it seems possible that slight inhomogeneities might still exist which would be large enough to account for at least a part of the discrepancies observed. A second possibility is the binding of dissolved carbon atoms to each other, to other dissolved impurity atoms or to lattice imperfections. That this binding may occur was observed experimentally earlier by the authors.[3]

Through the use of Eq. (12) and the experimentally determined values of τ, one can calculate the number of particles of precipitate per unit volume formed at a given temperature. Table I shows the result of such calculations. The values of N computed in this way are roughly the same as those computed earlier by the authors.[1,2]

The Response Characteristics of Linear Systems

MARCELLO CINI
Riv, Officine di Villar Perosa, Turin, Italy
(Received May 26, 1949)

For a linear system, steady-state response to sinusoidal stress cannot have a unique dynamic modulus and phase shift, but these quantities must be related to rate of creep; particularly they cannot be independent of external frequency.

A proof is given that such linear system is always equivalent to a viscoelastic system. Finally the discrepancy between the relations deduced and experimental results of various authors is pointed out and discussed.

ALTHOUGH hysteretic and elastic properties of rubber-like materials have been thoroughly investigated in the last years, no theory in good agreement with experimental results has been developed, at least as far as the author knows.

On one hand, very general and important results have been reached in the study of viscoelastic systems,[1–6] pointing out the various relationships which allow prediction of their behavior under given conditions of stress or strain; on the other hand many reports[7–14] have been published illustrating tests carried out on different stocks of natural and synthetic rubbers, and giving the derived values of dynamic modulus, loss factor, rate of creep and relaxation and similar quantities. In the present paper linear systems* will be examined from a very general point of view, and some fundamental properties of the response will be established, by means of which it is easy to prove that the most general linear system is equivalent to a viscoelastic model.**

Finally some experimental results of the above-mentioned papers are discussed using the derived relations and pointing out some reasons for the observed contradictions.

1. LINEAR SYSTEMS

We will assume as a fundamental property of a linear system that the steady-state response to a sinusoidal stress

$$P(t)=P_0e^{i\omega t}$$

[14] Mooney, Wolstenholme, and Villars, J. App. Phys. **15**, 394 (1944).

* All the following considerations hold as well for electric, acoustic or dielectric systems.
** This identity is also implicitly proved in the papers of Alfrey and Doty (reference 3) and Gross (references 5 and 6.)

be still sinusoidal and given by

$$y(t)=[P_0/E(\omega)]e^{i(\omega t-\varphi(\omega))}.$$

If the sinusoidal stress is given in real form

$$P(t)=a\cos\omega t+b\sin\omega t$$

the response will be

$$y(t)=[a/E(\omega)]\cos(\omega t-\varphi(\omega))+[b/E(\omega)]\sin(\omega t-\varphi(\omega)).$$

As is well known $E(\omega)$ is the dynamic modulus, and $\varphi(\omega)$ the phase shift, both functions of the external frequency ω: $E(\omega)$ and $\varphi(\omega)$ are related to the mechanical impedance, or its reciprocal the mechanical admittance, by simple relations, that we need not report here.

This assumption follows directly from the principle of superposition, and is quite as general. Furthermore, many tests developed to investigate dynamic properties of rubberlike materials are based upon the analysis of steady-state response to sinusoidal stress,*** so that a rather accurate check of its shape is often possible.

Let us impose on such a system an external stress defined as follows:

$$\begin{aligned} P(t)&=0 \quad \text{for } t<0\\ P(t)&=P_0 \quad \text{for } 0<t<\theta\\ P(t)&=0 \quad \text{for } t>\theta. \end{aligned}$$

This function can be developed in Fourier's integral in a well-known way:

$$P(t)=\frac{P_0}{\pi}\int_0^\infty\left(\frac{\sin\omega\theta}{\omega}\cos\omega t+\frac{1-\cos\omega\theta}{\omega}\sin\omega t\right)d\omega.$$

Each infinitesimal harmonic of the stress, divided by the dynamic modulus $E(\omega)$ and shifted by the angle $\varphi(\omega)$, gives the corresponding infinitesimal harmonic of the response: integration from 0 to ∞ gives:†

$$y(t)=\frac{P_0}{\pi}\int_0^\infty\left[\left(\frac{\sin\omega\theta\cos\varphi}{E}-\frac{(1-\cos\omega\theta)\sin\varphi}{E}\right)\cos\omega t+\left(\frac{(1-\cos\omega\theta)\cos\varphi}{E}+\frac{\sin\omega\theta\sin\varphi}{E}\right)\sin\omega t\right]d\omega. \quad (1)$$

In order that Eq. (1) have a physical meaning two conditions must be satisfied:

(a) the response $y(t)$ must be independent of θ, i.e. from the time of application of external load, for $t<\theta$;

(b) the response $y(t)$ must be 0 for $t<0$, i.e. before the application of external load.

*** The presence of an inertial mass does not alter the shape of the response.

† In the following $E(\omega)$ and $\varphi(\omega)$ will be handled as E and φ, it being understood that they are functions of ω.

The first condition means that

$$\frac{\partial y}{\partial\theta}=0 \quad \text{for } t<\theta; \quad \frac{\partial y}{\partial\theta}\neq 0 \quad \text{for } t>\theta. \quad (2)$$

The derivative of Eq. (1) with respect to θ is:

$$\frac{\partial y}{\partial\theta}=\frac{P_0}{\pi}\int_0^\infty\left[\frac{\cos\varphi}{E}\cos\omega(\theta-t)-\frac{\sin\varphi}{E}\sin\omega(\theta-t)\right]d\omega.$$

Then, setting

$$\begin{aligned} \theta-t&=\tau \quad \text{when } t<\theta\\ t-\theta&=\tau \quad \text{when } t>\theta \end{aligned}$$

$$\int_0^\infty\frac{\cos\varphi}{E}\cos\omega\tau d\omega=\frac{\pi}{2}f_1(\tau)$$

$$\int_0^\infty\frac{\sin\varphi}{E}\sin\omega\tau d\omega=\frac{\pi}{2}f_2(\tau),$$

condition (a) is fulfilled if

$$f_1(\tau)=f_2(\tau)=f_1(-\tau)=-f_2(-\tau)=f(\tau),$$

i.e. if $f_1(\tau)$ is an even function, $f_2(\tau)$ an odd function, which are identical for positive values of the variable, being $f(\tau)$ their common value.

Inversion of Fourier transform gives

$$\frac{\cos\varphi}{E}=\int_0^\infty f(\tau)\cos\omega\tau d\tau \quad (3a)$$

$$\frac{\sin\varphi}{E}=\int_0^\infty f(\tau)\sin\omega\tau d\tau. \quad (3b)$$

It is easy to demonstrate that if Eqs. (3) hold, condition (b) is also satisfied. Indeed, introducing Eqs. (3) in Eq. (1), and inverting the order of integrations, we have

$$y(t)=\frac{P_0}{\pi}\int_0^\infty f(\tau)d\tau\int_0^\infty\left(\frac{\sin\omega(\theta-t+\tau)}{\omega}+\frac{\sin\omega(t-\tau)}{\omega}\right)d\omega. \quad (4)$$

Remembering that

$$\int_0^\infty\frac{\sin kx}{x}dx=\begin{cases}\frac{\pi}{2} & \text{for } k>0\\ -\frac{\pi}{2} & \text{for } k<0\end{cases}$$

we obtain

$$\int_0^\infty\left(\frac{\sin\omega(\theta-t+\tau)}{\omega}+\frac{\sin\omega(t-\tau)}{\omega}\right)d\omega=\begin{cases}0 & \text{for } t<0\\ \pi & \text{for } 0<\tau<t<\theta\\ 0 & \text{for } 0<t<\tau<\theta.\end{cases}$$

Then Eq. (4) can be written

$$y(t)=P_0\int_0^t f(\tau)d\tau \quad \text{for } 0<t<\theta$$
$$y(t)=0 \quad \text{for } t<0. \tag{5}$$

The derivative of (5) with respect to time gives

$$dy/dt=P_0f(t), \tag{6}$$

which shows that $f(t)$ is the rate of creep under unit stress.

Equations (3) and (5) do not depend on the magnitude of θ and therefore hold as general laws that must necessarily be fulfilled correlating dynamic modulus and phase shift (or real and imaginary part of mechanical impedance or admittance) with rate of creep. In identical way analogous relations between dynamic modulus, phase shift and rate of relaxation could be developed.

From Eqs. (3) it follows immediately that

$$\lim_{t\to\infty} f(t)=0 \tag{7}$$

$$\lim_{t\to 0} tg\varphi=0. \tag{8}$$

2. CORRELATION WITH VISCOELASTIC SYSTEMS

Identity of the given system with a convenient viscoelastic model, is also proved by means of Eqs. (3). Indeed it is not *a priori* quite plain that all systems whose response to stress obeys the superposition principle can be represented by a model constructed from a discrete set, or a continuous distribution, of elements which obey Hooke's law, and elements which obey Newton's viscosity law.

Remembering that creep under a constant stress P_0 of a viscoelastic system having a distribution function of retardation times $F(\tau)$ is

$$y(t)=P_0\beta\left(1-\int_0^\infty F(\tau)e^{-t/\tau}d\tau\right)$$

with

$$\int_0^\infty F(\tau)d\tau=1,$$

we have

$$\frac{dy}{dt}=P_0\beta\int_0^\infty \frac{F(\tau)}{\tau}e^{-t/\tau}d\tau.$$

As Eq. (6) gives the rate of creep for the linear system, the condition for identity of this one and the former one is

$$f(t)=\int_0^\infty \rho(s)e^{-ts}ds, \tag{9}$$

where

$$s=\frac{1}{\tau}-\beta\frac{F(1/s)}{s}=\rho(s).$$

This means that $f(t)$ is the Laplace transform of the auxiliary distribution function $\rho(s)$.

The determination of $\rho(s)$ is always possible because $f(t)$ must obey the conditions that assure evaluation of integrals in Eqs. (3) which are sufficient to allow the inversion of the Laplace transform.

As Eqs. (3) and (9) are identical to Eqs. (6) and (25) in Gross paper,[6] all further developments such as methods of evaluation of distribution functions, are omitted here, having already been published there.

3. DISCUSSION OF EXPERIMENTAL RESULTS

Many of the above mentioned reports agree in the statement that the elastic modulus $E(\omega)$ and the phase shift $\varphi(\omega)$ are with good approximation, independent of frequency ω in the range from a few cycles per sec. to about 1300 c.p.s. This property has also been assumed as a general law of internal friction replacing Newton's viscosity law, not only to take account of experimental results, but also because calculations can be carried out in a very simple way.[15, 16]

As Eqs. (3) and (8) show that this deduction is not compatible with the assumption of linearity, we must conclude as follows:

(a) Experimental results are not sufficiently extended and a different behavior of E and φ is to be expected in the ranges of extremely low and very high frequencies.‡

(b) Tested materials do not give a linear response; in this case E and φ would no longer have a meaning, but energy loss per cycle could still be measured.

(c) The presence of plastic deformations may alter the results in a considerable way independently of frequency.

These reasons may also coexist together, and, more or less, explain the observed results, but further tests should be undertaken to check them.

‡ *Note added in proof.*—It has already been pointed out that E varies appreciably over a sufficiently large frequency range. See, for example, A. W. Nolle, J. App. Phys. **19**, 753 (1948).

The Use of Spraying Methods and of Volatile Suspending Media in the Preparation of Specimens for Electron Microscopy*

ROBERT C. BACKUS AND ROBLEY C. WILLIAMS
Department of Physics, University of Michigan, Ann Arbor, Michigan
(Received June 16, 1949)

Developments have been made in the use of spraying methods in the preparation of specimens for examination in the electron microscope. At the same time, two wholly volatile diluents, containing electrolytes and adjusted to normal *p*H, have been developed for use in forming the spray drops. The use of volatile electrolytes makes it unnecessary to wash the specimen after the droplet patterns have been formed on the specimen screens.

There are several qualitative and quantitative uses and advantages of the spray technique as described. The qualitative ones are these: (1) the brief drying time of the droplets helps to preserve the shapes of particles upon drying, and also allows studies to be made of rapidly reacting systems; (2) since the drop patterns are reproducibly representative samples of the suspension under investigation, qualitative assays of the particulate composition of the suspension can be made, and a comparison of the particulate composition of two closely similar suspensions can be made under ideal control conditions; (3) the droplet patterns are discretely bounded by blank areas of substrate film, and this fact makes practicable the detection of small and subtle differences between the fine structure of the specimen material and that of the substrate.

The quantitative uses of the spray technique are: (1) by use of reference particles of known numbers in a suspension it is readily possible to determine the volumes of droplets issuing from a spray-making device; (2) by use of reference particles it is also possible to make an assay of the number of other particles, such as a virus, per unit volume of mixed suspension; (3) if a suspension is highly purified, the particle weight of the material in suspension can be determined. Experiments involving the counting of about 10,000 particles show that the quantitative precision is as good as would be expected from the statistics of random sampling.

The construction and use of a spray gun are described, as well as the characteristics of two volatile diluents: ammonium acetate and ammonium carbonate.

I. INTRODUCTION

SPECIMENS for electron microscopy are commonly prepared by placing a drop of liquid containing some suspended material upon the film-covered specimen screen, and allowing the drop to dry either unassisted or hastened by the withdrawal of some of the liquid on a piece of filter paper. If the material is suspended in a non-volatile medium, such as one of the usual diluents containing salts, it is necessary to wash the microscope screen in distilled water subsequent to the initial drying of the suspension. It is generally agreed that this technique is unsatisfactory, owing to the chemical and physical changes that may occur during the drying period of several seconds to a few minutes, and to the inevitable non-uniform distribution of the suspended material as it dries on the screen. The exposure of biological materials of even moderate lability to an environment of high ionic strength, followed by immersion in distilled water, is a procedure likely to cause changes in the shapes and sizes of the specimen materials. Attempts have been made to alleviate some of these unfavorable conditions; notably by freeze-drying the specimen drop, and by treatment of the suspended material with a fixative such as formalin.

A method occasionally used since the earliest days of electron microscopy can be used to reduce many of the drawbacks of the usual procedure described above. This is a method by which the suspension is either allowed to settle on the specimen screen as tiny droplets, or is sprayed directly and forcibly upon the screen. As a result of this procedure, the screen is partially covered with discrete, roughly circular, droplet patterns from about 5 to 20 microns in diameter.

Spray methods have been described by Riedel and Ruska,[1] Haardick, Kausche and Ruska,[2] and by Cravath, Smith, Vinograd, and Wilson.[3] They appear not to have been put to any general use, however, probably because their advantages largely disappear when the specimen material is suspended in the non-volatile diluents commonly used. We have made developments in the spray technique with the primary purpose of applying it to the preparation of specimens of biological material, and have at the same time developed aqueous suspending media which are wholly volatile. The method now appears to be highly useful for both qualitative and quantitative electron microscopy. Its

advantages and uses will be detailed below, following a description of a spray gun and a discussion of volatile suspending media.

II. CONSTRUCTION AND USE OF A SPRAY GUN

A spray gun should be capable of depositing upon the specimen screens a pattern of discrete droplets of approximate uniformity of size, reproducibly representative of the suspension, without the presence of contaminants originating in the gun, and devoid of any sprayed material in the regions between the droplet patterns. The simple glass gun to be described has been found adequate to meet these requirements, although it is realized that other gun designs might be found to be equally adequate. Figure 1 is a schematic drawing of the gun in which the parts are shown unassembled.

The outer envelope G is made of apparatus-weight, 7 mm glass, and is provided with an air inlet I and a means for securing the insert tube C. Tube G is provided with a threaded Lucite union U_1 and U_2, with U_2 of an internal diameter less than the diameter of the enlarged flange at F. U_1 threads over U_2, but also has an unthreaded base section with a hole just large enough to fit over tube C. The tube C is provided with a rubber sleeve R and a retaining bulge at E, and upon assembly an air-tight seal is made by compressing R between the flange F and the base of U_1. The purpose of E is to ensure that the tube C will not be violently forced out of the end of G when the compressed air is admitted. Tube C is of uniform diameter except for the bulge at E and the finely drawn portion at the tip.

It has been found convenient to make a number of small pipettes P whenever a series of samples is to be sprayed. The use of these pipettes minimizes the chances of sample-to-sample contamination by restricting the area of contact between fluid and glass to the small region at the tip of C. The pipettes are inserted into C sufficiently far to cause their ends to wedge lightly into the capillary constriction in C. Each pipette is discarded after having been used with one sample of a series.

Extended trial has shown that the dimensions of the orifices are fairly critical. The I.D. of tube C should be about 0.1 mm, and the O.D. about 0.3 mm. The I.D. of the tip of tube G should be about 0.75 mm. A spraying pressure of 20 to 30 p.s.i. is satisfactory, with the gun some 15 to 20 inches from the filmed microscope screens. The screens can be mounted to a supporting surface with Scotch tape, or can be held in position magnetically. Very clean air must be used for spraying, and it appears that tank-compressed air, reduced with a suitable valve, is satisfactorily clean. The gun should be carefully aligned to cause the central region of the spray to intersect the screens; the alignment and other spray characteristics can conveniently be observed with the aid of a beam of light in a darkened room. The gun as described will deposit a convenient number of droplets from about 0.2 ml of sprayed material. A smaller orifice can be used at the tip of tube C (with higher air pressure and diminished distance from gun to screens), when the use of a smaller volume of suspension is necessary.

One of the commercially available all-glass nebulizers has been experimented with, but it has not been found to be as satisfactory for the production of representative drop patterns as is the high air-velocity gun just described. The nebulizer is not as conveniently kept free of contamination, and it does not produce drop patterns that are both discretely bounded and reproducibly representative of the specimen. We believe that the reason for the difference in the performance of the two kinds of spraying devices is that, in the case of the low air-velocity nebulizer, some material from droplets which have completely dried in transit is left in varying amounts and places upon the microscope screens.

III. VOLATILE SUSPENDING MEDIA

The preparation of materials in the form of spray-drop patterns loses most of its unique value when the suspending medium is non-volatile, since the dried salts must be rinsed off the specimen screens with consequent disturbance of the drop patterns. For many substances a satisfactory volatile medium is distilled water, but for others, particularly of a biological nature, a medium containing electrolytes is demanded. The requirements to be met by volatile electrolytes when used in electron microscopy can be stated only after consideration of the type of observation to be made. A minimum requirement would be that the chemical and physical properties of the substance, when suspended in one of the conventional diluents, should be maintained when the substance is suspended in the volatile diluent.

It is clearly necessary that the preparation of a volatile electrolyte be done in a manner calculated to avoid any chance of contamination with non-volatile material. If a non-volatile component is present as much as 1 part in 10^7 in an average spray droplet of 500 microns^3 volume, there will be 5×10^7 A^3 of residual material in the drop pattern. This amount is clearly visible in the electron microscope if it dries on the screen in a form other than a rather uniform film. Such a high degree of freedom from non-volatile contamination requires that only gaseous or freshly redistilled liquid components be used in the chemical preparation.

We have found a 2 percent solution of freshly made ammonium acetate at pH 7.0 to be a satisfactory suspending medium for use with several biological materials (for example: fibrinogen, serum globulins, plant viruses, and homogenized tissue suspensions). Ammonium carbonate at a similar ionic strength and pH has also been found to be useful. It is advantageous to consider spraying the same material suspended in both of these volatile electrolytes in turn, on account of the changes in pH that occur during the brief drying time

of the droplets. The ammonium acetate system will approach a *p*H of about 4.0 as it dries, while ammonium carbonate approaches a *p*H of 10. If differences of form observable in the electron microscope are believed likely to take place in a drying time of about 0.1 sec., their magnitude can be checked by spraying with each volatile system separately, or with the two systems used together in varying concentrations.

IV. USES AND ADVANTAGES OF THE SPRAY METHOD

The consequences of the use of droplets sprayed in a volatile suspending medium may be generally described thus: (1) the time taken for the specimen material to change from its free liquid environment to complete dryness is very short, (2) the droplet patterns are individually and reproducibly representative of the composition of the sprayed material, and (3) the droplet patterns are discretely bounded by areas of blank specimen film. The uses and advantages accruing from these consequences will now be described in detail.

A. Qualitative

1. *Short drying time*—The total time elapsed between the emergence of an aqueous drop of about 500 microns[3] volume from a high air-velocity spray gun and the state of complete dryness on the specimen screen is estimated to be somewhat less than 0.1 sec. The estimate is based upon the known rate of evaporation of water droplets in relatively dry air, and disregards any possible effect of the suspended material in slowing or accelerating the drying process. This drying time is to be compared with a time of several seconds to a minute or so taken by an ordinary, gross drop to dry when placed directly upon the filmed specimen screen.

The advantage of the short drying time is that the suspended material, such as a virus, for example, is exposed only very briefly to an unfavorable electrolytic and osmotic environment and has little time to be morphologically changed. There is also little time for the occurrence of gross aggregation or other particle interactions which must take place during the concentration of the solute materials during the long drying time of a large drop. A further advantage is that very small particles do not imbed themselves in the plastic film as much as they do when the film is softened and swollen by prolonged contact with a large drop of water. An important use of the fact of quick drying is in observations of interparticle reactions, where it is desirable to stop the reaction quickly and at a known instant. In this type of experiment the particulate components are mixed prior to, or during, their introduction into the gun, and the reaction is manifestly stopped within a fraction of a second after the spray drops leave the gun.

2. *Reproducibly representative fields*—It is difficult to overestimate the usefulness of a technique whereby well-defined areas of the microscope screen contain representative and complete samples of all the non-volatile material in the original suspension. This is particularly true when the suspending diluent is in itself free of non-volatile components. The common experience of microscopists is that searching for and photographing "typical" fields is time-consuming, frustrating, and is open to the dangers of subjective judgment. This difficulty has made comparisons between two samples of material, such as normal and infected biological material, relatively uncertain, with the result that the electron microscope has failed to be used to its fullest as an analytical tool. The use of drop patterns eliminates a fundamental difficulty in electron microscopy; namely, the small totally available field of search of about 0.25 mm^2. This restricted field leads to uncertainty as to whether or not the portion of the specimen of great significance lies outside the field, or is obscured by the wires of the specimen grid.

A few qualitative uses of observations on small, representative drop patterns are immediately apparent. The first use lies in making reliable assays of the particulate composition of a given suspension by photographing a few drop patterns. Assays can be made by even an inexperienced person, since the choice of what is typical is independent of his judgment. If the suspension is believed to be a fairly homogeneous one, such as a suspension of a purified plant virus, the microscope can also be used to assay sensitively the amount of particulate impurities present.[4]

The spray method allows a precise comparison to be made of the electron microscopic appearance of two different, but similarly prepared, suspensions. The comparison can be conveniently made in this way: Suspension *A* is sprayed upon a few filmed specimen screens. Suspension *B* is adjusted to have about the same concentration of suspended material as *A*, but to it is added a trace amount of an indicator substance of recognizable shape, such as tobacco mosaic virus. Suspension *B* is then sprayed upon the screens already containing the dried droplets of suspension *A*. The screens are shadowed and examined for regions where discrete, closely adjacent drop patterns of both *A* and *B* can be photographed. This technique seems to embrace all the requirements of controlled electron microscopy, since the methods of mounting the specimen materials are closely identical, even to the details of drying time and surface character of the substrate film, as well as film thickness, shadowing conditions, and circumstances of exposure in the microscope.

3. *Discretely bounded drop patterns*—A constant source of uncertainty in the examination of shadowed electron micrographs of inhomogeneous particulate material is the difficulty of distinguishing between the fine-structure of the specimen material itself and the fine-structure of the substrate film. A similar difficulty

[4] R. C. Williams and R. C. Backus, J. Am. Chem. Soc. (in press).

is present even when preshadowed replicas[5] are used, except that the source of uncertainty is not in the structure of the collodion surface but instead resides in the uncertain degree of cleanliness and discontinuities of the glass surface. When drop patterns are examined, the uncertainty largely disappears, since the patterns occupy discrete areas surrounded by areas of film whose undisturbed structure can be gauged. This separation of regions provides one with a sensitive internal control on the character and cleanliness of the surface of the substrate, and hence enhances the possibility of

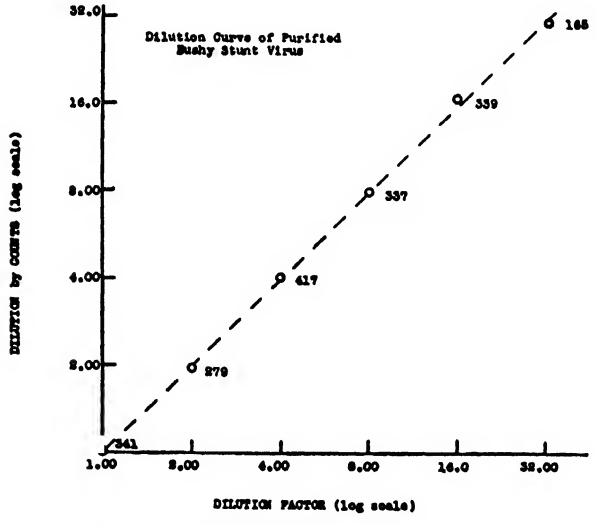

FIG. 2. Determination of the dilution of a suspension of purified bushy stunt virus by spraying and counting. Abscissae are the known dilution factors, obtained by pipetting; ordinates are the dilution factors calculated from the virus counts. The point at the origin has been arbitrarily called a relative dilution of unity. The diameter of the circles represents a 3 percent variation, while the numbers accompanying each circle are the numbers of reference particles counted in the establishment of each point.

making unequivocal observations of the presence or absence of very small particles.

B. Quantitative

The attainment of representative sample fields makes electron microscopy increasingly applicable to certain kinds of quantitative determinations. A technique to provide such fields by centrifugal deposition has been suggested by Crane.[6] A quantitative application of this technique has been made by Sharp[7] who obtained representative fields of swine influenza virus by sedimenting the particles on to a collodion surface. By counting the number of particles per unit area of the film he obtained a satisfactory correlation between counts and known dilution factors, although his results were rendered somewhat uncertain by the necessity of washing the dried buffer salts from the sedimented preparations.

[6] H. R. Crane, Rev. Sci. Inst. **15**, 253 (1944).
[7] D. G. Sharp, Proc. Soc. Exp. Biol. Med. **70**, 54 (1949).

1. *Determination of droplet volumes*—If reference particles[8] are present in a known concentration in the suspension being sprayed, a given droplet pattern will contain a number of these particles proportional to the volume of the droplet as it left the spray gun. It has been found that Dow latex particles[9] are particularly useful as reference particles, since they are obtainable in quite pure aqueous suspension, and remain intact and in uniform suspension in ammonium acetate and ammonium carbonate. The particles do not seem to interact with the biological materials we have handled, at least during the brief periods of contact necessary for their use, and their concentration in numbers per unit volume of suspension is readily determinable.[4] It is evident that one can use the latex reference particles directly in a determination of volumes of droplets as they issue from any spray-making device.

2. *Absolute virus assays*—When latex particles are mixed with some other particulate material, such as a virus, simple counts made on the droplet patterns will determine the ratio of the number of latex to the number of virus particles. If the concentration of latex is known, this ratio provides an absolute assay of the number of virus particles per unit volume of the mixed suspension. It is to be noted that this method can be used even though the suspension is not highly purified; as long as one species of particle can be recognized, it can be counted and assayed.

3. *Determination of particle weights*—The technique just described can be used to determine the particle weight of a homogeneous substance, such as a purified virus. The particle counts yield the number of particles per unit volume, and if the material is in highly purified form, this information can be combined with the value of the dry weight of material in an aliquot volume of suspension to allow the weight of an average particle to be computed. This weight in grams, multiplied by Avogadro's number, is the particle weight in molecular weight units. The advantage of this method of determining particle or macromolecular weights lies primarily in its directness, and also in the low concentration of material which can be sprayed and counted.* A satisfactory concentration is 0.0001 percent, and the total weight of material to be diluted and sprayed need be no more than 0.1 microgram.

4. *Assessment of quantitative precision*—Determinations have been made of the quantitative reliability and precision of the method of particle counts by the use of

[8] E. Chamot and C. W. Mason, *Handbook of Chemical Microscopy* (John Wiley and Sons, Inc., New York, 1938), Vol. I, p. 441.
[9] R. C. Backus and R. C. Williams, J. App. Phys. **20**, 224 (1949).
* When very dilute material consisting of small sized particles is sprayed, it is difficult to recognize the confines of the drop patterns in the electron microscope. The admixture of a small amount of highly purified tobacco mosaic virus to the suspension causes the drops to be nicely bounded by easily observed rod-like forms.

reference particles in the spray drops. Two sources of uncertainty might be anticipated: the mixing of the two kinds of particles may not be perfect, and there may be dislodgments of either species of particle from the microscope screens prior to shadowing.

The sources of uncertainty have been checked by measuring the statistical fluctuations of the counts, in a trial where particles of latex and of the bushy stunt virus were mixed in approximately equal numbers. It is found from counts of about 10,000 particles that the standard deviation of the mean ratio of particle numbers lies between 2 and 4 percent when 1000 pairs of particles are counted in 20 or more droplet patterns. Inasmuch as the statistically anticipated standard deviation of the mean ratio should be close to 3 percent, it is believed that the mixing of the particles is nearly perfect, and that they do not become randomly dislodged.

The adequacy of the entire method of quantitative assay of virus particles by electron microscopy has been checked by counts made on mixtures of reference and virus particles of greatly varying relative concentrations. Figure 2 shows the results of an experiment in which the concentration of latex particles was held constant, while the concentration of purified bushy stunt virus was varied through a dilution factor of 32. The evident agreement between the known dilution factors and the dilutions as calculated from the counts of virus and latex particles is very satisfactory, and implies that a quantitative assay of a purified, dilute virus suspension can be made as precise as the statistics of random sampling would indicate.

On the Diffraction of Radar Waves by a Semi-Infinite Conducting Screen*

C. W. Horton and R. B. Watson
Defense Research Laboratory, The University of Texas, Austin, Texas
(Received May 27, 1949)

The diffraction patterns of radar waves about a semi-infinite copper screen have been measured. The measurements were made by revolving a bisectoral horn in a circle of radius 15″ or 30″ about the diffracting edge. Measurements were made at three positions along the edge, one of which coincided with the corner of the screen so that the pattern obtained was actually that of a quarter-infinite plane. Measurements were made for two orientations of the screen corresponding to angles of incidence of 0° and −22½°. Theoretical patterns have been calculated for the entire 360° of rotation and these agree well with the experimental patterns. A comparison is made between the theory, measurements, and the equivalent optical measurements.

I. INTRODUCTION

A RIGOROUS solution of the problem of the diffraction of an electromagnetic wave by a semi-infinite perfectly-conducting screen has been obtained by Sommerfeld.[1,2] Optical measurements have shown deviations from the theory[3] which have usually been attributed to the finite thickness and conductivity of the screen and the irregularities of the edge of the screen.[4] All three of these difficulties are greatly reduced when the experiments are repeated at radar frequencies. A further advantage of the use of radar frequencies is that the smallness of the detector enables one to make significant measurements throughout nearly a full circle. Thus the theoretical results may be checked not only in the shadow region but also in the illuminated regions and especially in the region of geometric reflection. The disadvantages of the change in scale are (1) that a screen of manageable size is not large enough to eliminate diffraction around the other three edges and (2) that the effective aperture of the receiver is of appreciable area, though of the same order as the wave-length squared.

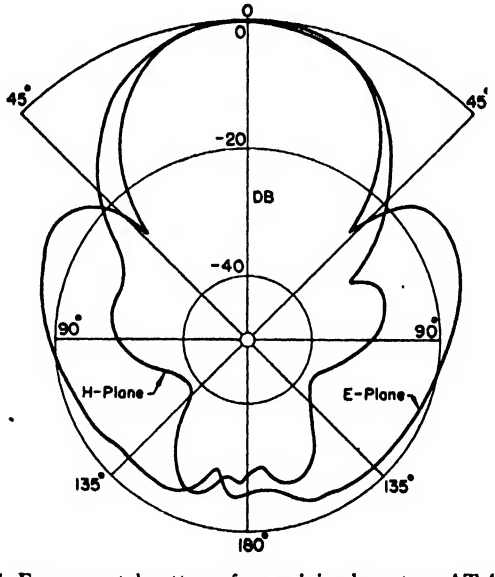

FIG. 1. Experimental patterns for receiving horn type AT-48/UP.

II. EXPERIMENTAL ARRANGEMENT

The experimental arrangement used in this work has been described previously.[5] A modification of this method has been made in which the receiving horn was mounted on a long arm so that it moved on a circle whose center coincided with the edge of the diffracting screen and which lay in a plane normal to the screen. The screen consisted of a single sheet of copper 30″×60″ and $\frac{1}{16}$″ thick which was mounted 30″ above the experimental bench with the long dimension horizontal. One of the 30″ vertical edges was the diffracting edge. The screen was supported by two U-shaped dural channels 2″×1$\frac{3}{8}$″ which were placed symmetrically about the vertical centerline. The channel nearer to the diffracting edge was 18″ from it. Small dural angles $\frac{3}{4}$″×$\frac{3}{8}$″ were required in order to stiffen the copper sheet and prevent vibrations since the sheet was mounted in the open air; however a space of 4$\frac{1}{2}$″ was left completely clear next to the diffracting edge. Some of these stiffeners were placed along the upper and lower edges of the screen.

The receiving horn was a bisectoral horn of the Type AT-48/UP manufactured for the armed services. The aperture of this horn is 1.9″×2.4″ or 1.47λ×1.82λ for a free space wave-length of 3.2 cm. Figure 1 shows the patterns of this horn in the *E*- and *H*-planes.

In order to observe the influence of the upper and lower reinforced edges, the free edge on the far end of the sheet, and the various supporting members, measurements were made with the receiving horn at two radii, 15″ (*ca.* 12 wave-lengths) and 30″ (*ca.* 24 wave-lengths), and at three positions along the diffracting edge. One position was at the midpoint, or 15″ from the upper or lower edges, a second position was 9″ from the upper edge, while the third position was at the upper edge of the screen. This last position really gives

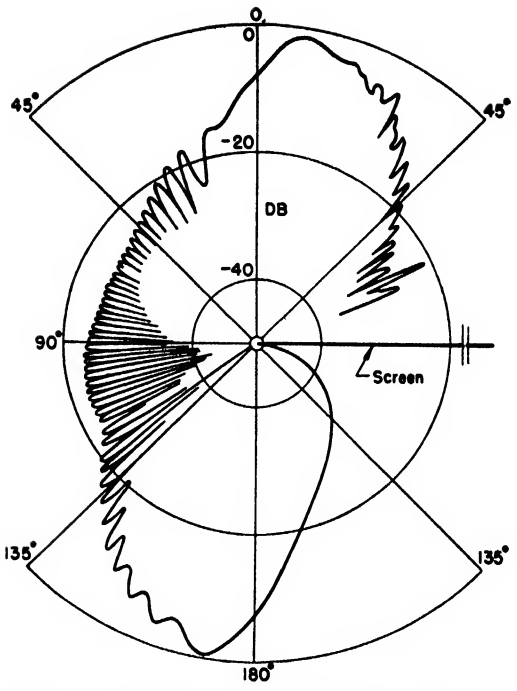

FIG. 3. Theoretical diffraction pattern for the conditions of Fig. 2.

patterns for a quarter-infinite screen. The agreement between the patterns measured about the center of the diffracting edge and the position 9″ from the upper edge is good. However, the presence of an interference pattern in the shadow region behind the screen for both of these positions shows that the screen was only a moderately good approximation to a semi-infinite screen.

Measurements were made for angles of incidence of 0° and of $-22\frac{1}{2}°$.

III. NORMAL INCIDENCE

Figure 2 is a polar plot of the received signal in db *versus* the angle about the edge of the semi-infinite screen for the case of an incident wave polarized with the electric vector parallel to the diffracting edge. The horn was always turned so that it faced the edge of the screen. Thus the diffracted wave was detected at maximum sensitivity and the directionality of the horn was used to discriminate against the incident and reflected waves. Figure 3 is a plot of the theoretical pattern for the same conditions. In computing the theoretical pattern the wave field was resolved into plane and cylindrical waves in accordance with the description of Baker and Copson.[6] The pattern of the horn was applied separately to each wave component in accordance with its orientation with respect to the horn. In the regions that are very near the line of propagation, the approximate expressions for the diffracted field recently developed by Horton[7] have been used.

Figure 4 is a polar plot of the received signal in db *versus* the angle about the edge of the semi-infinite screen for the case of an incident wave polarized with

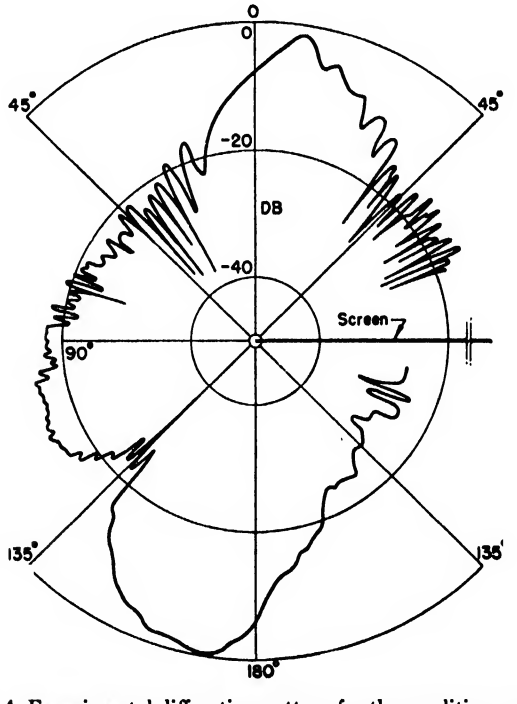

FIG. 4. Experimental diffraction pattern for the conditions of Fig. 2, except electric vector perpendicular to diffracting edge.

the electric vector perpendicular to the diffracting edge of the screen. Again the horn was always turned so that it faced the edge of the screen. The theoretical pattern for the same conditions is shown in Fig. 5.

The process of resolving the total wave field into

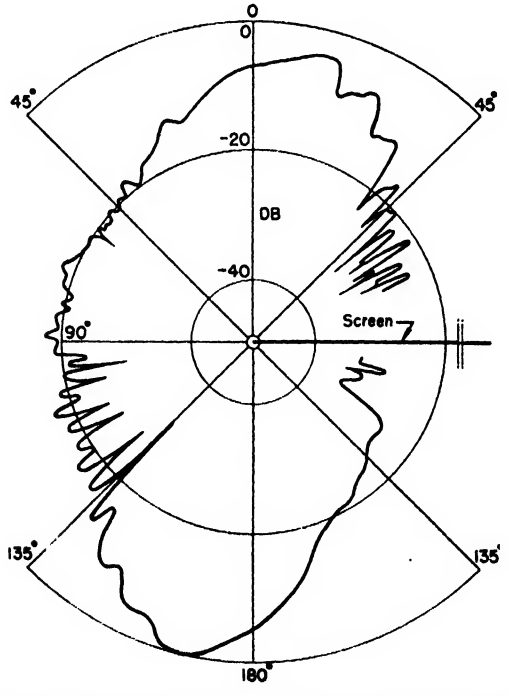

FIG. 6. Experimental diffraction pattern for semi-infinite screen for normal incidence, with incident wave from 0° direction. Receiving horn rotated in 15″ circle about center of diffracting edge. Electric vector parallel to diffracting edge.

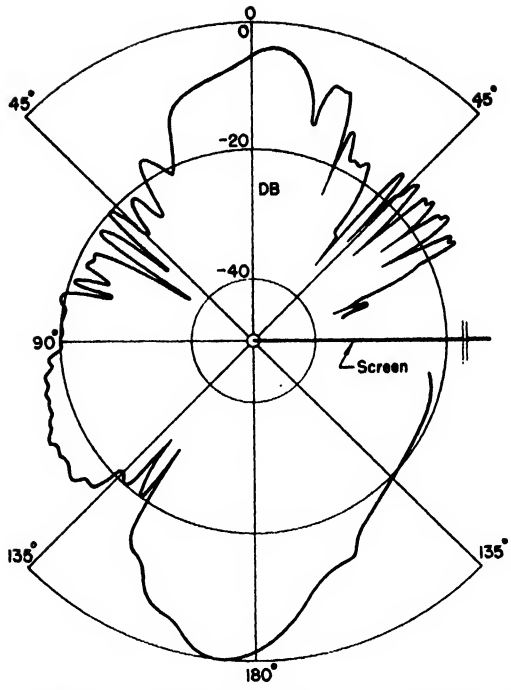

FIG. 7. Experimental diffraction pattern for the conditions of Fig. 6, except electric vector perpendicular to diffracting edge.

component fields has received a striking verification from these patterns. In the region of geometric reflection, the field can be resolved into three components; the incident plane wave, the reflected plane wave and a cylindrical wave diverging from the edge. To each of these the horn has a different response. Yet when the contributions of the three components are added, very good agreement with experimental patterns is obtained.

Figures 6 and 7 show the patterns for the case of the electric vector parallel and perpendicular respectively to the diffracting edge when the radius of the circle is 15 inches. The patterns were measured at the midpoint of the edge of the screen. The effective aperture angle of the horn is twice as large as in the case of the 30-inch circle and so the size of the lobes is correspondingly reduced.

Although an inspection of Figs. 2–5 is sufficient to show that there is good agreement between experiment and theory through all the angular range of the measurements it is of interest to compare for the shadow zone only the ratios of the amplitudes for the two cases of the electric vector parallel and perpendicular to the edge of the screen. Figure 8 shows the theoretical values of this ratio, the observed values for a circle of 15″ measured at the midpoint and at 6″ from the midpoint of the diffracting edge, and the values given by Maey[8] and Jentzsch[9] obtained by optical measurements. The

experimental data in Fig. 8 show clearly the effect of the interference fringes produced by the diffracted waves that come from the other three edges of the screen. It is difficult to draw a satisfactory average through the experimental curves. The general trend, however, is the same as the theoretical curve. Agreement is found with Maey's data, but Jentzsch's data

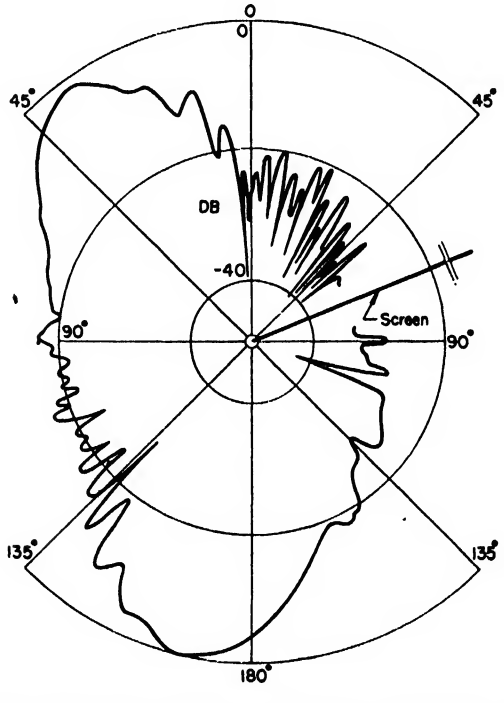

FIG. 9. Experimental diffraction pattern for semi-infinite screen for $-22\frac{1}{2}°$ incidence, with incident wave from 0° direction. Receiving horn rotated in 15″ circle about center of diffracting edge. Electric vector parallel to diffracting edge.

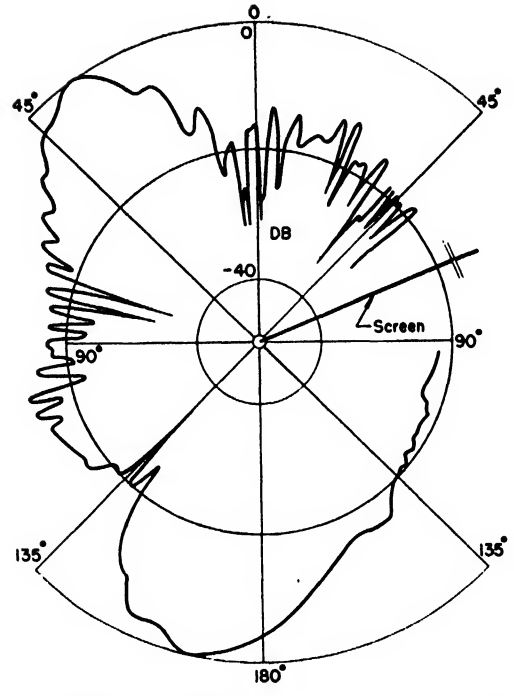

FIG. 10. Experimental diffraction pattern for the conditions of Fig. 9, except electric vector perpendicular to diffracting edge.

lie considerably below both the experimental and theoretical curves. At large angles the experimental data fall in general slightly above the theory. This effect may be in part explained by the smallness of the component values used in calculating the ratios. For such small values, inherent noise in the measuring apparatus plus diffracted contributions from surrounding objects as well as the other three edges of the screen may well increase the smaller component value more than the larger, and thus increase the ratio. Similar curves of $E_{\parallel}/E_\perp$ are obtained for the measurements at a radius of 30″ but the errors of measurement are larger because of the increased diffraction about the other three edges.

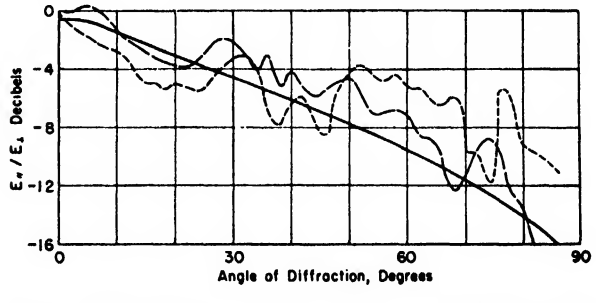

FIG. 11. Ratio of the amplitude of the measured electric vector for electric vector parallel to diffracting edge to that for electric vector perpendicular to diffracting edge in the shadow zone behind the screen, *versus* diffraction angle. FIG. 14. Experimental diffraction pattern for quarter-infinite screen for $-22\frac{1}{2}°$ incidence, with incident wave from 0° direction. Receiving horn rotated in 30″ circle about top diffracting edge. Electric vector parallel to vertical diffracting edge.

IV. ANGLE OF INCIDENCE −22.5 DEGREES

The measurements described above were repeated for the case that the direction of propagation of the incident wave made an angle of −22.5 degrees with the normal to the screen. Figures 9 and 10 show the two patterns for the cases of the electric vector parallel

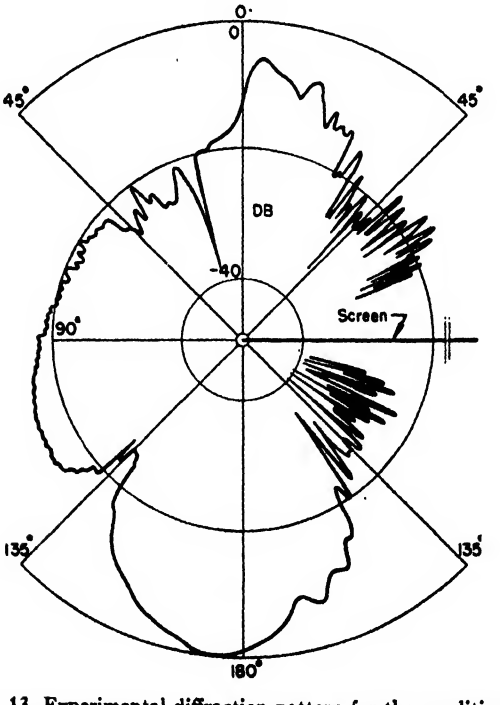

FIG. 13. Experimental diffraction pattern for the conditions of Fig. 12, except electric vector perpendicular to vertical diffracting edge.

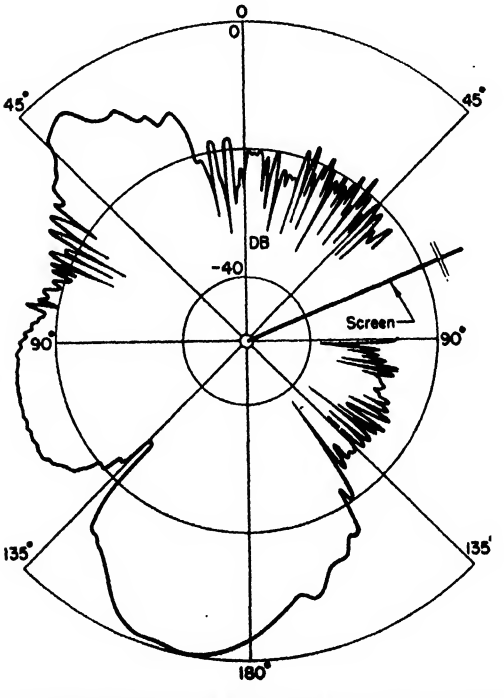

FIG. 15. Experimental diffraction pattern for the conditions of Fig. 14, except electric vector perpendicular to vertical diffracting edge.

and perpendicular to the diffracting edge of the screen respectively. Figure 11 shows a comparison between the theoretical and experimental values of the ratio of the amplitudes for the electric vector parallel and perpendicular to the edge of the screen. The experimental curves in Fig. 11 follow the theory quite well, with some deviations due to effects of extraneous diffraction. The experimental points tend to rise slightly above the theory at large angles, due in part to incidental noise and diffraction effects from the other edges.

V. QUARTER-INFINITE SCREEN

A rigorous theoretical solution of the diffraction pattern of a quarter-infinite screen has not been obtained. A first approximation is obtained by assuming both edges of the quarter screen to be infinite in extent so that the analysis described above may be applied to each edge. The effect of termination of the edges at the point of intersection is recognized by assuming a source of spherical waves at the corner. Contributions from the two diffracting edges, the incident wave, and the point at the corner are then added together to give the solution. Detailed calculations were carried out for the case of the electric vector parallel to the vertical diffracting edge, when the receiving horn is rotated in a circle whose plane contains the upper edge of the screen. These calculations were made for normal incidence only, and were restricted to the region in the shadow zone in which the angle of diffraction with respect to the vertical edge was between 20° and 50°. This restriction was made since it was felt that such an approximate analysis should apply best in the shadow region behind the screen.

Figures 12 and 13 show the experimental measurements, which were carried out for all angles for the case of normal incidence on the quarter-infinite screen. The theoretical data are plotted in the lower right quadrant of Fig. 12. The experimental and theoretical curves are much alike, but the theory shows larger lobes and a somewhat different slope from the experiment. A comparison of Figs. 12 and 13 with Figs. 2 and 4, respectively, shows that the diffraction pattern of a quarter-infinite screen is surprisingly similar to that of a semi-infinite screen.

Figures 14 and 15 show the experimental measurements for a quarter-infinite screen when the normal to the screen makes an angle of $-22.5°$ with the direction of the incident wave. Further similarity to patterns for the semi-infinite screen is observed by comparison with Figs. 9 and 10.

Measurement of the Surface Temperature of Evaporating Water Drops*

JOHN C. JOHNSON
Massachusetts Institute of Technology, Cambridge, Massachusetts
(Received July 14, 1949)

Measurements made of the surface temperature of evaporating water drops are in agreement with the requirements of the theory ennunciated by Fuchs which states that the temperature is determined by the difference between the ambient and saturated vapor density of the drop.

INTRODUCTION AND THEORY

FOR some years, studies, both theoretical and experimental, have been conducted on the rate of evaporation of liquids in the form of spherical drops. Studies using water droplets have been of particular interest to meteorologists, but evaporation processes are of concern in studies of liquid smokes, in atomizing fuel oils, and in studies of other volatile liquids. Both theory and experiment show that the drop diameter varies as a parabolic function of time when evaporation (or condensation) occurs, so that the surface area changes directly with the lapse in time. This leads to an expression of the type (Houghton 1933)

$$a^2=a_0^2-(8k/\bar{\rho})(\rho_0-\rho)t \tag{1}$$

obtained from the differential equation

$$dM/dt=-2\pi ka(\rho_0-\rho), \tag{2}$$

where dM/dt = the rate of change of the mass of the liquid, k = diffusivity of the vapor in the atmosphere surrounding the drop, a = diameter of the drop at time t, a_0 = diameter at $t=0$, $\bar{\rho}$ = density of the liquid, and $(\rho_0-\rho)$ is the difference in vapor density at the surface of the drop and the surroundings, the latter ambient condition being essentially the concentration of the vapor in the atmosphere in the absence of or at infinite distance from the drop.

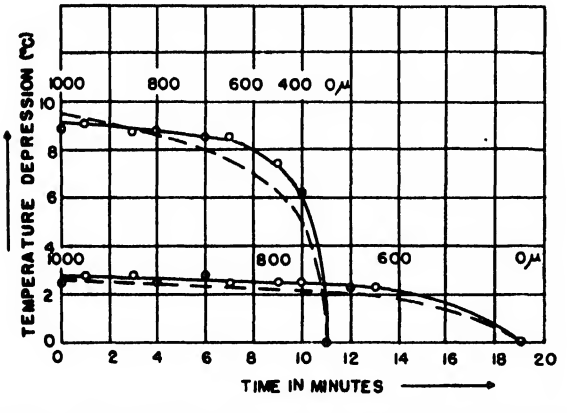

FIG. 1. The solid line of the upper curve is the measured data for a drop evaporating in an atmosphere with temperature and relative humidity of 25.4°C and 37 percent respectively. Number 2 thermocouple was used. The lower solid curve shows the experimental results using thermocouple No. 4, where the ambient temperature and relative humidity were 23.9°C and 68 percent respectively. The dashed curves are a plot of Eq. (6) using the same values of $(\rho-\rho_0)$ that were measured experimentally. $C=2.1\times10^{-4}$ was used.

In practice, the use of Eq. (1) requires a knowledge of the quantity $(\rho_0-\rho)$. Confining the discussion for the moment to water vapor, ρ is the ambient vapor density evaluated from the measurement of the relative humidity of the air, the temperature of the air, and a set of vapor pressure tables for water (neglecting the slight effect on this pressure by the pressure of a neutral gas). The quantity ρ_0, is the saturation vapor density at the temperature of the surface of the evaporating drop. Reason dictates that this latter temperature be colder than the surrounding atmosphere for an evaporating drop. The wet bulb temperature has been suggested for this temperature, but does not give the correct result. Fuchs (1934) [see Houghton (1938)] attacked this problem by considering the energy lost to the drop by diffusion to be balanced in the steady state by the conduction of heat from the air to the surface of the drop. If Eq. (2) be multiplied by the latent heat of vaporization, L, and equated to the expression for the radial conduction of heat by the air to the drop

$$dQ/dt=-2\pi K(T-T_0)a \tag{3}$$

where K is the thermal conductivity of the air, there is obtained a thermal condition

$$T-T_0=(kL/K)(\rho_0-\rho) \tag{4}$$

which must be satisfied as evaporation (or condensation) occurs. T and ρ are the ambient temperature and vapor density, while T_0 and ρ_0 refer to saturation conditions at the drop surface. As $\rho_0=f(T_0)$, Eq. (4) leads to a "cut and trial" solution. It is the purpose of this paper to present an experimental verification of Eq. (4), by direct measurement of the surface temperatures of evaporating water drops.

DISCUSSION OF EXPERIMENTAL PROCEDURE AND CORRECTIONS

The drop under consideration can be suspended from a small thermocouple in a suitable chamber where the humidity and temperature of the chamber's atmosphere can be controlled and measured. If there were no thermal losses due to heat from the air being conducted to the thermocouple junction by the thermocouple wires

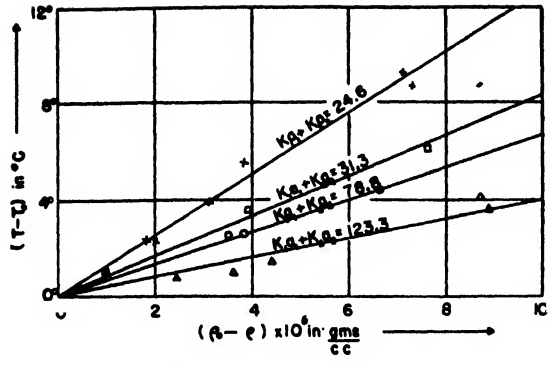

FIG. 2. Data used in determining the best value of A for the four different thermocouples. A is the slope of the curve, $(T-T_0)/(\rho_0-\rho)$.

TABLE I. Thermocouple data.

Thermocouple	No. 1	No. 2	No. 3	No. 4	Units
a_1	127	24	28	79	microns
a_2	127	49	104	117	microns
K_1	0.918	0.918	0.918	0.918	cal./cm°C
K_2	0.054	0.054	0.054	0.054	cal./cm°C
$K_1a_1+K_2a_2$	123.3	24.6	31.3	78.8	cal. microns / cm °C

$$\left(\frac{kL}{K}\right)_{20°C}=2.45\times10^{6}\frac{°C}{g}cc$$

themselves, and thereby helping to compensate the cooling effect of the evaporating drop on the thermocouple junction, the ratio $(T-T_0)/(\rho_0-\rho)$ could be directly measured and compared at once with the constant kL/K predicted by theory. Due to the error introduced by any real thermocouple, it is necessary to use several thermocouples with different heat losses for the measurements, extrapolating the results to one of zero loss for the comparison. If the two lead wires to the thermocouple junction are considered to be cylinders of uniform diameters a_1 and a_2, with conductivities K_1 and K_2 respectively, the heat loss from the wires is to the first approximation (Johnson 1948)

$$(dQ/dt)_{\text{wire}}=-2\pi C(K_1a_1+K_2a_2)(T-T_0), \qquad (5)$$

where C is a dimensionless constant due to the geometry of the system having an empirical value of $2.5\pm0.4\times10^{-3}$. The loss of energy by diffusion (Eq. (2) multiplied by the latent heat of vaporization of the liquid) is just balanced by the conduction of heat to the thermocouple junction both from the surface of the drop and from the wire to give

$$T-T_0=\frac{kL(\rho-\rho_0)}{K\{1+C[(K_1a_1+K_2a_2)/Ka]\}}=A(\rho-\rho_0). \qquad (6)$$

An inspection of Eq. (6) shows that A is a function of the drop diameter for a given thermocouple. For large drops or very fine wires $A\rightarrow kL/K$ and the second term in the denominator is small. At the other limit where the drop is very small in relation to the wires, $A\rightarrow0$ and no difference in temperature is measured. There is an

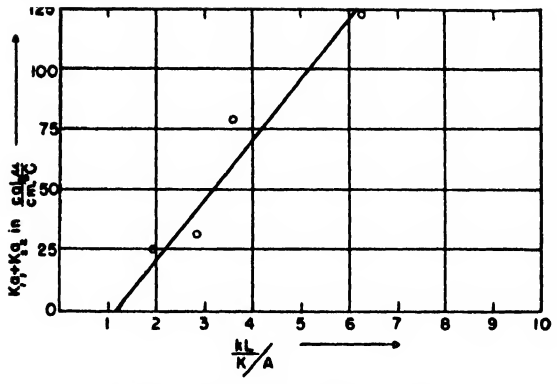

FIG. 3. An extrapolation of the observed data to a thermocouple having no thermal influence on the evaporating drop, to approximate the conditions of a cloud or small rain drop evaporating in the free atmosphere (assuming zero fall velocity).

intermediary region where $a\cong C(K_1a_1+K_2a_2/K)$ causing A to change rapidly. An example of this is given in Fig. 1. The temperature changes for the evaporating drop are shown for two constant vapor density differences.

RESULTS AND CONCLUSIONS

By observing the evaporation of several drops from a given thermocouple, the best value of A can be determined for the thermocouple. This was done for four thermocouples at a drop diameter where the temperature difference was large and nearly independent of drop diameter. The results are given in Fig. 2. Finally the ratio $(kL/K)/A$ is plotted against the wire constant $K_1a_1+K_2a_2$ and extrapolated to zero. Equation (6) on rearranging to

$$(kL/K)/A=(C/Ka)(K_1a_1+K_2a_2)+1 \qquad (7)$$

indicates that the relationship is linear when all measurements are made at one value of the drop diameter. This latter condition has been substantially met in Fig. 3. Least square analysis indicates that

$$(kL/K)/A_0=1.15 \quad A\rightarrow A_0 \text{ as } K_1a_1+K_2a_2\rightarrow0$$

for this series of measurements. From the experimental evidence, it appears that Eq. (4) adequately describes the surface temperature of an evaporation drop of water under steady state conditions where extreme conditions of radiation and convection are lacking. The values of the wire constants are given in Table I.

X-Ray Measurement of Order in Single Crystals of Cu_3Au*,**

J. M. Cowley†
Massachusetts Institute of Technology, Cambridge, Massachusetts
(Received August 4, 1949)

X-ray diffraction methods have been used to measure long- and short-range order parameters for single crystals of the alloy Cu_3Au held at elevated temperatures. It is shown that short-range order parameters may be obtained by a three-dimensional Fourier analysis of the "scattering power" for the diffuse background scattering of x-rays, expressed as a function of reciprocal lattice coordinates. Appropriate experimental and computational procedures are outlined. Intensity measurements have been made with a special arrangement of a bent-crystal monochromator and a Geiger-counter spectrometer. Short-range parameters are given for the first ten shells of atoms surrounding a given atom for three temperatures above the critical temperature of Cu_3Au. These results, and those for the long-range order parameter agree well with theoretical predictions.

INTRODUCTION

X-RAY diffraction methods allow quantitative determinations to be made of the amount of order present in an alloy. When long-range order is present, super-lattice reflections appear in the x-ray diffraction pattern with intensity proportional to the square of S, the long-range order parameter defined by Bragg and Williams.[1] Above the critical temperature of ordering of the alloy, the long-range order is zero, but short-range order persists in that there is a tendency for each atom to be surrounded by more than an average number of unlike atoms. In this case, the randomness in the lattice gives rise to a diffuse background scattering of x-rays, and the presence of short-range order gives broad maxima in this diffuse background at the positions of the super-lattice reflections of the ordered lattice. Values of the parameters defining short-range order may be obtained by an analysis of the diffuse scattering.

Measurements of short-range order parameters have been made by Wilchinsky[2] using powder samples of the alloy Cu_3Au. The accuracy of this work was limited by the difficulty of making an accurate separation of the diffuse scattering due to the thermal motion of the atoms from that due to the state of short-range order. This difficulty is largely overcome by the use of a single crystal. In a single-crystal diffraction pattern, the thermal diffuse scattering occurs mostly about the strong "fundamental" reflections, well separated from the maxima of the diffuse scattering due to short-range order. Hence the two effects may be distinguished.

Measurements of long-range order in Cu_3Au have been made by Wilchinsky[2] and by Komar and Buinov,[3] using powder samples. Chipman and Warren[4] have measured the long-range order in a single crystal of the alloy CuZn. The single crystal method has the advantage of giving greater intensity for Geiger-counter measurements, and also permits the detailed study of the time-variation of intensity and shape of super-lattice reflections.

MEASUREMENT OF SHORT-RANGE ORDER IN CU_3AU

Diffraction Theory for Short-Range Order

When an x-ray beam is reflected from a crystal, the intensity reflected in a given direction may be expressed in electron units, in the form

$$I=\sum_m \sum_n f_m f_n \exp\left[\frac{2\pi i}{\lambda}(\bar{S}-\bar{S}_0)\cdot(\bar{r}_m-\bar{r}_n)\right],$$

where f_m and f_n are the atomic scattering factors for the atoms at the end points of the vectors $\bar{r}_m$ and $\bar{r}_n$ drawn from some origin, and $\bar{S}_0$ and $\bar{S}$ are the unit vectors representing the incident and reflected beams. The summations are made over all atoms of the crystal.

We consider a crystal composed of N unit cells of simple structure, such as body-centered or face-centered cubic, with A and B atoms present in the proportions m_A and m_B. If short-range order is present in the crystal, there will be a relationship between the value of f_m and the values of the f_n for atoms close to the atom denoted by m. We say that among the c_i atoms which are i^{th} nearest neighbors of a B atom, on the average n_i are A atoms. If, then, such relationships are incorporated in the expression for the intensity, the scattered intensity is found to consist of sharp "crystalline" reflections plus a diffuse background intensity given by

$$I_D=Nm_Am_B(f_A-f_B)^2 \times\left\{1+\sum_{i=1}^{\infty}\sum_{j=1}^{c_i}\left(1-\frac{n_i}{m_Ac_i}\right)\exp\left[\frac{2\pi i}{\lambda}(\bar{S}-\bar{S}_0)\cdot\bar{r}_{ij}\right]\right\},$$

where $\bar{r}_{ij}$ is the vector from the origin to the j^{th} atom

[3] Komar and Buinov, J. Phys. (USSR) 11, No. 5 (1947).
[4] B. E. Warren and D. Chipman, Phys. Rev. 75, 1629 (1949).

of the i^{th} shell of atoms surrounding a B atom. The vector $\bar{S}-\bar{S}_0$ may be expressed in terms of the continuous coordinates h_1, h_2, h_3, and the vectors $\bar{b}_1$, $\bar{b}_2$, $\bar{b}_3$, of the reciprocal lattice as

$$\bar{S}-\bar{S}_0=(h_1\bar{b}_1+h_2\bar{b}_2+h_3\bar{b}_3)\lambda.$$

Similarly the vector $\bar{r}_{ij}$ may be expressed in terms of the coordinates l,m,n, of the atoms, and the vectors $\bar{a}_1$, $\bar{a}_2$, $\bar{a}_3$, of the crystal lattice, as $\bar{r}_{ij}=l\bar{a}_1+m\bar{a}_2+n\bar{a}_3$. Putting $\alpha_{lmn}=\alpha_i=l-(n_i/m_AC_i)$, the summation in the intensity expression, abbreviated by I_D', then becomes

$$I_D'=\sum_{l=-\infty}^{+\infty}\sum_{m=-\infty}^{+\infty}\sum_{n=-\infty}^{+\infty}\alpha_{lmn}\exp[-2\pi i(lh_1+mh_2+nh_3)].$$

Thus I_D' is expressed by a three-dimensional Fourier series in terms of the reciprocal lattice coordinates, and is a periodic function with the periodicity of the reciprocal-lattice unit cell.

The coefficients of the Fourier series are given in the usual way as

$$\alpha_{lmn}=\int_0^1\int_0^1\int_0^1 I_D'\exp[2\pi i(lh_1+mh_2+nh_3)]dh_1dh_2dh_3.$$

From the diffraction theory, these Fourier coefficients are given as $\alpha_{lmn}=\alpha_i=l-(n_i/m_AC_i)$; or, in terms of the probability p_{lmn} that the atom with coordinates l,m,n with respect to a B atom should be an A atom, $\alpha_{lmn}=1-p_{lmn}/m_A$.

The probability that an atom is an A atom is given by $P_{lmn}=m_A(1-\alpha_{lmn})$ if a B atom is at the origin, and by $P_{lmn}=m_A+m_B\alpha_{lmn}$ if the origin is an A atom.

The Fourier coefficients have the conventional features of short-range order parameters in that they are zero for the completely random arrangement, and have a maximum (absolute) value for the perfectly ordered state. For even-numbered shells the value for perfect order is unity. For odd-numbered shells the value for perfect order is unity. For odd-numbered shells, the value for perfect order is negative and may be fractional. For example, for Cu_3Au type alloys, α_i°, the value of α_i for perfect order, is equal to $-1/3$, for i odd. It is evident that short-range order parameters defined in this way are the best suited to considerations of the x-ray diffraction effects. It has also been found that they are very convenient for theoretical considerations of order in alloys.[5] Hence the coefficients α_{lmn} or α_i have been used as short-range order parameters in preference to parameters defined in analogy with Bethe's[6] σ. For AB alloys, such as CuZn, the α_{lmn} are equivalent to the r_{hkl} defined by Zernike,[7] and for this case, $\alpha_1=-\sigma$.

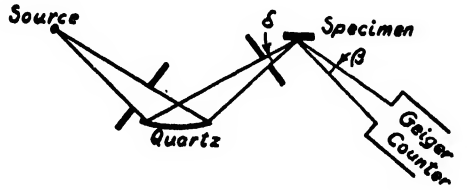

FIG. 1. Arrangement used for measurements of diffuse scattering from single crystals, using a bent-crystal monochromator.

It may be shown readily[6] that the limiting value of α_i for i very large is given by $\alpha_i^\circ\cdot S^2$. Thus the value of α_i falls off to zero with increasing distance from the origin above the critical temperature, but approaches a finite limit when long-range order is present. For the case of finite long-range order, the Fourier series representing the scattering power in reciprocal lattice space may be divided into two series, as MacGillavry and Strijk[8] have suggested: one series with coefficients equal to $\alpha_i^\circ\cdot S^2$, representing the sharp super-lattice reflections with integrated intensity proportional to S^2, and the other with coefficients $\alpha_i-\alpha_i^\circ\cdot S^2$, giving broad maxima in the diffuse background surrounding the sharp super-lattice reflections.

The experimental determination of short-range order parameters involves the measurement of a large number of intensities of the diffuse background scattering of x-rays from a single crystal, the calculation of the quantity I_D' as a function of the reciprocal lattice coordinates, and the three-dimensional Fourier analysis of this function.

Experimental Methods

Measurements were made of the intensity of reflection of copper $K\alpha$ radiation from the face of a single crystal of Cu_3Au cut parallel to the (1,0,0) lattice plane. The crystal was held at a temperature above the critical temperature of Cu_3Au, and intensity measurements were made with a conventional Geiger counter and scaling circuit.

For measurements of diffuse background intensities it is necessary to use monochromatic radiation such as that given by a crystal monochromator. However, it was found that the intensity given by a plane monochromator, such as a well-ground rocksalt cube face,

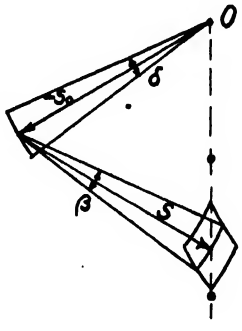

FIG. 2. The volume-element of reciprocal lattice space defined by the divergence of the x-ray beams.

was insufficient to allow accurate intensity measurements with a Geiger counter. Hence a focusing monochromator, using an elastically bent quartz crystal, was employed in an arrangement sketched in Fig. 1. This arrangement gives sufficient intensity by taking advantage of the fact that a low divergence beam, such as that given by a plane crystal monochromator, is not necessary for the measurement of slowly-varying background intensities, but a relatively large divergence of incident and reflected beams may be used without serious decrease in the accuracy of measurement. In

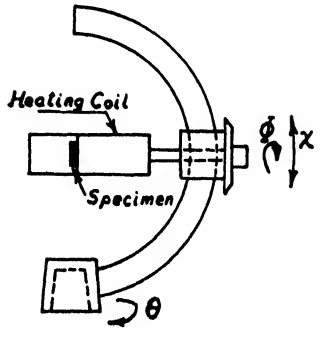

FIG. 3. Specimen mount, for measurement of intensities reflected from single crystal faces at elevated temperatures.

Fig. 1, the incident beam has an effective divergence δ in the horizontal plane. The rectangular aperture at the entrance to the Geiger counter gives the reflected beam a divergence β in the same plane and a divergence γ, not shown, in the perpendicular plane. Figure 2 shows the equivalent of this arrangement in the reciprocal lattice. The vector, S_0, representing the incident beam, varies through an angle δ. The vector S representing the reflected beam varies through an angle β in the same plane and an angle γ in the perpendicular plane. All the "scattering power" contained in the volume element of reciprocal space so defined contributes to the measured intensity. In practice the angles δ, β and γ were made equal to three degrees.

In order to obtain measurements of the intensity for orientations of the single crystal corresponding to various positions of the volume element in reciprocal lattice space, the specimen mount sketched in Fig. 3 was used. The large semicircular arcs stood in a vertical plane on the table of a spectrometer. The specimen was heated by a heating coil and surrounded by a shield having nickel or beryllium windows. An atmosphere of hydrogen was maintained within the shield to prevent oxidation of the surface of the crystal. Three calibrated rotations are provided; rotation through the Bragg angle θ, rotation about the (1,0,0) crystal axis, perpendicular to the crystal face, through the angle Φ, and a tilting of this axis through an angle χ in a vertical plane.

The function I_D' may be found throughout the whole of a unit cell of the reciprocal lattice by applying symmetry operations to values found for a relatively small portion of the unit cell. Thus, for Cu_3Au, intensity measurements were made, and values of I_D' were calculated only for the region contained in the triangular prism *ABCDEF* shown in Fig. 4. This prism has one thirty-second of the volume of the whole unit cell, which may be built up from the prism by use of the center of symmetry, *G*, and planes of symmetry.

From the observed intensities, the values of I_D' were calculated using the relation

$$I_D' = K(I_{Obs} - I_T - I_C)\left[\frac{(\sin 2\theta)}{(1+\cos^2 2\theta)}\right]\frac{1}{(f_{Au}-f_{Cu})^2}\frac{1}{A(\theta)},$$

where I_T and I_C represent the "temperature-diffuse" and Compton scattering contributions to the diffuse background intensity, K is a constant, and $A(\theta)$ is a correction for the absorption in the nickel or beryllium foil surrounding the specimen. Since the experimental conditions were such that the angles made by the incident and reflected beams with the crystal face were equal, no correction for absorption in the specimen was necessary.

The contribution of the Compton scattering was calculated to be approximately one-tenth of the average value of I_D'. The temperature diffuse scattering was evaluated by measuring diffuse background intensities at temperatures of 360°C, which is just below the critical temperature of about 385°C, and room temperature. At 360°C, the diffuse scattering consisted of temperature-diffuse scattering, Compton scattering, and a small amount of scattering due to disorder. For a specimen cooled quickly from 360°C to room temperature, the amounts of Compton and disorder scattering were unchanged, but the temperature-diffuse scattering was decreased. Thus the rate of variation of the temperature-diffuse scattering was obtained, and by extrapolation to absolute zero of temperature, the amount of disorder scattering at 360°C was found. The correction term for temperature-diffuse and Compton scattering, to be subtracted from the observed intensity at any elevated temperature, was then defined as the intensity measured at 360°C, minus the contribution of the disorder scattering at 360°C, plus a term proportional to the difference between the temperature of observation and 360°C.

At each of three temperatures greater than the critical temperature, more than 450 intensity measurements were made for settings of the angles θ, Φ, and χ, corresponding to positions of the measuring volume-element spaced regularly throughout the portion of the reciprocal lattice cell shown in Fig. 4. The value of I_D' was calculated for each position. Values of I_D' were then interpolated on to a cubic net of points spaced at intervals of 0.05 in the coordinates h_1, h_2, h_3, which are so defined that the unit of distance is the distance of the (2,0,0) reflection from the origin of the reciprocal lattice. By use of appropriate symmetry operations, the values of I_D' at the 8000 points of this cubic net within the unit cell were obtained.

The values of the Fourier coefficients α_{lmn} are given

by the integration of the product of I_D' and the appropriate exponential function throughout the unit cell of the reciprocal lattice. In practice, the presence of a center of symmetry allows the exponential functions to be replaced by cosines, and the integration is approximated by a summation of the values of the product at regularly spaced points. Thus,

$$\alpha_{lmn}=K\sum_{h_1}\sum_{h_2}\sum_{h_3} I_D' \cos 2\pi(lh_1+mh_2+nh_3).$$

The summation was carried out over the 4000 points of the cubic net contained in half of the unit cell. The normalizing constant, k, was obtained from the relation,

$$\alpha_{000}=K\sum_{h_1}\sum_{h_2}\sum_{h_3} I_D'.$$

The summation was greatly simplified when one or two of the atom coordinates were zero. Thus

$$\alpha_{l00}=K\sum_{h_1}(\sum_{h_2}\sum_{h_3} I_D') \cos 2\pi l h_1$$

and

$$\alpha_{lm0}=K\sum_{h_1}\sum_{h_2}(\sum_{h_3} I_D') \cos 2\pi(lh_1+mh_2).$$

For the general case, in which no such simplification was possible, a "template" method of performing the multiplication and addition was used. The values of I_D' were tabulated at regularly spaced positions for values of h_2 and h_3 from 0 to 1, for each value of h_1. Templates were made by cutting holes in stiff paper so that, when the templates were placed over the tables of values of I_D', only numbers to be multiplied by given values of the cosine functions were visible.

In some cases the values of the α_{lmn} so obtained did not show symmetry with respect to the three reciprocal lattice aces. Thus, for example, the values obtained for α_{200} and α_{020} were different. Such differences arose from imperfect correction for temperature-diffuse scattering, and were small for carefully determined backgrounds. In order to minimize the errors arising from such asymmetry, the values of the α_{lmn} were obtained for various permutations of the indices, and the weighted average was found.

Experimental Results for Short-Range Order

Intensity measurements were made for Cu_3Au at temperatures of 405, 460, and 550°C. The distribution of scattering power in the reciprocal lattice, calculated from these measurements, showed interesting features. Figure 5 is a contour plot of the scattering power due to short-range order, in arbitrary units, in the (1,0,0) plane of the reciprocal lattice of Cu_3Au at 405°C. The corners of the square are sites of the sharp fundamental reflections. The diffuse maxima at the super-lattice reflection positions appear to be flattened into a disk-like shape. At the center of the square, one of these disks is seen in section by the plane of the disk, and on each side of the square is the section of a disk with its plane perpendicular to the plane of the section. It is seen that the flattened sides of the disks face the nearest fundamental reflections, and each fundamental reflection is surrounded by six such flattened sides.

The disk-like shape of the diffuse maxima seems to be a consequence of the structure of the Cu_3Au lattice, rather than any particular values for the short-range order parameters. Qualitatively, the same shape is given by calculation assuming a wide variety of values for the order parameters for the first two shells, ignoring the effects of further parameters.

The same disk-like shape has been found, on a much smaller scale, for the relatively sharp super-lattice reflections from single crystals of Cu_3Au[9,10] for temperatures below the critical temperature. For this case, the shape of the super-lattice reflections was explained by Wilson[11] in terms of the domain-structure of the ordered alloy.

The short-range order parameters calculated by Fourier analysis of such distributions of scattering-power are given in Table I. The third column of the table gives the coordinates of representative points of the successive shells, referred to half of the length of the face-centered cubic unit cell as unit distance. The values of the order parameters for a perfectly ordered lattice are given in the fourth column. The magnitudes of the short-range order parameters decrease, in general, with increasing temperature and with increasing distance from the origin. At 405°C, the magnitude of the nearest-neighbor order parameter is seen to be almost half that for perfect order. The

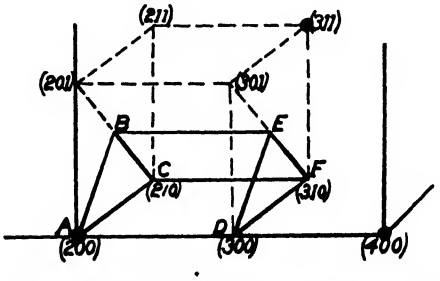

FIG. 4. The prism-shaped portion of reciprocal-lattice space, $ABCDEF$, throughout which the scattering power was determined.

parameters for the fifth and tenth shells indicate that, with a gold atom at the center, there is an excess of one copper atom among the 24 atoms of the fifth shell, and a defect of half a copper atom among the 24 atoms of the tenth shell. Thus the influence of the atom at the origin is appreciable at greater distances than those which have been considered in previous theoretical and experimental work.

[10] Edmunds, Hinde, and Lipson, Nature **160**, 304 (1947).
[11] A. J. C. Wilson, Proc. Roy. Soc. **A181** (1943), Nature **160**, 305 (1947).

It is difficult to make an accurate estimate of the probable error in the values of the short-range order parameters found. However, it is believed that the error in the parameters for the inner shells does not exceed 0.01. For more distant shells, the absolute error is probably slightly less, and the relative error greater. The principal sources of error are inaccuracies in the correction for temperature-diffuse scattering and in the interpolation of the values of I_D' from a conical-polar to a cubic net of points.

In general, the experimental order parameters given

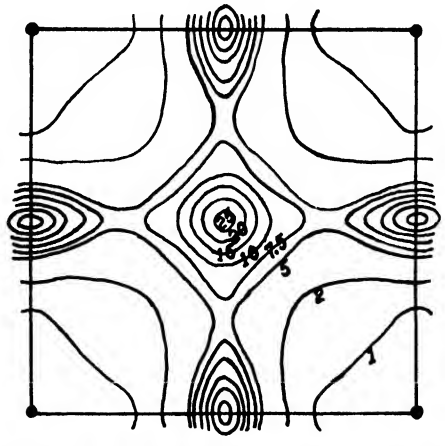

FIG. 5. Contour plot of scattering power due to short-range order in the (1,0,0) plane of the reciprocal lattice of Cu_3Au at 405°C.

in Table I have the same sign as the corresponding parameters for the case of perfect order. However, for some of the parameters for the third, sixth, and ninth shells, the signs are reversed, indicating a defect of copper atoms in a shell surrounding a gold atom instead of an excess, or an excess instead of a defect. The significance of these reversals of sign becomes apparent when the number of copper atoms in excess or defect in each shell is considered as a function of the radius of the shell. In Fig. 6 the number of copper atoms in defect (as compared with the number for a completely random arrangement) for each shell, given by the product $\frac{3}{4}c_i\alpha_i$, is plotted as a vertical line at the abscissa value corresponding to the radius of the shell. This is done for perfect order and for temperatures of 405 and 550°C. For the case of perfect order, alternate shells show an excess and a defect. However, for the elevated temperatures there is a marked tendency for groups of shells to show a common excess or defect, so that the alternation is less rapid. Thus, after the large excess of copper atoms in the first shell about a gold atom, the next three shells have a defect, the next three have a common tendency to show an excess, and so on.

One way of interpreting this behavior is to consider that the predominating force is that tending to surround each atom with unlike neighbors. The first shell surrounding a gold atom is thus copper-rich. All atomic sites which are nearest neighbors to atoms in this first shell will then tend to be gold-rich. The atoms of the second, third, and fourth shells are all nearest neighbors of points in the first shell, and so will show a common defect in copper atoms. Similarly, the atoms of the fifth, sixth, and seventh shells are nearest neighbors of atoms in these three shells, and will tend to be copper-rich, and so on.

Such a variation in density of copper atoms with radial distance from the origin is analagous to the variation in density of the atoms about a given atom in a monatomic liquid. Debye and Menke[12] determined the radial distribution of the density of mercury atoms about a given atom in the liquid by x-ray methods. Their curve has been added in Fig. 6 with the dimensions adjusted so that the first peak coincides with the point representing the excess of copper atoms in the first shell. It is seen that the positive and negative portions of the curve coincide with the regions of copper defect and excess. The curve as drawn would represent the distribution in a liquid of "atoms" consisting of a copper atom plus half of its gold-rich shell of nearest neighbors. The distribution of copper atoms about a gold atom may thus be likened to a "melting" of the ordered structure to give a "liquid-like" arrangement of the atoms on the atomic sites.

This liquid-like dependence of the density of copper atoms on the radial distance is combined with the dependence on the lattice coordinates associated with ordering. The radial dependence becomes more important as the temperature is raised, and seems to predominate at temperatures as high as 550°C.

MEASUREMENT OF LONG-RANGE ORDER IN Cu_3Au

When an x-ray beam is reflected at the face of a single crystal by planes parallel to the face, the integrated intensity of the reflection is given by

$$E=K(N^2F^2/\mu)[(1+\cos^2 2\theta)/(2\sin 2\theta)]\exp(-2M),$$

where N = number of unit cells per unit volume, K = constant for given primary beam conditions, F = structure factor for the given reflection, μ = linear

absorption coefficient of the crystal, $\exp(-2M)$ = correction factor for thermal vibration of atoms.

For a single crystal of Cu_3Au, with long-range order parameter S, the structure-factor for the super-lattice reflections is given by $F^2=(f_{Au}-f_{Cu})^2\cdot S^2$.

Wilchinsky[2] used the fundamental lines of Cu_3Au as intensity standards in his determination of S from powdered samples. Such a standardization is not possible when a single crystal is used, because the intensities of the strong fundamental reflections are decreased by an unpredictable amount by extinction effects. Hence an intensity standard was used; namely, the (600) reflection from a well-ground rocksalt cube face.

Measurements of the integrated intensities of super-lattice reflections from single crystals of Cu_3Au were made using the same apparatus as for the short-range order measurements outlined above. The entrance slit of the monochromator was narrowed to reduce the divergence of the primary beam to less than half a degree. Thus the volume element of reciprocal-lattice space shown in Fig. 2 was reduced to a thin plate-like element. This plate was swept through the region of a super-lattice reflection by a rotation of the single crystal specimen. The measured intensity was plotted against angle of rotation of the specimen. The area of the resultant peak was then proportional to the integrated intensity of the reflection. Similar measurements on the rocksalt reflection provided the standardization from which the value of S could be calculated. The results of two series of measurements are summarized in Fig. 7 and compared with the predictions of theory.[5]

The experimental results show agreement with the theory in the slow decrease in S and then the sharp fall to zero S at the critical temperature. The drop in S at the critical temperature was observed experimentally to take place within a temperature range of two or three degrees.

For such measurements, the single-crystal specimen was first heated at some temperature below the critical temperature for 70 to 100 hours. It was then found that, on raising or lowering the temperature, the integrated intensity reached a new equilibrium value in one hour or less. When the critical temperature was exceeded, the intensity of the super-lattice reflection became too small to measure within 15 minutes. Once the crystal was disordered, an annealing time of 70 hours or more was required to bring it to an equilibrium ordered state again.

These observations confirm the results and conclusions of Sykes and Evans,[13] who measured the electrical resistance of Cu_3Au as a function of time and temperature. They showed that two processes with very different time-constants could be distinguished; the slow growth of "anti-phase domains," and the much more rapid increase of order within the domains. Starting from a disordered sample, a long annealing time is necessary for the domains to grow large enough so that the presence of the domain boundaries has no appreciable effect on the electrical resistance or the integrated intensity of x-ray reflection. Once this domain size has been attained, an equilibrium state may be obtained rapidly at another temperature by increase or decrease of order within the domains.

A few observations have been made of the changes of integrated intensity, peak intensity, and half-width of super-lattice reflections from an initially disordered specimen heated below the critical temperature. A crystal, previously heated to 410°C to disorder it, was held at 360°C. After 15 minutes the integrated intensity of the reflection was about half of its maximum value, but the width of the reflection was much greater than

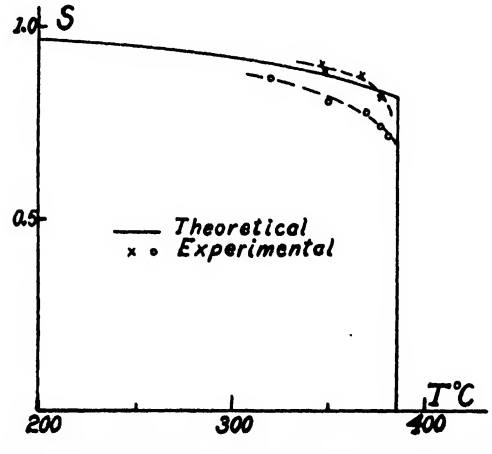

FIG. 7. Experimental values of the long-range order parameter, S, for Cu_3Au, compared with a theoretical curve.

[13] C. Sykes and H. Evans, J. Inst. Metals 58, 255 (1936).

for long annealing times. With further heating, the integrated intensity of the reflection increased more and more slowly. The rapid initial increase in intensity presumably corresponded to the propagation of order in the lattice outward from a number of nuclei until the domains so formed either coalesced or formed inter-domain boundaries. From a more detailed study of the shape and size of the super-lattice reflections at the end of this initial stage of growth, it should be possible to deduce the shape and size of the initially formed domains, and hence the directions of growth from the nuclei, and the number of nuclei.

The author wishes to express his indebtedness to Professor B. E. Warren, who suggested this research and provided valuable discussion and advice during the course of the work.

Integrating Crystal Detectors for High Energy Photons and Particles*,**

R. S. ALGER
Laboratory for Insulation Research, Massachusetts Institute of Technology, Cambridge, Massachusetts
(Received July 18, 1949)

Three of the alkali halides, LiF, KBr, and NaCl were examined as integrating detectors for high energy photons and particles. Dosage measurements were based on the number of color centers formed in single crystals under x- and cathode-ray bombardment. Exposures of 20 to 10^4r (30-kv x-rays) were measured photoelectrically and 10^5 to 10^7r (3 Mev x- and cathode rays) were measured optically. The crystals have advantages in measurements where wide range, high absorption, small size, and simplicity are desirable; however, their use is restricted by the length of the bleaching period required between exposures.

INTRODUCTION

CERTAIN of the effects produced in the alkali halides under high energy particle or photon bombardment, namely, color center formation and photoconductivity, suggest the possibility of a simple type of integrating detector which uses these materials. Quantitative measurements can be made, either of the optical absorption or the photoelectric currents, and the high absorption coefficients of the heavier crystals such as KBr would permit the detection of high energy particles with a relatively small volume of crystal. Consequently, three of the alkali halides, LiF, NaCl, and KBr were examined as to their characteristics as integrating detectors for x- and cathode rays up to energies of 3 Mev. Although, in this study, the emphasis was placed on experiments clarifying the usefulness of the crystals as detectors, data were obtained on the trapping and migration of electrons which, when further expanded, promise to give new information of general interest.

COLOR CENTERS IN THE ALKALI HALIDES

The following known facts concern the problem at hand. When the crystals are exposed to high energy photons or particles, they become colored by the *F*-absorption bands, which appear in the visible or ultraviolet region of the spectrum.[1] The *F*-centers responsible for this absorption seem to be electrons trapped at halogen ion vacancies;[2] such vacancies are always present in the alkali halides as Schottky defects.[3]

When x-ray photons transfer energy to the crystal, either by photoelectric absorption, Compton absorption, or pair production, primary electrons of high energy are released which dissipate their energy in secondary ionization processes, thus creating a number of conducting electrons and neutral halogen atoms. The electrons move through the crystal until they recombine with neutral halogen atoms or are trapped by negative ion vacancies to form *F*-centers. When crystals are bombarded with electrons, the final result is the same as with x-rays. Cathode and beta-rays may be stopped in the crystal and trapped as additional *F*-centers, but this contribution is negligible because of the space charge formed.

The *F*-center density can be calculated from the bell-shaped optical absorption band by an expression derived by Smakula.[4] Seitz[5] has simplified Smakula's equation, for the case where the half-band width is small compared to the frequency of the absorption maximum, to the form

$$N_0 f = 1.31\times 10^{17} K W \frac{n_0'}{(n_0'^2+2)^2} \qquad (1)$$

where N_0 = number of *F*-centers per cc, f = oscillator strength of the absorbing center, K = maximum optical absorption coefficient in cm^{-1}, n_0' = refractive index at K, W = interval from K to $K/2$ in e.v. If an oscillator strength of 0.7 is used for NaCl at room temperature, Eq. (1) reduces to

$$N_0 = CK. \qquad (2)$$

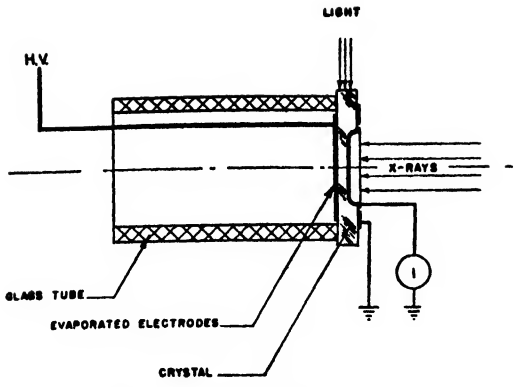

FIG. 1. Photoelectric dosimeter.

NaCl and KBr at room temperature are 3.6×10^{15} and 4.45×10^{15} respectively.

In addition to the principal absorption bands, for which the F-centers are responsible, a number of subsidiary bands have been observed at longer wavelengths, e.g., the F'-, R_1-, R_2-, and M-bands. Molnar[7] has measured the F-bands and the subsidiary bands for the majority of the common alkali halides.

When crystals colored with x-rays are heated or illuminated with light in the F-band, the whole F-band bleaches out uniformly; simultaneously some of the subsidiary bands may appear and a photo-current will be observed in case an external field is applied. Pohl and his co-workers,[1] who investigated the photoelectric processes extensively, found that one F-center was destroyed for every quantum of light absorbed. The conducting electrons move through the crystal until they are trapped by a vacancy or recombine with a halogen atom. The drift distance in the field direction depends on the strength of the electric field and the number of traps present. Pohl and his co-workers[1] designated the current due to photo-electrons as the "primary photoelectric current" whereas other currents resulting from the primary current flow were called "secondary photo-currents." These secondary effects occurred only above room temperature and were not observed in the experiments reported here. Since the electron drift distance is proportional to the field strength, the photo-current can be enhanced by the use of very strong electric fields. With photo-currents of the order of 10^{-10} amp., von Hippel[8] observed a photo-current saturation in thin KCl crystals beginning at a field strength of about 0.6 million volt/cm. Under more intense illumination thicker crystals break down electrically before a saturated photo-current can be obtained. At the saturation point the electron drift distance becomes equal to the thickness of the crystal, and all the electrons released in the crystal are swept to the anode.

[7] J. P. Molnar, thesis, Physics Department, M.I.T. (October, 1940).

[8] A. von, Hippel Phys. Rev. 54, 1096 (1938).

When a very weak source of illumination was used for short intervals of time, in which case the charge released was of the order of 10^{-12} coulomb, Pohl[1] found the primary photo-current remained nearly constant with time and had a magnitude proportional to the light intensity. When larger amounts of charge, e.g., 10^{-9} coulomb, are released, a space charge builds up in the crystal, which may nullify the external field, and no further photo-current is obtained. Because the range of the electrons is altered due to the field distortion, not all the photo-electrons contribute equally to the photo-current in this space charge region. Thus it becomes difficult to determine the F-center density from photo-electric measurements at high light intensities.

EXPERIMENTAL PROCEDURE

Crystal Preparation and Crystal Holders

For our photoelectric measurements NaCl and KBr crystals† were split to a size of $\frac{1}{2}\times\frac{1}{2}\times\frac{1}{16}$ in. and hollowed on one side to keep the electric field low at the edge of the electrode. The cavities were produced with an automatic wet cloth lap. Gold electrodes were evaporated onto the polished crystals after they had been heated to 350°C in vacuum to expel surface moisture. Figure 1 gives a schematic view of a finished crystal mounted for photoelectric measurements. The glass tube, cemented to the crystal with polybutyl methacrylate, supports the sample and prevents surface flashover. X-rays are admitted through the concave electrode and the light is focused on the edge of the crystal.

LiF, NaCl, and KBr samples, $1\times1\times0.1$ in. and $1\times1\times0.01$ in., were prepared with optical surfaces for the F-band absorption measurements.

Exposure Methods

Two radiation sources were used; a Machlett x-ray diffraction tube at 30 to 45 kv with a copper target and a 1 mil thick nickel filter, and a 3-million volt source for x- and cathode rays (van de Graaff generator).

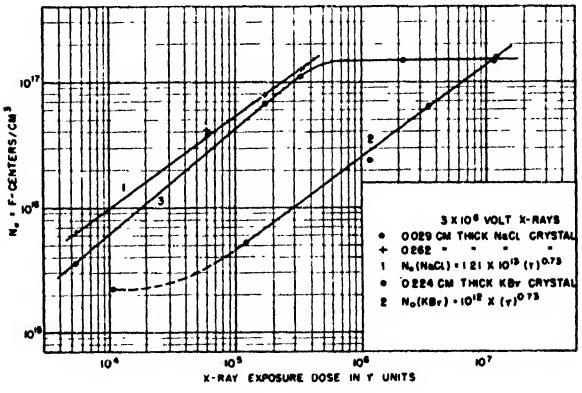

FIG. 2. F-center concentration as function of x-ray exposure.

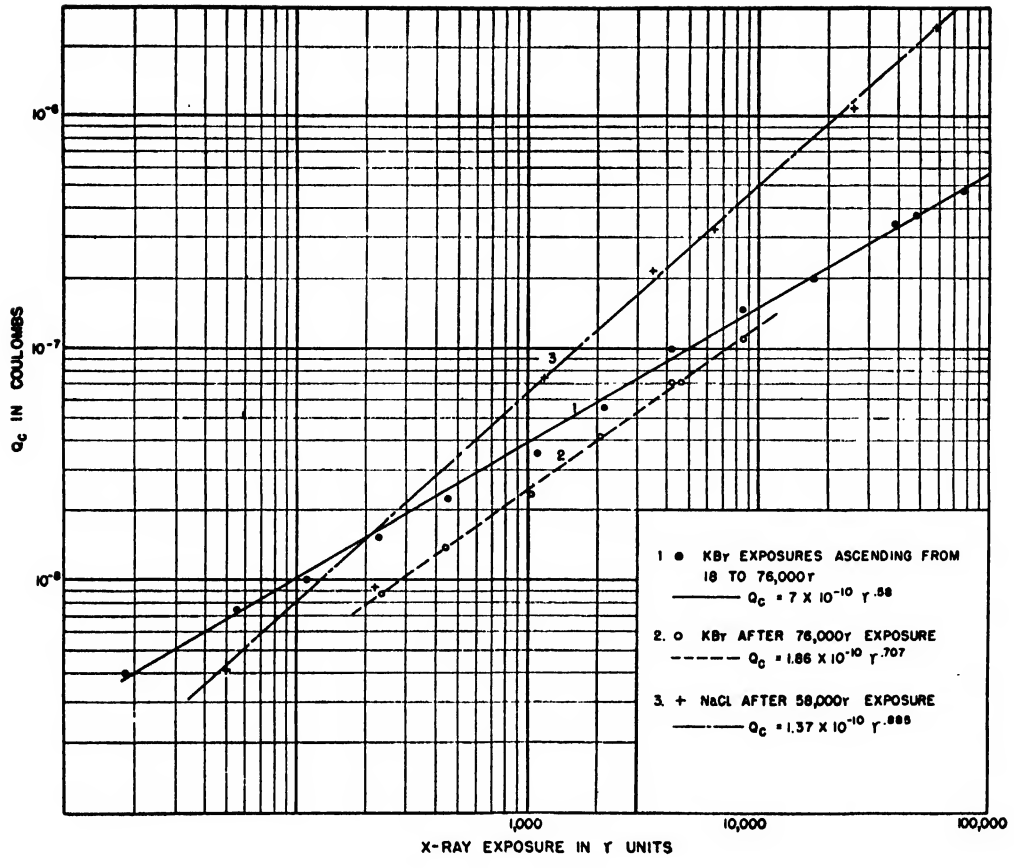

FIG. 3. Charge bleached from crystals as function of x-ray exposure.

All x-ray exposures were measured in roentgens (r units) with air ionization chambers. The chamber used with the diffraction tube was copied, with some change of dimensions, from a design of Taylor and Stoneburner.[9] Exposures to 3-million volt x-rays were measured with a roentgen meter built into the van de Graaff generator. While the relative values measured with this meter are accurate to better than 5 percent, the actual calibration in roentgens may be in error by a factor of 2. Cathode-ray exposures were measured in joules and converted to roentgen-equivalent-physical (rep) units in air for comparison with the x-ray doses. (1r$\simeq$83.8 ergs/g of air at standard conditions and 1 rep=83.0 ergs/g of material.) Due to the simplifying assumption of a uniform ionization intensity and the unknown distribution of cathode rays over the target plate, the accuracy of the rep values is probably less than that of the r.

Since the production of F-centers depends on ionization, the F-center concentration will vary throughout the crystal according to the ionization intensity. For the 30 to 45-kv x-rays the ionization is most intense at the incident surface and decreases rapidly in accordance with the large coefficient of absorption for the crystals. At 30 kv and exposures up to 10^4 r, the visible coloring extended less than 1 mm into the KBr crystals. Photoelectrons resulting from the absorption of 3-Mev photons have an appreciable velocity in the direction of the x-ray beam; therefore, the peak ionization intensity occurs beyond the incident surface and may well be at the exit surface of a thin crystal. Consequently a given x-ray exposure below the saturation value might produce a smaller average F-center concentration in a thin crystal than in a slightly thicker one because the latter contains more of the peak ionization.

Photoelectric and Absorption Measurements

The coloration produced in the crystals by exposure to an x-ray dose of from 20 to 10^4 roentgens was measured photoelectrically by the charge Q_c traversing the crystal under strong illumination. After the crystal had been colored (Fig. 1), an electric field of about 10^5 volts/cm was applied, the crystal illuminated and the photo-current recorded as function of time. The space charge formed during the measurement of Q_c cuts off the photo-current before all of the F-centers are removed; the remaining centers can be bleached by illuminating the crystal until no photo-current is obtained with either polarity of the external field.

The coloration of crystals given larger exposures (10^4 to 10^7 r or rep, of 3-million volt rays) can be measured optically. Values of the maximum absorption co-

[9] L. S. Taylor and C. F. Stoneburner, Bur. Stand. J. Research 9, 769 (1932).

efficient K, from which N_0 is obtained by Eq. (2), were measured with a Model 12M Cary recording spectrophotometer. The minimum measurable transmission was about 0.03 percent, and no F-center bleaching due to the scanning beam could be detected. Absorption measurements covered the region from 3400 to 7200A in KBr and NaCl, and from 2100 to 3400A in LiF. Desiccated holders protected optical surfaces of the hygroscopic crystals from atmospheric moisture.

The KBr and NaCl crystals were bleached with white light between experiments, while a 4-watt germicidal lamp, which has its major intensity concentrated in the 2537-Hg line, was used to bleach LiF. A residual absorption was bleached out by heat.

Parameters influencing both N_0 and Q_c are: besides the crystal material and prehistory, the energy and intensity of the radiation, the temperature and time of storage, the voltage and crystal thickness used. The effects of each of these variables were examined in turn.

RESULTS

Effect of Exposure

The relation between the F-center concentration N_0 in KBr and NaCl and the x-ray exposure in roentgens over the range from 10^4 to 10^7 r is shown in Fig. 2. N_0 increases with exposure until an equilibrium condition is reached (curve 3), where a saturation value of 1.5×10^{17} F-centers per cc was obtained for NaCl. This saturation can be measured only in thin crystals; in thicker crystals (curves 1 and 2) practically all the light is already absorbed at lower concentrations, and the sensitivity range of the spectrophotometer is exceeded. Over the straight line portion of the log-log curves 2 and 3 the F-center concentration fits the empirical relation

$$N_0 = C_1 r^{0.73}, \tag{3}$$

where $C_1 = 1.0 \times 10^{12}$ for KBr and 1.2×10^{13} for NaCl. Since the F-band was barely detectable in KBr at $r = 10^4$, this point may be considerably in error.

Typical photoelectric measurements of Q_c for 30-kv x-rays and exposures ranging from 20 to 10^4 r are given for KBr and NaCl in Fig. 3. The empirical equations obtained between Q_c and the x-ray exposure in roentgens are similar to Eq. (3).

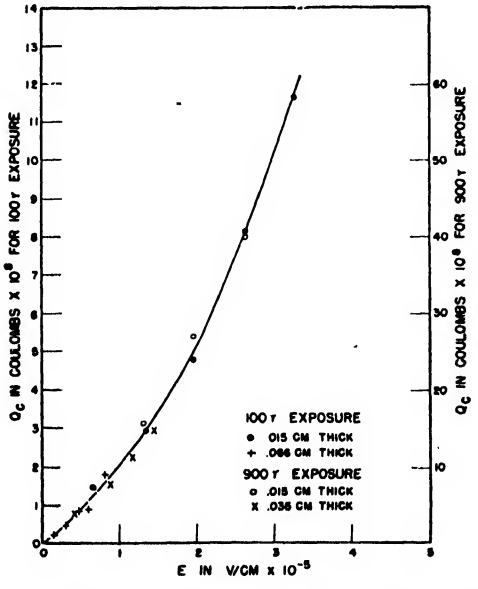

FIG. 4. Effect of applied field on charge bleached from KBr crystals.

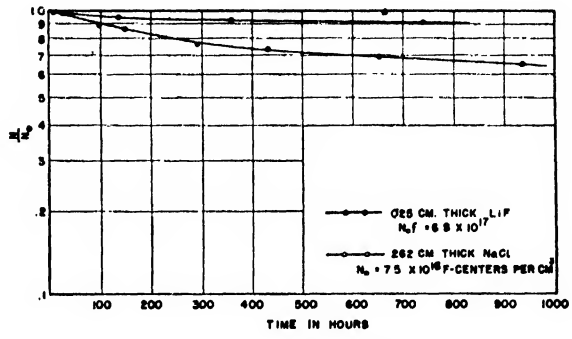

FIG. 5. F-center decay at 21°C due to thermal release.

For KBr (curve 1) $Q_c = 7 \times 10^{-10}$ $r^{0.68}$, KBr (curve 2) $Q_c = 1.86 \times 10^{-10}$ $r^{0.707}$, NaCl (curve 3) $Q_c = 1.37 \times 10^{-10}$ $r^{0.885}$.

It becomes apparent from curves 1 and 2 that a preceding exposure can affect the characteristics obtained in later measurements (see later section on Polarization).

Influence of Crystal Type and Thickness

The crystal material has a pronounced effect on the F-center density N_0 and charge Q_c obtained for a given x-ray exposure (Figs. 2 and 3). When the crystals are exposed to x-rays, the F-center formation rate (i.e., N_0/roentgen) diminishes in the order LiF→NaCl→KBr. Comparing LiF with NaCl for an exposure of 10^7 rep, the ratio $N_0 f_{(\mathrm{LiF})}/N_0 f_{(\mathrm{NaCl})} = 4.6$ was found (see Eq. (1)). A 1 mil thick crystal of LiF became practically opaque under a 3-million volt x-ray bombardment before the F-band of a similarly treated KBr crystal was readily detectable. In Fig. 2 the F-center density $N_{0(\mathrm{NaCl})}$ is seen to be greater than $10 N_{0(\mathrm{KBr})}$ for identical x-ray exposures below the saturation value.

Since the optical measurements show more F-centers formed in NaCl than KBr, it would be expected that for crystals of the same thickness and subjected to the same electric field, a larger charge Q_c would be obtained for NaCl. A comparison of the curves in Fig. 3 shows that this is the case; $Q_{c(\mathrm{NaCl})}/Q_{c(\mathrm{KBr})}$ varied from about 2 to 4. Selection of the proper crystal material provides some control over sensitivity and usable range of these integrating detectors.

N_0 is slightly higher in a thicker crystal for a given exposure of 3-Mev x-rays (Fig. 2), which agrees with

the result predicted by the distribution of the ionization intensity. This variation should affect N_0 only before the crystal becomes saturated. Figure 4 shows Q_c as a function of the applied field strength for 3-crystal thicknesses. No definite thickness effect is apparent over the limited region covered.

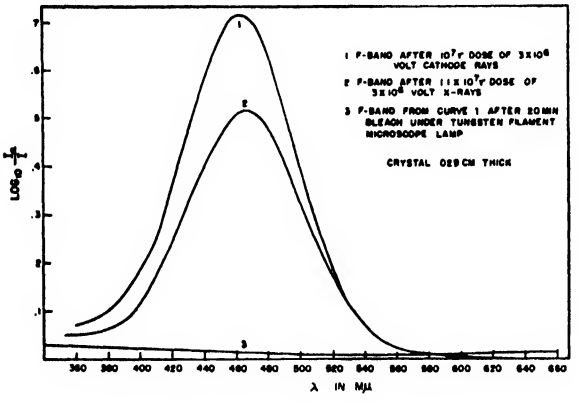

FIG. 6. Bleaching of F-centers in NaCl.

Thermal Bleaching

In alkali halide crystals colored by x-rays, some thermal bleaching occurs at room temperature. The bleaching rate may be very slow, e.g., Joffé observed some color centers remaining in an x-ray colored NaCl crystal after it had been stored in the dark for about 20 years.[10] The heavier crystals, with their lower activation energy, bleach more rapidly than the crystals composed of the lighter elements. Since the thermal bleaching would produce an error in dosimeter readings, a series of measurements were made on colored NaCl, LiF, and KBr crystals to determine the bleaching rate. The results for NaCl colored by 3-million volt x-rays, and LiF colored by 3-million volt cathode rays are given in Fig. 5 which shows N/N_0 plotted as a function of time. (N = the F-center concentration at any time t and N_0 = the initial concentration.) The decay curves are not simply exponential, but a half-life of about 0.87 year fits the LiF characteristic quite well.

A consideration of the mechanism of decay indicates that a more complicated expression would be required to describe completely the decrease in the F-center density as a function of time. When the electron is thermally released from an F-center, it has the possibility of being captured by a neutral halogen atom or another halogen lattice vacancy. Each time an electron is captured by a neutral halogen atom the number of neutral halogen traps is decreased by one, and at the same time the ionized F-center increases the number of lattice vacancies by one. Consequently, as bleaching continues, the ratio of halogen vacancies to halogen neutral atoms increases, and the probability that the thermally released electron will be captured by a lattice vacancy to reform an F-center also increases. Therefore the F-center density decreases more rapidly the higher the coloration. Thus the thermal bleaching produces a larger error in the optical measurements where high F-center densities are employed than in the photoelectric measurements. In the case of photoelectric measurements with KBr, the time between x-ray exposure and the photoelectric measurement was allowed to vary from a few seconds up to 20 hr. at room temperature, and no decrease in the charge Q_c was observed. However, a slight decrease in the optical density of the F-band in highly colored KBr and NaCl can be detected after several hours.

Optical Bleaching

If the crystals are to be used more than once, the remaining color centers must be removed and the space charge redistributed between measurements. The required bleaching period depends on the F-center density, bleaching light intensity, and the crystal material. For example, 5 minutes of illumination were sufficient to bleach a KBr crystal exposed to a 100-r dose, while an NaCl crystal given the same dose required 30 minutes of illumination.

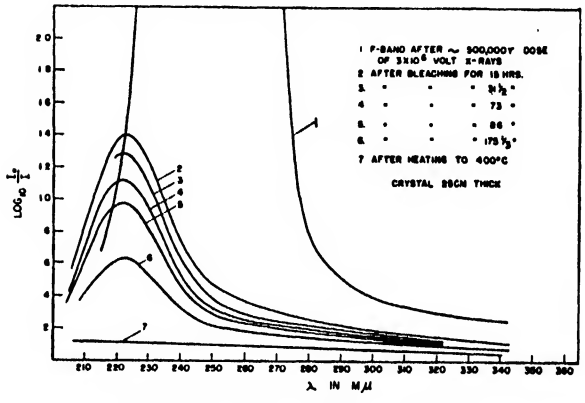

FIG. 7. Bleaching of F-band in LiF.

The optical measurements show the results of photo- and thermal bleaching more directly. Curve 3 of Fig. 6 gives the result of 30-minutes' bleaching with white light of the F-band absorption (curve 1) in an NaCl crystal exposed to approximately 10^7 rep. The F-band has been completely bleached, and no R- or M-bands are present; however, the absorption through the entire spectrum has increased from 0.015 to 0.02 density units.

The bleaching of LiF produced an effect not encountered thus far in the other crystals. An LiF crystal with an F-band absorption well above the upper limit of measurement (Fig. 7, curve 1) was exposed to the light from a 4-watt germicidal lamp for 175 hours. After the first 15 hr., the F-band was almost completely bleached except for a small peak centered at 2230A (curve 2). With continued bleaching the subsidiary

[10] A. F. Joffé, *The Physics of Crystals* (McGraw-Hill Book Company, Inc., New York, 1928) p. 128.

peak decayed symmetrically as shown in curves 2 to 6. Normally, illumination with any frequency in the F-band causes the whole band to decay symmetrically with the possibility of the F'-, R-, and M-bands appearing at longer wave-lengths. The auxiliary band at 2230A is singularly different from the usually subsidiary bands since it is on the short wave-length side of the F-band. When the crystal was heated to 400°C and allowed to cool, the F-band and the subsidiary peak were eliminated (curve 7). Once more, the final curve (7) exhibits some neutral absorption over the entire spectrum investigated; it may be due to surface deterioration.

Effect of Vacancies on Performance

Since the number of vacancies is dependent on the crystal temperature, the vacancy concentration can be increased by heating the crystals almost to the melting point and cooling them rapidly to room temperature. The number of vacancies frozen into the crystals quenched in this way will correspond to some intermediate temperature. Many of the vacancies appear to be paired up, i.e., halogen and alkali vacancies are attached to each other. A method for determining the number of paired vacancies from low frequency dispersion measurements has been described by Breckenridge.[11]

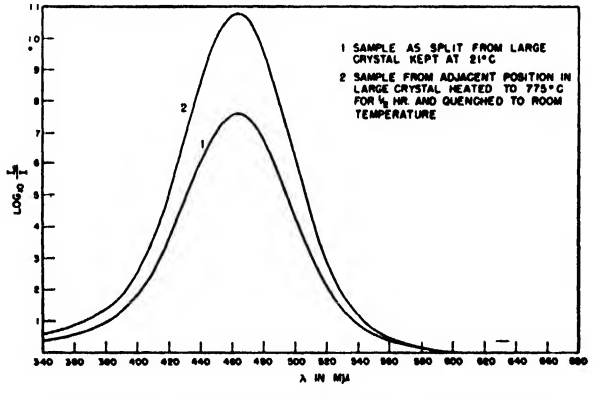

FIG. 8. Effect of vacancies on F-band in NaCl crystals.

If the dielectric loss ($\tan\delta$) is measured at a constant frequency of about 10^4 cycles/sec. over a range of temperatures, the alkali halide crystals containing sufficient vacancies exhibit a peak in the $\tan\delta$-curve at a temperature characteristic of the crystal. The number of paired vacancies can be determined from the height of the $\tan\delta$-peak by the following equation:[11]

$$n=\tan\delta_{\max}\frac{(18\epsilon_0 k)T\kappa_\infty'}{(Zea)^2(\kappa_\infty'+2)^2}, \qquad (4)$$

where $\epsilon_0=8.856\times10^{-12}$ farad/meter, $e=1.59\times10^{-19}$ coulomb, $k=1.38\times10^{-23}$ joule/degree centigrade, $\kappa_\infty'\simeq\kappa'=5.9$ for NaCl. By measuring $\tan\delta$ as a function of temperature before and after a crystal has been heat-treated, the number of paired vacancies produced by the heat treatment can be determined from the above relation. Crystals of LiF, KBr, and NaCl, which had been heated to increase the number of vacancies present, were compared with unheated crystals by measuring both the number of paired vacancies and F-centers formed in the crystals with a given dose of x-rays. Since electrodes were required for the dispersion measurements, two sets of crystals were used, one for the electrical and one for the optical measurements. The crystals to be compared were split from adjacent positions in the original crystal. NaCl was kept at 775°C for 30 minutes, KBr at 710°C for 30 minutes, and LiF at 825°C for 60 minutes and all were quenched to room temperature. This heat treatment produced only a slight hump in the $\tan\delta$-curves for KBr and LiF, and a more pronounced jump in NaCl, which, according to Eq. (4) corresponded to $n=1.5\times10^{15}$ vacancy pairs/cm.[3]

A 250,000-r dose of 3-million volt x-rays produced a stronger coloration in the heated samples; the effect was larger in NaCl than in either LiF or KBr as was to be expected from the $\tan\delta$-characteristics. Figure 8 shows the result for NaCl. The values found for the F-center densities per cc were:

$$N_{01}=5.8\times10^{16} \text{ for the heated samples}$$
$$\frac{N_{02}=4.1\times10^{16}}{\Delta N_0=1.7\times10^{16}} \text{ for the unheated samples.}$$

The value of N_{01} is a factor of 40 higher than the number n of paired holes obtained from the dispersion measurements (see Eq. (4)), although the F-center concentration is less than half the saturation concentration shown in Fig. 5. If, as Seitz suggests,[12] the vacancies are completely paired after the crystal stands for a few days at room temperature, the maximum number of F-centers should not exceed the number of

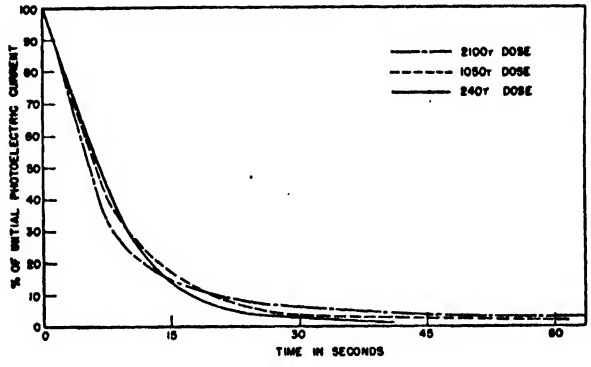

FIG. 9. Reduction in photo-current in KBr due to polarization.

[11] R. G. Breckenridge, Technical Report XI, Lab. Ins. Res., M.I.T. (April, 1948).

[12] F. Seitz, Rev. Mod. Phys. 18, 384 (1946).

paired vacancies if no new vacancies are created by the x-ray bombardment. The ratio of $n/N_0=0.025$ obtained in this experiment would indicate that only a small percent of the vacancies were paired.

The rate of F-center formation was increased in the crystals containing the larger concentration of vacancies. Consequently, crystals containing the largest possible number of vacancies might make the most sensitive detectors, but the effect is not very large.

Polarization

In photoelectric measurements, the space charge formed has a pronounced effect on the value of Q_e observed. When the crystal is illuminated in a strong electric field the electrons released from the F-centers will move toward the anode. Some electrons will be removed from the crystal while others are retrapped to form new F-centers or trapped by neutral halogen atoms to form ions. A positive space charge, presumably of neutral halogen atoms, develops in the vicinity of the cathode, and reduces the primary photo-current essentially to zero as the applied field is nullified. This behavior is illustrated by the curves of photo-current *vs.* illumination time in Fig. 9. Some of the reduction in primary photo-current is due to the loss of charge carriers to halogen neutral traps; however, the reduction in current shown in Fig. 9 is primarily related to space charge.

Increasing the F-center concentration results in a greater space charge density and consequently a steeper potential gradient at the cathode. When the gradient becomes sufficiently steep, electrons can enter the crystal and a semicontinuous photo-current is observed. After the electrons have entered the crystal they are indistinguishable from the electrons released from F-centers. Gradually the competing neutral halogen traps reduce the F-center concentration thereby preventing continuous photo-conductivity. In KBr crystals exposed to 10^7 rep of 3 million-volt cathode rays the total photo-current may drop by a factor of 3 during half an hour with the rate diminishing with time as the ratio of halogen vacancies to halogen neutral atoms increases. At high F-center concentrations Q_e is dominated by the rate of trapping by halogen neutral atoms, while at low F-center concentrations, the polarization predominates. With the equipment used in these experiments a practical upper limit of about 50,000 r for KBr was dictated by the bleaching time required to reduce the total current to zero. Bleaching the crystal with light does not restore the crystal completely to the initial condition of electrical neutrality. After the initial exposure r_1, with subsequent bleach and polarization, a series of reproducible values of Q_e can be obtained for exposures less than r_1. However, with $r_n > r_1$, a change occurs in the charge distribution when Q_{e_n} is measured and a pronounced decrease in Q_e is observed for all future exposures less than r_1. This effect is illustrated in Fig. 3. Curve 1 was obtained for exposures progressing from 18 to 78,000 r. After the 78,000-r exposure, smaller exposures fall along curve 2. The same effect was observed with NaCl before curve 3 was obtained. The polarization effects are being studied in more detail.

CONCLUSIONS

The results obtained demonstrate that the color centers in the alkali halides can be used to measure radiation or particle exposures. However, there are a number of restrictions which limit the usefulness of crystal dosimeters.

The main advantages of the crystal dosimeters are: small size, high absorption, wide range, and simplicity of the detecting element. Although the smallest crystals used in the experiments were $\frac{1}{2}\times\frac{1}{2}\times\frac{1}{16}$ in. in size, smaller crystals could be used if desired. When compared to gas-filled detectors such as ionization chambers, the higher absorption coefficient of the crystals is an advantage, especially when high energy radiations are being detected. Exposures of 20 to 10^7 r measured with KBr crystals illustrate the wide range possible. The crystal material offers some choice in the range and sensitivity that can be obtained. Based on the optical measurements, the crystals listed in descending order of sensitivity are: LiF, NaCl, and KBr.

The bleaching period required to eliminate the F-centers between successive measurements is a major limitation of the speed with which measurements can be repeated.

The polarization effects complicate the photoelectric measurements and make frequent calibrations necessary; consequently the optical method is more attractive for exposures above 10^5 r.

The vacancy concentration has only a slight effect on the F-center formation rate, and thermal bleaching at room temperature can be neglected except in the case of large F-center concentrations or long storage periods.

The author is indebted to Professor A. von Hippel under whose supervision this work was carried out, to Professor G. J. Trump for the use of the 3-million volt generator, to K. A. Wright who operated the generator and to M. A. Gilleo for assistance with the optical measurements.

Thermionic Emission from Oxide Cathodes: Retarding and Accelerating Fields*,†

C. S. HUNG‡
Massachusetts Institute of Technology, Cambridge, Massachusetts
(Received August 3, 1949)

An experimental investigation of the thermionic emission from oxide-coated cathodes is presented in which the applied voltage range extends from the retarding potential region through zero field and up to an average accelerating field of 50,000 volts per cm. The retarding potential range yields information concerning the energy distribution of the electrons emitted, and indicates an excellent agreement between theory and experiment for high retarding fields. Near zero field, cathode inhomogeneity or patch effect may be responsible for the deviations found. Consideration is given to the influence of a possible reflection effect, but theoretical calculation indicates that with the large area cathode used, the simultaneous reflection at the emitter and the collector surfaces so alter the observed current voltage relationship, that the existence or non-existence of a reflection effect cannot be determined by the experiment. Results shown in the accelerating field region up to 50,000 volts per cm are accounted for on the bases of two assumptions which are (1) patch effect for small accelerating fields and (2), the intensification of the field at sharp points expected in view of the inherent roughness of the cathodes studied. The deviation of the experimental results from those predicted by the Schottky mirror image theory is explained over the whole range of observation by these two assumptions.

INTRODUCTION

THE object of this work is to study two of the properties of the surface potential barrier of an oxide cathode. The first is the reflection effect on electrons crossing this barrier, and the second is the lowering of this barrier height in the presence of an external electric field. The surface potential barrier of a uniform thermionic emitter is usually assumed, for distances large compared to the lattice constant, to be due to the mirror image force alone. The quantum-mechanical reflection coefficient for an image force barrier, according to Frank and Young,[1] is only six percent for the low energy electrons and is a slowly varying function of the electron energy in the direction normal to the cathode surface. One way of determining the reflection coefficient experimentally is to measure the electron current to the anode as a function of the retarding potential of the anode relative to the cathode. The thermal equilibrium energy distribution of electrons in the emitter, with energies above the height of this barrier, is known to be Maxwellian since the height of the barrier from the μ-level is always large compared to kT at all operating temperatures of the cathode. This retarding field current, for cylindrical electrodes and assuming zero reflection coefficient is, as given by Schottky:[2]

$$J_v = J_0[2/(\pi)^{\frac{1}{2}}]\left\{e^{-n}\int_0^{(\lambda n)^{\frac{1}{2}}} \exp(-\theta^2 x^2)dx + \int_{(\lambda n)^{\frac{1}{2}}}^{\infty} \exp(-x^2)dx\right\}, \quad (1)$$

where J_v, and J_0 denote the currents per unit length of the cathode when the retarding potentials are V and zero respectively. And $n=eV/kT$, $\theta=r/R$, $\lambda=R^2/(R^2-r^2)$, where r, R denote the radii of the cathode and the anode respectively. The J_v/J_0 *vs.* V/T curves are independent of T under the conditions of this equation. Using this retarding potential method, Nottingham[3] found that for pure tungsten and thoriated tungsten of all degrees of coverage at the same temperature, the plots of $\log(i_v/i_0)$ against V/T all coincide, but the plots for different temperatures differ from each other and from the theoretical curve assuming no reflection

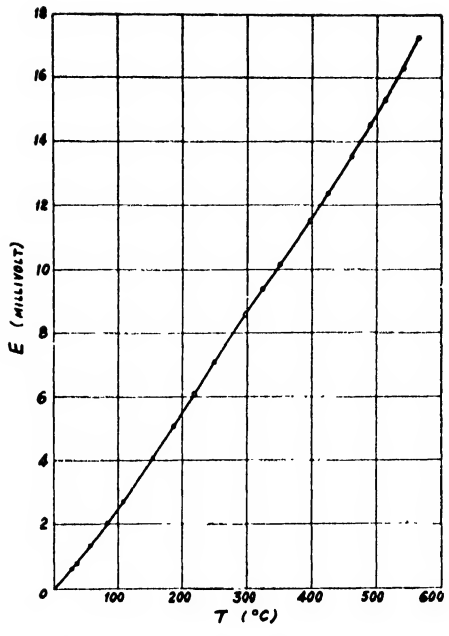

FIG. 2. Calibration curve of tungsten-nickel thermocouple. T is temperature of hot junction above that of cold junction (at 25°C).

as given by Eq. (1). A reflection coefficient of the form

$$R(p_z)=\exp(-p_z^2/2m\omega) \tag{2}$$

was proposed, where p_z denotes the momentum normal to the cathode surface that the electrons would have with zero applied field at distances beyond the range of mirror image forces. With the constant $k/\omega=4.5\times10^{-4}$ (deg.)$^{-1}$, all his data could be explained. This result was interpreted to mean that this reflection coefficient is probably related to the image field and not the surface patches, and therefore a reflection effect of at least this amount should exist at the surfaces of all electrodes including the anodes and the oxide cathode. Experiments on oxide cathodes by Heinze and Hass,[4] Fan,[5] and Brown,[6] have shown agreement with Eq. (1) for high retarding potentials. Deviations at low retarding potentials were reported and demand further study.

The lowering of the image force barrier in an external field is, according to Schottky,[2]

$$\Delta\phi=(eE)^{\frac{1}{2}} \tag{3}$$

and the anode current in an accelerating field is

$$J_v=J_0\exp[(eE)^{\frac{1}{2}}\cdot e/kT] \tag{4}$$

where E is the accelerating field at the cathode surface. Equation (4) is exact in the case of parallel plane electrodes and is also valid in the case of cylindrical electrodes except at very low anode voltages. Investigations on tungsten and thoriated tungsten cathodes by Nottingham[3] have shown agreement with Eq. (4) except for deviations at low accelerating potentials which have been explained satisfactorily by the patch theory. Measurements on oxide cathodes by Fan,[5] Mahlman,[7] Sproull,[8] and others have shown that the slopes of the Schottky plots, $\log(J_v/J_0)$ *vs.* $(E)^{\frac{1}{2}}/T$, in accelerating fields up to 10,000 volt/cm are 2 to 6 times higher than

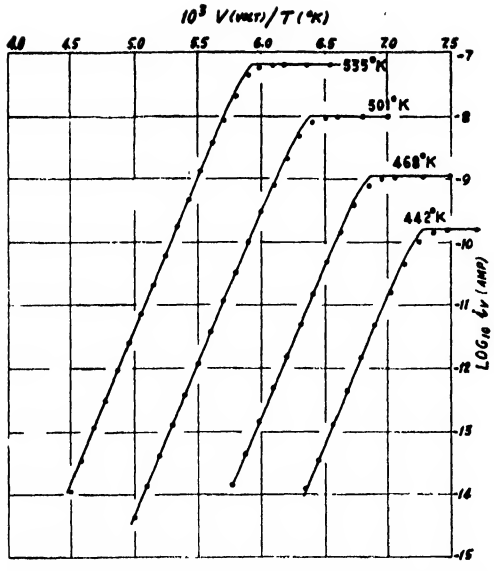

FIG. 4. Retarding field plots. Circles indicate the experimental points, and solid line the theoretical Schottky curves.

the theoretical image theory line. This effect was usually attributed to the patches, and it was suggested that the theoretical line might be approached at high enough accelerating fields.

In making further studies of these properties of the surface potential barrier, we notice that there are two more defects of the oxide cathode which should be considered: namely, the non-uniformity of the work function of the anode due to contamination, and the roughness of the oxide cathode surface. In this work we have managed to keep the anode free from the materials evaporated from the cathode so that the anode work function was uniform and did not change with the anode current. The roughness of the oxide cathode surface has been taken account of in analyzing our results.

EXPERIMENTAL SET-UP

The Experimental Tube

The main feature in the design of the experimental tube involved the use of a sliding anode structure in order to keep the anodes clean. A drawing of the sliding structure is shown in Fig. 1. The cathode (K) and the auxiliarly anode (AA) are fixed in position while the main anodes, the collector (C) and the guard rings (G), are removable. During the processing of the tube, the main anodes (GCG) were drawn up and were kept hot during the breakdown and the activation of the cathode so that materials evaporated from the cathode did not contaminate them. The auxiliary anode served as anode for drawing emission during activation. After the tube was sealed off, when the main anodes were suspected of being dirty, they were drawn up and heated to high temperatures to drive off the deposits. The collector and the guard rings were supported by a "bird-cage-like" structure, which is restricted to up and down motion through the use of the glass sleeves (A). The main anodes and the auxiliary anode were made of tantalum which does not show "anode effect"[3] after it has been properly cleaned.

The cathode sleeve was made of 2-mm diameter grade A nickel tubing. The cathode temperature was determined by the thermocouple method as used by Fan[5] and others. A 2-mil tungsten wire was welded to the center of the inside of the cathode sleeve. The point of welding served as the hot junction. The tungsten wire and a 5-mil nickel wire welded to the end of the cathode sleeve were brought out through a separate press. This press was immersed in an oil bath to keep the cold junction temperature constant. The disturbance of the cathode sleeve temperature[6] by this tungsten wire may be neglected. The temperature of the coating surface is believed to be within a few degrees of the sleeve temperature at all operating temperatures.[9] The tungsten-nickel thermocouple was calibrated against Chromel-P-Alumel thermocouple and checked against the readings of a glass thermometer for every hundred degrees. The calibration curve is shown in Fig. 2.

The main anodes and the auxiliary anode were chemically cleaned and induction heated to 1600°C for a prolonged period.

The cathode coating consisted of $(BaSr)CO_3$ sprayed onto the sleeve to an amount of 5 mg/cm^2. The tube was baked out thoroughly at 500°C, and after this the cathode was broken down and activated. The pressure of the tube after seal-off was around 10^{-8} mm Hg with the use of getter.

The Measuring Circuit

The measuring circuit is as shown in Fig. 3. The experimental tube was shielded in a copper box against disturbances. All leads coming out of the box were shielded. The heater current was measured by the

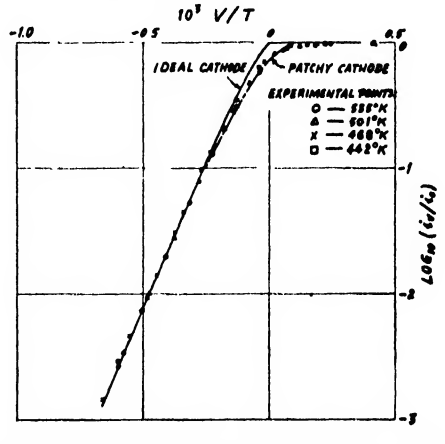

FIG. 5. Retarding field plots matched together. Solid line—theoretical Schottky curve; dot-dash line—calculated curve for a patch model at 500°K assuming no reflection.

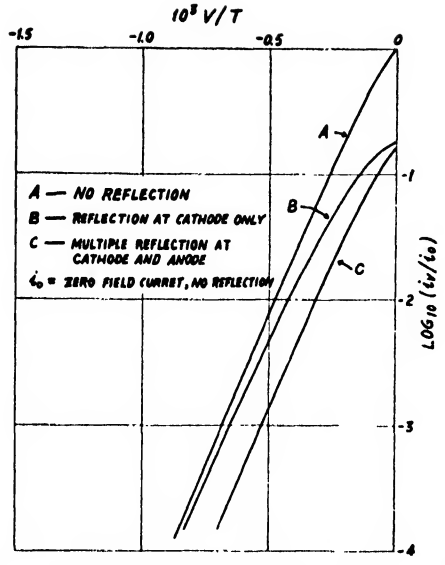

FIG. 6. Calculated retarding field plots for a uniform cathode with different assumptions of reflection effect.

voltage drop across a 0.1 ohm resistance with a Leeds and Northrup K-2 potentiometer. The negative lead of the heater was made 6 volts positive with respect to the cathode to suppress electron emission from the heater. The connections for thermocouple e.m.f. measurement were all copper wires from the cold junction to the meter. A change of cathode temperature by 0.2°C, resulting in a change of thermocouple e.m.f. of 0.007 mv, was indicated by a deflection of 0.2 mm on the galvanometer scale. The cathode was grounded through a 0.5 μf condenser in parallel with a 100 $\mu\mu$f mica condenser to shunt off electrical disturbances. The anodes were grounded and the cathode voltage was variable. Retarding voltages were obtained from dry cells and measured with the K-2 potentiometer. Accelerating voltages below 200 volts were obtained from dry cells, while those from 200 up to 8000 volts were obtained from a high voltage rectifier and controlled by a voltage stabilizer. The voltage stabilizer employed an amplification factor bridge circuit with an 811 tube. When properly adjusted, the variation in output voltage of the stabilizer was below 1 percent of the input variation for all load currents up to 1 μamp. The guard rings and the auxiliary anode were connected directly to ground, while the collector lead was led to the current measuring equipment through a coaxial copper tubing which was grounded. The wire was insulated from the tubing using polystyrene disks. The current measuring equipment consisted of a resistance and balancing e.m.f. circuit and a Compton quadrant electrometer. The voltage drop across a high resistance or a condenser due to the collector current was balanced out, as indicated by the zero deflection of the electrometer, and measured with the potentiometer. Vacuum tube platinum resistors up to 10^{10} ohms were used for current measurement down to 10^{-12} amp. and the charge accumulation method employing a 100 $\mu\mu$f air condenser, and a 10 $\mu\mu$f air condenser (built in the electrometer) were used for current measurement down to 10^{-14} amp.

RETARDING FIELD STUDIES

Retarding Field Current from a Non-Uniform Cathode

It is known that because of the different crystal faces, the crystal defects, and the various amounts of foreign matter adsorbed on the crystal faces, the work function of an oxide cathode is not uniform but varies over short distances along its surface. This non-uniformity of the cathode work function, the patches, causes the retarding field current to be different from

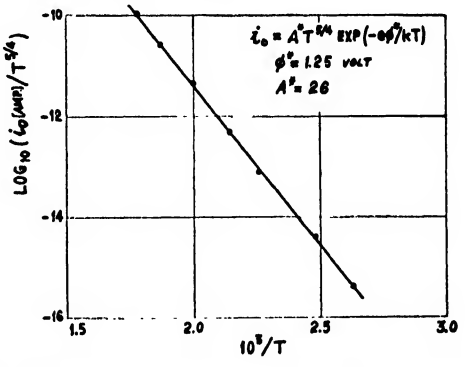

FIG. 7. Observed saturation current against temperature.

that predicted by Eq. (1) which is derived for an ideal uniform cathode. In the actual case, electrons emitted from the various parts of the cathode experience different retarding fields. The retarding potential which an electron experiences in going from the cathode to the anode is the difference between the height of the potential barrier at the anode surface and that near the patch from which the electron is emitted. The total retarding field current is the sum of the component currents from the various patches, each of which varies according to Eq. (1) when the proper value of retarding potential is used, and each saturates at a different anode potential. A plot of this total current against the applied retarding potential would show a slower approach to the saturation current than in the ideal case of a uniform cathode, and consequently an apparent shortage of slow electrons in the energy distribution of the emitted electrons. The effective work function of the non-uniform cathode can be defined as ϕ^* in the following equation:

$$J_0 = A^* T^{5/4} \exp(-e\phi^*/kT), \qquad (5)$$

where J_0 is the observed saturation current, and A^* is the effective A constant. Since in general the plot of $\log(J_0/T^{5/4})$ *vs.* $1/T$ for oxide cathodes can be represented by a straight line, this effective work function is equivalent to the work function for an ideal uniform

cathode which has the same thermionic emission as the actual cathode over the temperature range studied. The effective zero field V_0^* can be defined from the following equation:

$$V_0^* = \phi_{\text{anode}} - \phi^*. \tag{6}$$

It is determined from experiment by matching the experimental retarding field plot to the theoretical Schottky plot at both high retarding fields and at saturation. The zero field point on the theoretical curve marks the effective zero field, because when thus matched the theoretical curve represents the retarding field plot of an ideal cathode which has its work function equal to ϕ^*. The effective work function and effective zero field defined in Eqs. (5) and (6) are necessarily temperature dependent even if the work functions of the patches are independent of temperature, however the temperature dependences are only slight.

Experimental Result and Interpretation

The experimental study was made at temperatures between 442°K and 535°K. The maximum current density reached in these runs was below 0.1 μamp./cm^2. Experiment shows that at such low temperatures and low current densities no measurable change of the cathode state took place. The curves for increasing and for decreasing retarding potentials coincided very well. The changes in temperature during each run at one particular temperature were always within 0.2°C. Anode effect was found to be not present.

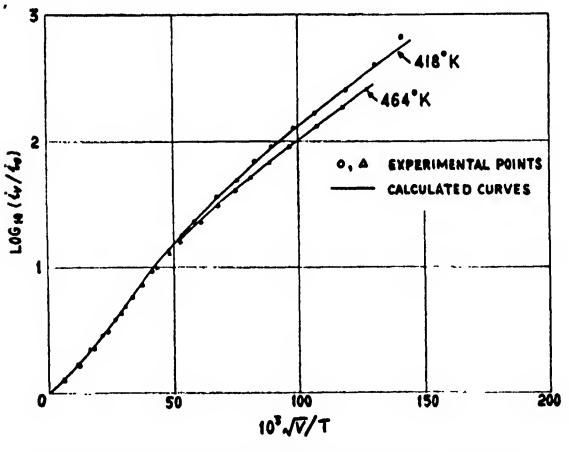

FIG. 8. Accelerating field plots for the same cathode as used for Figs. 4, 5, and 7.

The experimental curves were shown in Fig. 4. An enlarged drawing with all the curves matched together is shown in Fig. 5. It is seen that at retarding potentials above 0.2 volt, all the experimental curves coincide with the theoretical curve assuming no reflection. Therefore, at least for the high energy electrons, the energy distribution obeys Maxwell's law, and the electron temperature agrees with the cathode temperature. The departure of the experimental curves from the theoretical is seen to occur in a range of 0.3 volt. Even at the maximum current density of 0.1 μamp./cm, space charge distortion of the curves should not be detectable. The anode was found to be free from contaminations, so that the condition of uniform anode surface potential is approximately satisfied. Although the temperature of the cathode was not uniform along its whole length, it is believed that the temperature variation over the cathode under the collector was not more than 2 or 3°C, and the temperature variation over the entire cathode was within 30 or 40°C at the measuring temperatures we used. This temperature distribution along the cathode does not make the experimental curve deviate noticeably from the theoretical curve for a cathode with uniform temperature.

It remains now for us to examine the effects of first the non-uniformity of the cathode work function and second the reflection at the surfaces of the electrodes. The distribution of work function along the cathode being unknown, we use a crude model for discussion. We take our cathode as made up of patches that can be grouped into seven equal areas with work functions ranging in equal steps from ϕ to $\phi+0.15$ volt. As a first approximation, we neglect the distortion of the electron trajectories by the patch field, and sum up the component currents from the separate patches directly, using Eq. (1) with different retarding potentials for the different groups of patches. The calculated retarding field curve is shown in dot-dash line in Fig. 5 for the temperature of 500°K. Similarly calculated curves for temperatures from 450°K to 550°K show only slight deviation from each other. The experimental curves for the temperature range of 442°K to 535°K are also seen to be very close. The calculated curve fits the experimental curves quite well, and the use of a more elaborate model with a slightly larger range of work function variation would enable us to make a perfect match. It will be seen in the analysis of our accelerating field measurements that this value of work

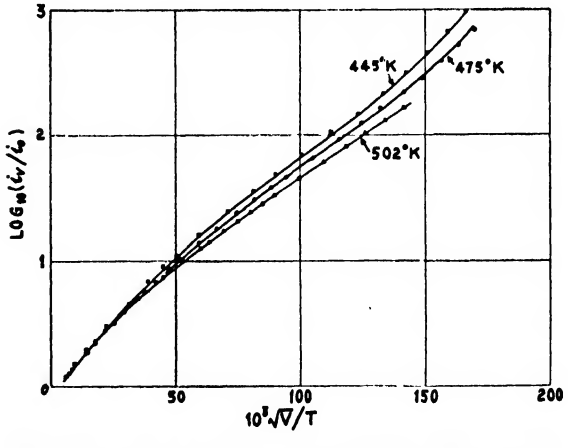

FIG. 9. Accelerating field plots for another oxide cathode; note similarity to plots in Fig. 8.

function variation agrees with the value we found there.¶

The Reflection Effect

As mentioned in the introduction, according to Nottingham's measurements on tungsten and thoriated tungsten filaments, a reflection coefficient as given by Eq. (2) with $k/\omega=4.5\times10^{-4}$ deg.$^{-1}$, should occur at both the cathode and the anode. Electrons that are reflected from the anode should go back to the cathode if the field is strictly radial. Since Nottingham used a filament wire of about 0.08 mm in diameter, a slight departure of the electrodes from being strictly coaxial would cause the electrons that are reflected from the anode to miss the cathode and go back to the anode again. Thus the anode current would not be affected appreciably by the reflection effect at the anode. However, with our tube, the cathode was 2 mm in diameter so that the electrons that are reflected from the anode had very good chance of landing on the cathode as they should in the ideal case. This reflection effect at the anode would reduce the anode current more at high retarding fields than at near zero field. Measurements yield information on the reflection effect only as the reflection near zero field differs relative to that at high retarding fields. Therefore the apparent reflection effect is greatly reduced when the reflection at the anode is included. The current expression for a uniform cathode when reflection effect is present is

$$J_v=(2e/h^3)(2\pi mkT)^{\frac{1}{2}}\exp(-e\phi/kT)\times\int_{-\infty}^{\infty}dp_y\int_{0;\,(2\text{ Mev}-(1-\theta^2)p_y^2)^{\frac{1}{2}}}^{\infty}\times(1-R)\exp\left(-\frac{p_x^2+p_y^2}{2mkT}\right)\frac{p_x}{m}dp_x, \quad (7)$$

where p_x and p_y are the normal and tangential components of the momentum of the electron at the cathode surface (the length of the cathode is along the z axis), and θ is as defined in Eq. (1). R is the reflection coefficient, and is given by Eq. (2) when reflection at the cathode alone is considered. When multiple reflections at both electrodes are considered, it is as follows:

$$1-R=\frac{(1-R_c)(1-R_a)}{1-R_cR_a}, \quad (8)$$

where $R_c=\exp(-p_x^2/2m\omega)$, $R_a=\exp(-P_x^2/2m\omega)$ and $P_x^2=p_x^2+p_y^2(1-\theta^2)-2$ Mev, P_x being the normal component of electron momentum at the anode surface. In Fig. 6 are shown the retarding field currents for different assumptions of reflection effects. It is seen there that while Curve B, where reflection effect at the cathode alone is considered, is markedly different from Curve A for zero reflection; Curve C, for which the multiple reflection effect is considered, has a form very nearly the same as Curve A. Therefore we see that the reflection effect, if it does exist, is not observable in our case. The possibility of the existence of an appreciable reflection effect at the electrode surfaces should not be excluded although we have found a satisfactory explanation of our retarding field measurements with the patch theory. A decisive check on this reflection effect would be to use a fine filament wire, in which case the reflection effect, if it does exist, would show up strongly.

Work Function and Zero Field

The thermionic emission against temperature curve is shown in Fig. 7. The currents used in the plot are the observed saturation currents so that the slope of the plot gives the effective work function. The points lie approximately on a straight line. The effective work function is found to be 1.25 volts and the A value around 26. The effective zero fields obtained from the matching of the experimental retarding field plots to the Schottky plot are shown below:

Temperature in °K	V_0^* in volts
535	3.17
501	3.19
468	3.21
442	3.22

This variation of the effective zero field is quite large and could be due to the changes in work functions of the patches and to the effect of the patch field distortion on the electron trajectories which we have neglected in our previous analysis. The anode work function obtained from the values of ϕ^* and V_0^* given above is around 4.4 volts. This is higher than the thermionic value of 4.07 volts obtained for tantalum by Dushman, Rowe, Ewald, and Kidner;[10] and the photoelectric value of 3.92 to 4.05 volts obtained by Cardwell.[11]

ACCELERATING FIELD STUDIES

Measurements

Emission currents were measured with accelerating potentials up to 7 kv and at temperatures below 500°K. The maximum electric field, calculated from the geometry of the electrodes, was 50,000 volt/cm at the cathode surface. The drop in potential across the coating was negligible according to Mahlman's measurements on the conductivity of oxide coating prepared in the same way as in this experiment. The emission

¶ It should be emphasized that what we mean here by the work function of the patches are the potential barriers, in the presence of the field due to the neighboring patches, which an electron climbs over in traveling along the normal to the patch area. In our later use of Becker's hill and valley checkerboard approximation for accelerating field studies, the work functions of the patches are as defined by Becker, i.e., they are the values when each patch is considered as an infinite plane with no neighboring patches.

[11] A. L. Hughes and L. A. Dubridge, *Photoelectric Phenomena* (McGraw-Hill Book Company, Inc., New York, 1932).

current was always below 1 μamp. and therefore there was no heating up of the cathode when high voltage was applied between the electrodes. The current was steady on the application of high accelerating potentials, and the current at low field did not change before and after a run was made. The results for the same cathode as we used in the retarding field studies are shown in Fig. 8. Measurements on two more cathodes show similar current voltage characteristics. Results on one of them are shown in Fig. 9. The curves are seen to decrease in slope as the voltage is increased and remain almost linear for a range of moderate voltages and increase rather fast in slope as 3 kv is exceeded. The minimum slopes near the linear part of the curves in Fig. 8 are about 2.6 times the theoretical Schottky line if one takes the field at the cathode surface to be that calculated according to the dimension of the electrodes. The slopes for the curves at the two temperatures are about the same. According to patch theory, we would expect a deviation of the experimental curve from the Schottky line at low voltages and that deviation should go to zero at high voltages. There are two difficulties if we were to rely on the patch theory alone to explain our results: first the rapidly rising parts of the curves at high voltages cannot be explained; and second, since the curves did not approach the theoretical Schottky line even at 5 kv, the average linear dimensions of the patches would have to be smaller than 10^{-6} cm. It is conceivable that there be patches of that size or smaller, but their contribution to the emission current would not be important owing to their small areas, unless their work functions are greatly reduced by a very strong accelerating field, a point which we will take up immediately.

The Effect of the Roughness of the Cathode Surface

Owing to the difficulties with patch theory alone, it is desirable to look into the other possible reasons for this deviation. It is easy to see that the roughness of the cathode surface has an important effect on the actual fields at the different parts of the cathode. With the oxide cathode built up of crystals of sizes of from one micron to a few tens of microns, piled up on one another, the field variation along the cathode would be very large. And it is likely to have a considerable fraction of the cathode surface with fields ten times or more higher than the average field. At low voltages, this effect will not be important. The lowering of the potential barriers at low accelerating potentials will be small even for the sharp points where the fields are many times higher than the average field. The change in the logarithm of the emission from a small area of the cathode is proportional to the lowering of the potential barrier there. When the latter is small, the change in the emission current itself is also nearly proportional to it, and therefore to the square root of the field. Thus the net field effective in increasing the emission for the entire cathode is close to the average field. (The effective field would be equal to the average field at low accelerating potentials if the lowering of the potential barrier were proportional to the field itself and not to its square root.) At high accelerating potentials, the lowerings of the potential barriers are large, and the change in the emission current at any spot is then no longer proportional to the lowering of the barrier. Emission currents from places where the fields are strong are far more important than those from places where the fields are relatively weak, and the effective field for the entire cathode is then very different from the average field, and is close to the field at the strong field places. It is thus seen that the ratio of the effective field to the average field increases from unity at low accelerating potentials to higher and higher values as the accelerating potential is increased. It is not surprising thus to find that the experimental curves did not approach the theoretical curve even at the highest average field of 50,000 volt/cm as we have used. The explanation of the entire curve is as follows: At low applied accelerating potentials the effective field is approximately the average field and the initial large slope of the curve and the subsequent decrease in slope is mainly due to the patch effect. At higher accelerating potentials, the patch effect becomes smaller but the effective field to average field ratio becomes greater so that the slope of the curve no longer decreases. For voltages above 1 kv, the patch effect becomes almost negligible and the curve has an almost constant slope over a considerable range of voltage. This slope is 2.6

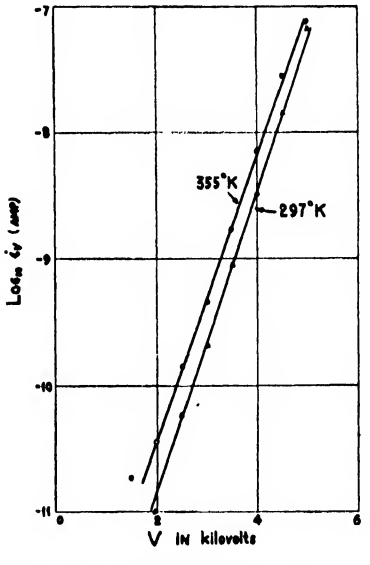

FIG. 10. Electron emission at near room temperatures under high accelerating voltages.

times higher than the slope calculated from the average field because the field effective in increasing the emission current is 2.6^2 times higher than the average field. For accelerating potentials above 5 kv, the slope of the curve increases rather fast because of the further in-

crease of effective field to average field ratio; and probably at some extremely sharp points, field emission was taking place. Based on this explanation, we can estimate the average linear dimension of the patches and the variation in work function of the patches using Becker's hill and valley checkerboard approximation.[12] Estimates have been made for two extreme cases: first, that the effective field to average field ratio is 2.6[2] throughout the whole range of accelerating potential up to 5 kv; and second, this ratio is unity for accelerating potentials below 1 kv and is 2.6[2] for potentials above that. The actual case should lie between these two extremes. The results of estimation are: the maximum work function variation (assuming sinusoidal variations from patch to patch) is 0.16 volt from average for both cases; and the average linear dimension of the patches are 2×10^{-5} cm and 2×10^{-4} cm for the first and the second cases respectively. The calculated curves for the first extreme case are shown in Fig. 8. This value of work function variation agrees with the value of 0.15 volt we have obtained in our analysis of the retarding field measurements. The linear dimensions of the patches of 2×10^{-5} to 2×10^{-4} cm are rather small compared to the sizes of the oxide crystals which run from 10^{-4} to 10^{-2} cm. It should be noted that in our analysis, perhaps it is around the smaller crystals that we have higher fields and therefore more important contributions to the observed current; and it is also likely that the patches correspond to crystal defects and not to the entire crystal faces.

Measurements at near room temperatures lend support to this view of the important effect of the roughness of the cathode surface. At high accelerating potentials, fluorescent spots appeared on the glass wall of the experimental tube indicating that the emission came from local spots of the cathode where the fields are very high. Curves in Fig. 10 show that the current is temperature sensitive suggesting that at least part of it is thermionic emission from local sharp points where the potential barriers are lowered to perhaps two- or three-tenths of an electron volt by the extremely high fields there.

It is suggested that further accelerating field measurements be done with single crystals or with cataphoretically deposited cathodes whose surfaces are far more smooth than the ordinary cathodes with sprayed-on coatings.

The author wishes to express his gratitude to Professor W. B. Nottingham for the suggestion of this work, his constant interest in it and his many helpful suggestions.

Augmented Flames in Half-Open Tubes[1,2]

MARJORIE W. EVANS, MILTON D. SCHEER, LOUIS J. SCHOEN, AND EMMY L. MILLER
Research Division, New York University, University Heights, New York City
(Received July 18, 1949)

High velocity flames in half-open tubes produced by placing a grid augmenter in the path of an advancing flame are described. High speed schlieren motion pictures and instantaneous pressure measurements are used to study flame structure and accompanying flow in the tube. It is found that the grid augmenter causes a mixing of burning and unburned gases, resulting in an increase in reaction surface. As a result the total amount of reaction per unit time per unit volume is increased, thus leading to the observed high velocities.

INTRODUCTION

THE velocity of propagation of flames burning in gas is determined by the normal combustion velocity (which is dependent upon thermal conductivity, diffusion, and the detailed reaction kinetics), and by the flow processes in the system. A hydrocarbon-air mixture ignited by a spark at the closed end of a half-open tube (i.e., a tube closed at one end and open at the other), generally has a maximum flame front velocity of about 100 feet per second.[2] Certain flames such as those in pulse jet engines have been observed to move with a considerably greater velocity. Flames of high velocity, in some cases approaching 1000 feet per second, have been produced in this laboratory by placing in the path of the advancing flame a grid augmenter consisting of a sheet of metal containing holes with trailing edges. Such a sharp increase in velocity after the flame front has passed through a twenty-hole grid may be seen in Fig. 1, which shows the flame velocity recorded in an experiment in which the grid was placed two feet from the closed end.

This paper reports investigations into the nature of the high velocity or augmented flame produced by the grid augmenter, utilizing schlieren techniques in conjunction with a high speed motion picture camera, and pressure measurements.

[1] This research was conducted under the auspices of Project Squid, sponsored by the ONR under Contract N6ori-11, Task Order II.

[2] This material is a further development of work first reported at the Third Symposium on Combustion, Flame, and Explosion Phenomena, University of Wisconsin, Madison, Wisconsin, September, 1948, in a paper entitled, "A study of high velocity flames developed by grids in tubes," Evans, Scheer, Schoen, and Miller.

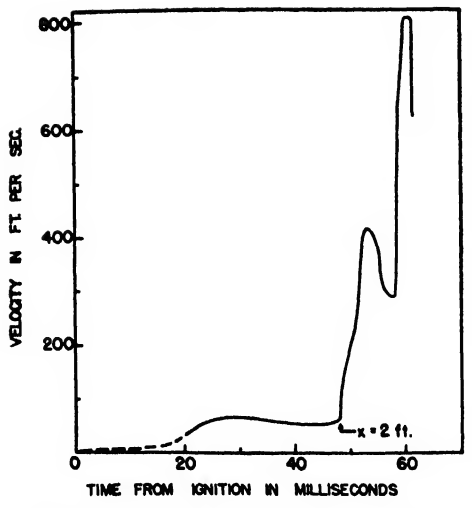

FIG. 1. Velocity-time curve for a flame front in a tube in which a twenty-hole grid augmenter was placed two feet from the closed end.

SCHLIEREN AND PRESSURE MEASUREMENTS

The flame tube was six feet in length with an inner square cross section approximately 3.5 inches on a side. The grid augmenter in these experiments had three rectangular nozzles 0.3 square inch in area with trailing edges 0.3 inch long. The grid was placed 3.1 inches from the spark igniter, which was supplied by a high frequency induction coil. The tube was filled with a 6.6 percent by volume propane-air mixture.

The optical arrangement consisted of a double-mirror knife-edge schlieren system with parabolic mirrors sixteen inches in diameter, having sixty-inch focal lengths. The parallel beam of light between the two mirrors passed through the plate glass side-walls of the flame tube. The light source was a Western Union 100-watt zirconium arc lamp, and a 16 mm Fastax camera, with a speed booster, was used at a speed of 4000–9000 frames per second to record the gas motions in the tube. In order to follow the motion of a particular layer of gas during the flow which accompanies combustion, observations were made of the positions of local thermal gradients produced by stretching across the tube a nichrome wire heated electrically to a temperature well below the ignition point.

Pressure measurements were made with the frequency modulated condenser type pressure gauge developed in this laboratory by J. H. Hett and R. W. King, Jr.[3] The time of ignition, t_{ig}, was correlated with the occurrence of the pressure pulse and with events as recorded in the schlieren motion pictures by means of the circuit shown in Fig. 2. This circuit utilized the light emitted by the igniting spark, as picked up by a photo-cell, to trigger indicating lights which registered on the motion picture film and on the film recording the pressure trace.

Figure 3 is a reproduction of nine selected frames from a schlieren motion picture of the flame as it passes through the grid augmenter. Apparently, in this case only two holes were effective. The flame before reaching the grid shows several large cells and has a relatively smooth surface. These cells strongly resemble those recently observed by Markstein in flames held stationary in tubes by adjustment of the flow velocity.[4] The augmented flame, on the other hand, shows a much more complex structure with fine-grained eddy motion. As it progresses down the tube it assumes a more homogeneous structure. The faint patterns showing gas flow through the grid nozzles in pictures *B*, *C*, and *D*, of Fig. 3 are caused by gas which has been heated by the flame.

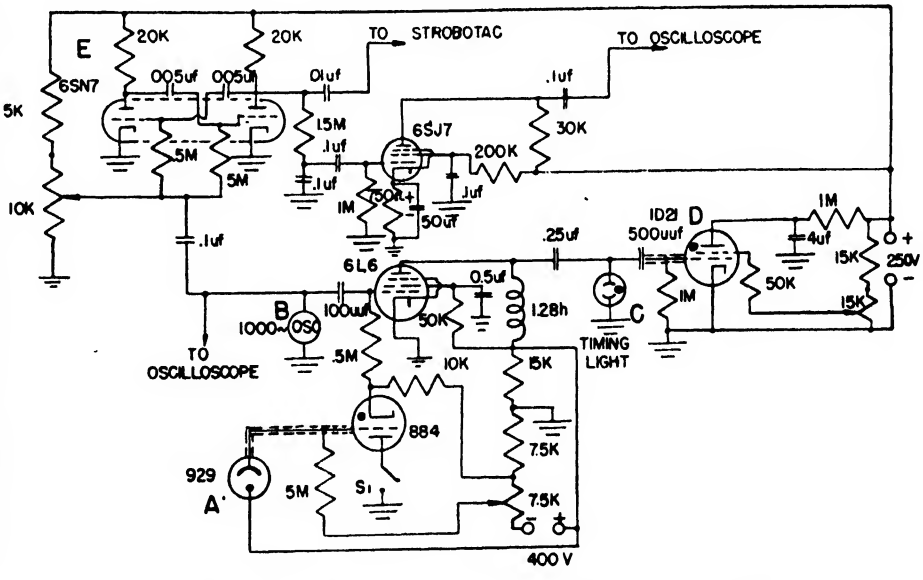

FIG. 2. A circuit for the simultaneous indication of zero time on the schlieren motion picture and pressure recording film. The photocell *A*, picking up light from the igniting spark, triggers a thyratron tube which allows the oscillator *B* to energize the timing light *C* in the Fastax camera, thereby providing a zero time mark t_{ig}, as well as timing marks at 1000 cycles per second for the schlieren motion pictures. *D* is a gas tube which flashes when the photo-cell begins to conduct, thus providing a zero time mark on the pressure recording film. *E* is a frequency divider which divides the 1000-cycle output by 4, thereby furnishing 250 cycles per second to a strobotac which provides timing marks for the pressure recording film. The oscilloscopes were used for the calibration of the oscillator and the frequency divider in conjunction with a 1000 cycle tuning fork oscillator as a standard.

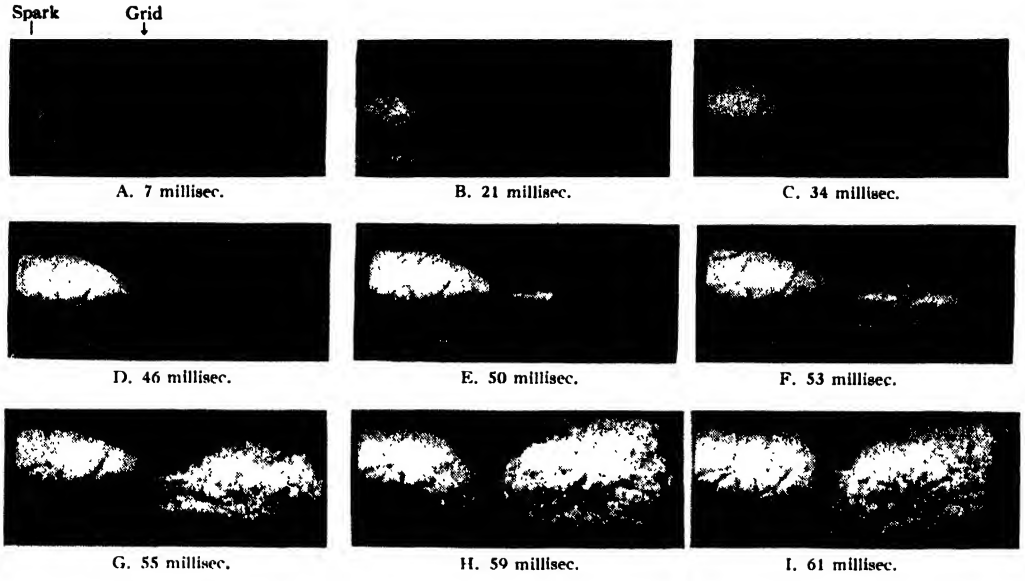

FIG. 3. Schlieren motion pictures taken at 4400 frames per second of flame moving through a three-hole grid augmenter.

Figure 4 shows schlieren pictures of the progress down the tube of a layer of gas in front of the flame. In these early pictures is seen a spark indicator, in series with the igniting spark, placed in the field of view to indicate the time of ignition. This method was later replaced with the timer circuit mentioned above. The position of the heated wire used to produce the thermal gradient is shown in *A*. In subsequent pictures the gradient is observed moving toward the open end. The flame comes into the field of view in *C*, and overtakes the gradient in *E*. The data plotted in Fig. 5 were obtained from measurements made from pictures such as these.

Figure 5 is a plot of position *versus* time for layers of gas as the augmented flame expands and moves down the tube. The solid line represents the motion of the flame front, the dashed lines that of layers of gas which were labeled with thermal gradients. The plot shows that all gas between the grid and a point ten inches from the grid at zero time is enclosed by and becomes part of the augmented flame. This volume is termed the augmentation region. The gas which is initially beyond this ten-inch region is pushed ahead of the flame during the expansion which occurs as a result of the combustion reaction, and is not burned.

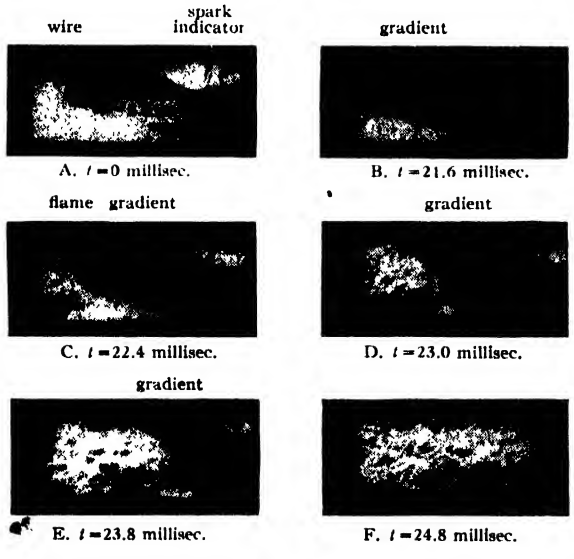

FIG. 4. Schlieren motion pictures taken at 4300 frames per second showing a thermal gradient moving down the tube ahead of an augmented flame.

While the position-time curves for unaugmented flame fronts vary radically from experiment to experiment, the characteristics of the augmented flames are quite reproducible.[2] Under identical experimental conditions the position-time points for several flame fronts fall on the same curve. The lateral growth of the flame in the augmented region is likewise reproducible. A plot of the growth of the augmented flame in the y direction (perpendicular to the axis of the tube) at a point 2.5 inches from the grid augmenter is shown in Fig. 6. It is at this point that the developing augmented flame first reaches the sides of the tube.

Pressure measurements shown in Fig. 7 were made with the gauge placed at points *B*, *C*, and *D*, in the tube as indicated in the figure. The time t_p in Fig. 6, when the flame reaches the sides coincides with the beginning of the first pressure pulse at position *B*. This suggests that the origin of the pressure pulse is in the region near *B*. Pressure measurements in a tube without grid showed only a small rise over atmospheric pressure, the peak pressures being approximately a factor of ten smaller than those shown in Fig. 7. When the tube with grid was filled with propane-air mixture, simultaneous pressure measurements at *B* and in the initiating chamber (i.e., between spark and grid) gave two essentially

identical curves, the method of timing not being accurate enough to indicate the difference in the time of occurrence of the pulse at the two points. When only the initiating chamber was filled with gas, the reaction produced only a small pressure rise. This confirms the conclusion that the pressure pulse is generated near position B, in the augmentation region.

Observation of the schlieren motion pictures shows that at time t_p when the flame reaches the sides of the tube the region 2 to 2.5 inches downstream from the grid augmenter is the center of an expansion of the burning gases. The observation together with the facts cited above indicates that the augmented flame is produced in the augmentation region by a mixing process between t_g (when the flame emerges from the grid augmenter) and t_p. After time t_p the dominant phenomenon is rapid burning and expansion of burning gases with the consequent rapid motion of the flame toward the open end of the tube. It has been previously noted[2] that streak photographs of the augmented flame show that the flame apparently first appeared several inches below the grid, and proceeded to burn simultaneously toward the open end and back toward the grid. This can now be explained, in view of the above observations, by assuming that burning vigorous enough to produce sufficient illumination to record a trace does not occur until time t_p, with the vigorous burning beginning at the center of expansion, 2 to 2.5 inches downstream from the grid.

DISCUSSION

It is clear that the high flame front velocity of the augmented flame is to be attributed to a rapid expansion during the burning of the gas in the augmentation region. In the normal unaugmented flame in the same tube somewhat less gas is burned, but over a longer period of time. This greater rate of burning of the augmented flame is due to an increased burning area or reaction surface. When the burning or burned gas from the initiating chamber flows through the nozzles into the stationary gas a mixing process occurs so that burning surfaces are interspersed with unburned gas. As a result there is more burning area per unit volume than in the normal flame, which presents a relatively smooth surface with a few large cells.

The details of the mixing are not clear. The two-dimensional problem considering the spread of a mixing region in the case of the turbulent mixing of a stream of fluid (of uniform velocity at the mouth of the nozzle) with a fluid at rest has been analyzed by others.[5] The

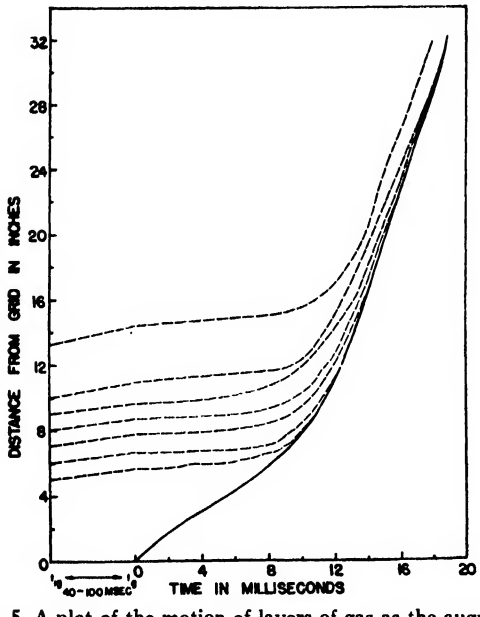

FIG. 5. A plot of the motion of layers of gas as the augmented flame grows and moves down the tube. The solid line represents the flame front, the dashed lines layers of unburned gas ahead of the flame. t_{ig} is the time of ignition, t_g the time of appearance of the flame at the grid. Measurements were made from motion pictures taken at 5000–7500 frames per second.

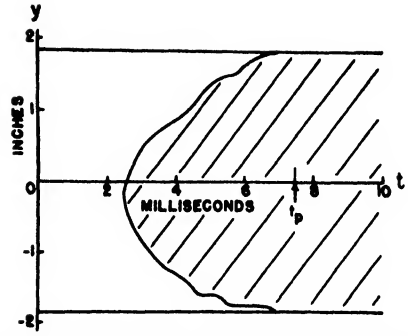

FIG. 6. A plot of the rate of growth, in the y direction, of the mixing region, at a point 2.5 inches below the grid. $y=0$ is the axial line of the tube. Time is measured from the appearance of the flame at the grid. t_p is the time of the beginning of the first pressure pulse shown in B of Fig. 7.

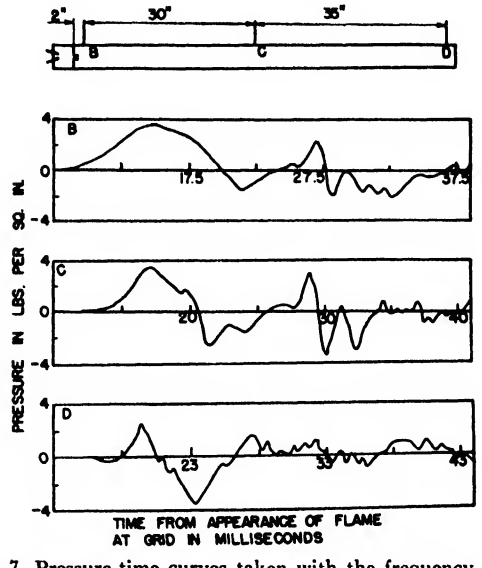

FIG. 7. Pressure-time curves taken with the frequency modulated condenser type pressure gauge at the points B, C, and D, in the augmented flame tube. The flame tube, with spark and grid augmenter, is shown diagrammatically.

[5] *Modern Developments in Fluid Dynamics*, edited by S. Goldstein (Oxford University Press, New York, 1943), Vol. II, p. 597.

TABLE I. Comparison of average pressure and specific impulse of a small pulse jet engine using gasoline as fuel, and the augmented flame tube using a propane-air mixture (6.6 percent by volume) as fuel.

	Small pulse jet	Augmented flame tube
Average pressure (lb./sq.in.)	3.3	1.1
Specific impulse (lb. thrust/lb.fuel/sec.)	760	410

present situation is more complicated in at least four respects, *viz.*, 1) the flow field is not two-dimensional, 2) the velocity of the discharging jet at the mouth of the nozzle is not constant, 3) three or more nozzles are in juxtaposition, and 4) a combustion reaction at an elevated temperature is occurring in the jet and at the boundaries. The qualitative observation may be made from Fig. 3 that the core of fluid in which laminar flow occurs disappears within two or three nozzle diameters downstream, after which the mixing region occupies the whole jet. One can speculate that regions of vorticity and turbulence spread from each jet and ultimately interfere with one another creating additional unstable swirling type flow of an even more complex nature. In this process large vortices may perhaps break up into smaller ones during the lateral growth of the mixing region.

It is of interest to inquire as to whether the augmented burning described here resembles the burning observed in jet engines, particularly with respect to the rate of burning. This is conveniently done by comparing the average pressure in a typical small-scale pulse jet, which uses gasoline as fuel, with the average pressure in the flame tube. In order to carry out this comparison it is assumed that the flame tube could be fired at a frequency which would correspond to a period comprised of the time for the pressure to rise from atmospheric to a peak, back through a minimum, and then to atmospheric again, and that such repetitive firing would not materially alter the pressure record, shown in Fig. 7. Such an assumption is suggested in part by the fact that a similar sequence of pressure changes occurs in a combustion chamber of a pulse jet during a cycle of operation. At any rate, following this hypothesis, if the curve B of Fig. 7 is integrated from 7.5 to 23.9 milliseconds and the result divided by the elapsed time the average pressure in the flame tube is obtained, i.e.,

$$P_{Av}=\left(\int_{7.5}^{23.9} P(t)dt\right)\Big/ 16.4.$$

The specific impulse is calculated on the assumption that the augmentation region is filled with propane-air mixture at 16.4 millisecond intervals. Inasmuch as the heats released per unit mass for gasoline and propane differ by only 5 percent and the calculations are only approximate, no correction was made for the difference. Table I lists the results in terms of average pressure and specific impulse, and the quantities are found to be of the same order of magnitude for the small pulse jet and the augmented flame tube.

CONCLUSION

Despite an incomplete understanding of the mixing process in the flame tube, it is possible to draw some conclusions with regard to the effect of swirling or eddy motion on combustion processes. Such motion is an important factor in determining the rate at which a given fuel-air mixture can be burned, its function being, at least under the conditions of these experiments, to increase the total reaction surface, thus increasing the amount of mixture reacting per unit time per unit volume.

In situations where sufficient fuel and air are available an increase in the intensity of the swirling and mixing may make possible a greater rate of energy release in the same reaction chamber volume. Conversely, under these conditions for a given desired rate of energy release a smaller volume of combustion chamber may be used. These possibilities could conceivably be of interest in the design and operation of industrial furnaces and internal combustion engines as well as jet engines.

Static Magnetic Storage and Delay Line*,**

AN WANG AND WAY DONG WOO
Computation Laboratory, Harvard University, Cambridge, Massachusetts
(Received July 27, 1949)

Magnetic cores with a rectangular hysteresis loop are used in a storage system which requires no mechanical motion and is permanent. The binary digit "1" is stored as a positive residual flux, and the binary digit "0" as a residual flux in the opposite direction. When a negative probing field is applied to the core, a large voltage is induced in another winding if the digit stored has been a "1," and very small voltage if it has been a "0." The induced voltage in the former case is large enough to magnetize another core of identical construction. Binary digits can thus be transferred from one core into another. Many cores are arranged in tandem to form an information delay line. Binary digits can be advanced along the line step by step. The present upper limit of the speed of propagation is about 35,000 digits per second, and there is no lower limit.

I. INTRODUCTION

ONE of the most important research problems in the field of large-scale digital calculating machines is that of information storage. Electronic trigger pair tubes, cathode-ray tubes, acoustic delay lines, rotating drums, or tapes are used in present machines. Electronic trigger pair storage is, of course, the most versatile, but it is extremely expensive and its reliability poor. Cathode-ray tube and acoustic delay line storage systems need constant regeneration to preserve the information stored. All three systems lose the information if there is interruption of power. Magnetic drum or tape storage preserves information indefinitely, but it involves a mechanical system, and the operating speed is limited by mechanical considerations. Both in acoustic delay lines and rotating magnetic drums, the operation is necessarily synchronous. The speed depends upon the physical nature of the system and cannot be changed at will during operation.

This paper describes a storage system which operates like electronic trigger pairs but does not use vacuum tubes other than a relatively small number for control purposes.

A binary digit which takes the value of "0" or "1" is stored in a ferromagnetic core in the form of positive or negative residual magnetism, depending on the direction of the last magnetizing force. As shown in Fig. 1, a binary digit is represented by the point "0" or "1" on the hysteresis curve of the core. To store a binary digit, only the application of a magnetizing pulse of proper polarity is necessary.

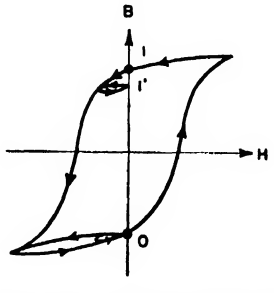

FIG. 1. Hysteresis loop.

The reading out of the stored information presents a more difficult problem. For a small negative pulse of magnetizing force H, applied at point "0," there results less change in the flux density B than for a similar negative pulse applied at point "1." Thus the relative amplitude of the induced voltage indicates what information has been stored in the material. However, this is true only for the first-read-out pulse, since after "0" information has been read out, the material returns to the point "0," whereas after "1" information has been read out, the material goes to a new point "1'" instead of returning to "1." Further negative pulses of H produce very nearly equal changes of B for starting positions "0" and "1'." Thus, whereas small read-out pulses do not actually destroy the positive or negative residual magnetism representing the stored information, they make reading out by like pulses impossible after the first.

When a large negative read-out pulse of H is impressed, the information is destroyed. The state of the material returns to position "0" in the B–H curve, no matter what information was previously stored. However, the secondary induced voltage is much larger when B changes from "1" to "0" than when B changes from "0" to "0." The ratio of these voltages was found to be as high as 30:1 for suitable magnetic materials. The large induced voltage can be made to drive another core from state "0" to "1." Thus one can construct (1) a storage unit in which digits can be stored and read-out continuously, and (2) an information delay line in which a series of binary digits can be propagated at

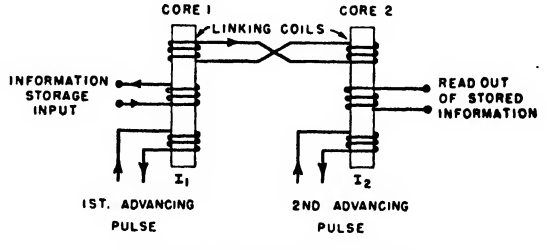

FIG. 2. Two-core storage unit.

any desirable speed up to about thirty thousand information pulses per second.

II. A SINGLE-INFORMATION STORAGE UNIT

Since the large secondary induced voltage is sufficient to drive another core of similar size to its saturation, a means is available to transfer the information.[1] Such a storage unit is shown in Fig. 2. Core 1 and Core 2 are wound of strips of material with a nearly rectangular hysteresis loop to insure that the states of residual magnetism, 1 and 0, are well defined and stable. Assume

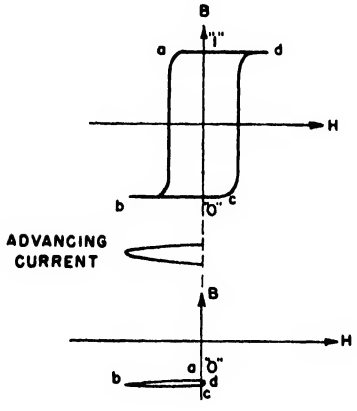

FIG. 3. Flux changing path.

that the 1 state of residual magnetism corresponds to flux in the cores in the upward direction, and the 0 state to flux in the downward direction. Then, whenever a 1 is stored in Core 1 through the information input coil, the first current pulse I_1 will change its state from 1 to 0. This generates a large induced voltage in the linking coil and drives Core 2 to state "1." After that the second current pulse I_2 shifts this state "1" back to Core 1 again. Thus the state "1" is transferred between Core 1 and Core 2 when the current pulses I_1 and I_2 are applied alternately. However, if both cores are originally in the "0" state, the I_1 pulse cannot change much of the flux of Core 1. The linking current is very small, and Core 2 remains in the "0" state. The alternate application of I_1 and I_2, which will be called advancing pulses from now on, therefore will not produce any change of the states of the cores. This constitutes a single-information storage, in which a binary digit can be stored indefinitely and read out at any given time by the application of a pair of advancing pulses.

Physically this is possible due to the existence of two limit cycles of the hysteresis loop when the two alternate advancing pulses are applied. As shown in Fig. 3, the upper loop represents the cyclic change of magnetization of cores when digit "1" is stored. The lower small loop represents the cyclic change of magnetization of cores when digit "0" is stored. In either case an advancing pulse changes the magnetization of one core along the curve *a* to *b* to *c* while that of the other core, through the linking coils, changes from *c* to *d* to *a*. Depending on the initial state of magnetization of the first core, the hysteresis loop follows either the upper or the lower curve.

III. PROPAGATION OF INFORMATION ALONG A DELAY LINE

The requirement for a magnetic delay line is that it should be able to store a series of information pulses and deliver them back at a later time. A number of magnetic cores are needed. These should be so constructed as to work in the following manner: When the first information pulse has been stored in the first magnetic core, an advancing pulse is applied to this core to transfer the information to the next core. This is necessary in order to make the first core ready to receive and store the second-information pulse. Next, these two signals are advanced further to make room for the storage of the third. This process of advancing and storing continues to the end of the line, where the information signal is sent out. If, after the line is loaded with information, no further advancing pulses are applied, the information will stay in the cores indefinitely. When advancing pulses are once again applied, the stored information is discharged. If the output of the delay line is connected to its input, a closed ring results. Information can be kept circulating around the ring continuously by the advancing pulses, and can be reproduced at any time. The same is true for magnetic recordings on a rotating storage drum, except that in the latter case the mechanical rotation of the drum is used to carry the information along, whereas in the present scheme advancing pulses are used to propagate the information.

Since all the magnetic cores in such a delay line are connected in tandem through the linking coils, two possible effects must be prevented before the desired information transfer can be made. First, an advancing pulse should advance a digit only in the forward direction; any backward flow of information is to be avoided. Second, an advancing pulse should advance a digit to the next core only; any effect of the digit on cores beyond this would interfere with previous digits. Of course it is imperative for successful operation that the signal should not fade along the line.

IV. A DELAY LINE OF THREE CORES PER BINARY DIGIT

A circuit has been developed which is based on the fundamental requirements of a delay line, discussed in Section III. The connections are shown in Fig. 4. Three cores are necessary for the storage of each binary digit. Three such cores together will therefore be referred to as one storage unit. Three successive pulses are required to advance the information from one storage unit to the next. These pulses, respectively, advance the signal from the first core to the second core,

[1] Chapter IV, Progress Report No. 2, November 10, 1948; the Computation Laboratory, Harvard University, under Contract W19-122-ac-24 with the U. S. Air Force.

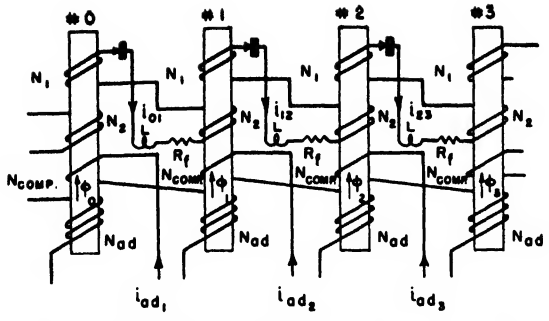

FIG. 4. Delay line structure of three cores per digit.

from the second core to the third core, and then from the third core to the first core of the next storage unit.

The operation can briefly be summarized as follows: All advancing pulses are connected so as to drive all the cores to negative saturation. When there is no information in the line, all the cores have negative residual magnetism and are thus in the "0" state. When information is stored, every third core may be positively or negatively magnetized and thus be in either state "1" or "0." Consider the case of a "0" being stored in Core 1. All advancing pulses are so connected so as to drive the cores to negative saturation. Since the residual magnetism on Core 1 is already negative and the core has essentially a square hysteresis loop, only a very small change of flux results when Advancing Pulse #1 is applied. There is no effect on other cores. The next core remains negatively magnetized. One can consider that the digit "0" information has been transferred to Core 2. On the other hand, if a "1" is stored in Core 1, it is positivcly magnetized. The application of i_{ad1} drives it to negative saturation. This large change of flux in Core 1 induces a large electromotive force in coils N_1 and N_2 of that core, causing i_{01} and i_{12} to flow. The current i_{12} drives Core 2 from negative magnetization to positive saturation.

The current i_{12} satisfies the following equation

$$N_1(d\phi_1/dt)+N_2(d\phi_2/dt)=[R_f+L(d/dt)]i_{12}, \quad (1)$$

where R_f represents the total resistance of the link circuit in the forward direction of i_{12} and L the leakage inductance of the linking coil. Integrating Eq. (1),

$$N_1\Delta\phi_1+N_2\Delta\phi_2=R_f\int i_{12}dt+L\Delta i_{12}.$$

Note that i_{12} is always a positive quantity due to the presence of the rectifier. Δi_{12} vanishes as the fluxes of Cores 1 and 2 reach a constant value. We get

$$\Delta\phi_2=-(N_1/N_2)\Delta\phi_1+R_f\int i_{12}dt. \quad (2)$$

The last term in Eq. 2 is always a positive quantity. If Cores 1 and 2 have the same dimensions, the flux change of ϕ_2 is not complete unless N_1 is greater than N_2. The optimum ratio of N_1 to N_2 is found to be close to 2:1.[2] The resultant change of flux of Core 2 has no effect on Core 3 because the linking current i_{23} is blocked by the rectifier in the circuit. This satisfies the requirement that information may not advance to cores beyond the next one. The current i_{01} is not desirable because it has the tendency to transfer information backward from Core 1 to Core 0. This current must be balanced by the use of a compensating winding, so that the net magnetizing force is always negative in Core 0 to maintain its negative saturation when information is being transferred from Core 1 to Core 2. Since this process of transfer affects only the three cores 0, 1, and 2, another digit in Core 4 can be transferred at the same time without interference in any other cores except 3, 4, and 5.

A static magnetic storage system is then obtained in which three cores are needed to store each binary digit. Information can be stored in the cores indefinitely and can be stepped along the line in the forward direction by the application of advancing pulses. Three advancing pulses are necessary to advance the information by a single storage unit.

Figure 5 shows a breadboard connection of such a delay line for the storage of four binary digits. The information can be advanced through each storage

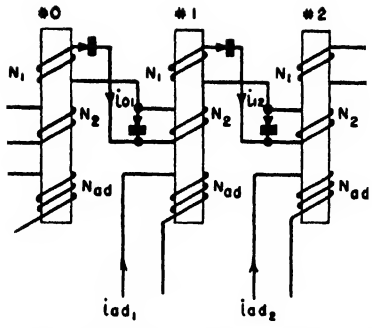

FIG. 7. Delay line structure of two cores per digit.

unit of three cores as fast as thirty thousand digits per second. Oscillographs showing flux variation of a core rate of 3000 and 30,000 digits per second are given in Fig. 6.

Small selenium rectifiers are used in the linking circuit. The rectifiers can be replaced by saturable reactors which offer a high reactance for current in one direction and a low reactance for current in the other direction. But since a reactor is not a highly dissipative element, its use prevents the linking current from dying down fast. This greatly reduces the maximum possible rate of advancing.

An analytical investigation of the sotrage unit in which rectifiers are used in the link circuits is given in reference 2.

V. A DELAY LINE OF TWO CORES PER BINARY DIGIT

As shown in the last section (Fig. 4), the compensating winding is necessary to counteract the effect of the current i_{01} flowing in the coil N_1 of Core 0. If this current can be eliminated, clearly no compensating winding is necessary. It can be done by the introduction of another rectifier,[3] as shown in Fig. 7. In the drawing the leakage inductance and circuit resistance have been omitted in the linking circuit for simplicity. The shunting of a rectifier across the coils N_2 is in such a direction that the current i_{12} is unaffected and produces the useful effect of transferring information from Core 1 to Core 2. But the current i_{01} is greatly reduced by the rectifier which short-circuits the electromotive force generated across N_2 of Core 1. The information then does not flow backward. Since only two cores are now involved in transferring the information, the next two cores can be used for another digit. It is then possible to use only two cores per binary digit.

Figure 8 shows an assembly of a delay line of this design to hold ten digits. Only two advancing pulses are needed to advance the information along the line. A few patterns of the flux variation in cores of this type of delay line are shown in Fig. 9, the repetition rate being 2.5 kc and 25 kc.

The only disadvantage of this connection is that the current flowing in coil N_2 of Core 1 is larger than before. This necessitates a more powerful advancing pulse to change the flux of Core 1.

Another possible arrangement is to apply a series voltage in the link 0–1 when i_{adv} is applied to Core 1 (Fig. 10). This series voltage is opposite to, and slightly greater than, the voltage generated in coil N_2 of Core 1. The transfer of information from Core 1 to Core 2 is made still easier. This scheme has also proved to be successful.

VI. PROPERTIES OF MAGNETIC CORE MATERIAL

As shown in Fig. 11, the ideal hysteresis characteristics of the magnetic storage and delay line are a perfectly rectangular hysteresis loop and a very low coercive force.

In actual practice, unfortunately, such characteristics cannot be realized. Figure 12 shows a typical hysteresis curve for one of the cores manufactured by the Allegheny-Ludlum Steel Corporation of wound strips of Deltamax. The hysteresis loop is close to the ideal; nevertheless, the saturated region is not absolutely of zero slope, and the sharply rising portion is not quite vertical. In addition, the corners are somewhat rounded. But delay lines using such cores have been constructed and operate reliably. The criteria of how good the hysteresis loop is must have been discussed in reference 2.

As the frequency of operation becomes higher, the hysteresis and eddy current losses become appreciable. The heat generated is considerable at the highest frequency of operation. Moreover, the eddy current acts like a short-circuited secondary around the core. The presence of the eddy current requires a larger advancing current to drive the core from one polarity to the other.

At an operating frequency of 50 kc, every core alternates its flux between two saturation values in 10 microseconds. Assume that the flux changes linearly. This is a fairly accurate assumption, as seen from an oscillograph of flux variation. The cores used are made of a strip of one-mil thickness, $\frac{1}{8}$ inch wide, wound into a single-turn core of $\frac{1}{2}$-inch diameter. The hysteresis loss is estimated to be of the order of 7 milliwatt/core, the eddy current loss 25 milliwatt/core, the electrical resistivity of the core being taken as 50 microhm centimeters. For such a core the equivalent demagnetizing ampereturns can be calculated to be about 1.2. It is also equivalent to an increase of coercive force of 0.37 oersted. Apart from the upper frequency limits imposed by these losses, the fundamental operation of the storage and delay line is independent of the frequency.

VII. APPLICATIONS

It may be helpful to point out the unique features of this form of storage. No power is needed to maintain the storage of information. No mechanical movement is needed in recording and pick-up. The speed of recording, transfer, and read out has no lower limit and can be varied to an upper limit which is sufficiently high to be very useful. At the present stage, this maximum rate is of the order of 50 kc. These features represent improvements over the characteristics of the storage devices mentioned in the introduction.

Possible applications include the following:

1. *Information storage.* Individual binary digits can be stored in pairs of cores, as discussed in Section II. If a series of digits is to be stored, the information can be sent into a delay line. After the whole series of digits is in the line, stopping the flow of advancing pulses suffices to store the information indefinitely in the line. It can be read out at any time at the end of the line by applying the advancing pulses again. Development work is being done at the Computation Laboratory of Harvard University to construct a line holding 40 binary digits in a plug-in component container unit which will be no more than two inches in diameter and six inches in length.

2. *Input and output link for high speed computers.* This form of delay line provides an excellent medium for transfer of information between systems of different digital rate. Data and commands can be put into the line manually and then read out to the machine at its operating speed. Again, results from the machine can be fed at high speed into the delay line, from which later a set of slow advancing pulses can step the results out at a speed suitable, say, to operate a typewriter directly.

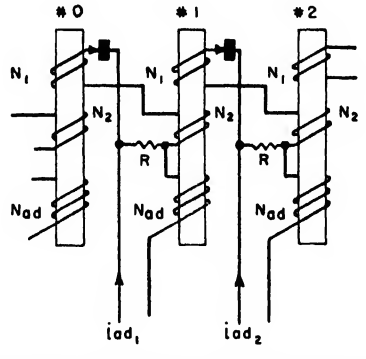

FIG. 10. Another form of delay line of two cores per digit.

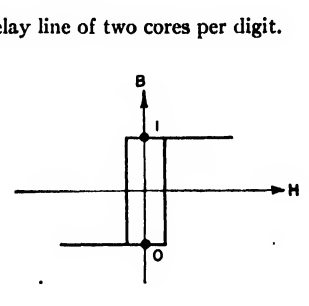

FIG. 11. Ideal hysteresis loop.

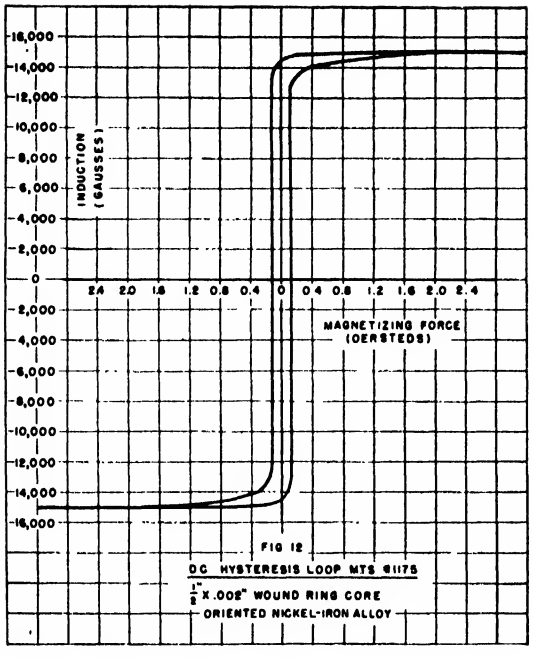

FIG. 12. Typical hysteresis loop of materials used.

3. *Counter.* Since the information stored in the delay line must be stepped along by advancing pulses, it is possible to register a single digit at the beginning of the line, and by the location of this digit along the line at a later instant to determine the number of advancing pulses that have been applied. So far the speed of counting is limited to about 50 kc. This, however, is sufficiently rapid to find wide applications.

4. *Telegraphy.* Because the speed of propagation is variable, a magnetic delay line may serve as the terminal storage for a high speed telegraphy system. The information on a high speed telegraphic line can be distributed to several delay lines. While some lines are being filled, any one of them can be discharged much more slowly to a separate line or directly to a typewriter. Similarly, several slow speed information sources can be read into the magnetic delay lines and then be fed into a high speed telegraphic line by electronic switching control of the advancing pulses.

VIII. ACKNOWLEDGMENTS

The magnetic core materials employed in this research were supplied by the Allegheny Ludlum Steel Corporation, whose cooperation and assistance the authors wish to acknowledge. The use of magnetic cores as a means of obtaining static magnetic storage was originally proposed by Howard H. Aiken, director of the Computation Laboratory, who has worked closely with the authors.

A General Solution for the Bending of Beams on an Elastic Foundation of Arbitrary Continuity*

M. Hetényi
Northwestern Technological Institute, Evanston, Illinois
(Received July 29, 1949)

In the analysis of beams which are supported elastically along their entire length, it is usually assumed that the elastic support is provided either by a series of independent springs, or by a completely continuous elastic medium.

The present paper proposes a method of solution for the intermediate cases, that is, for foundations of partial continuity, by assuming that such foundations may be represented by beams imbedded into an otherwise discontinuous supporting material. In a foundation of this type, there are three independent elastic constants, the resilience of the discontinuous spring layers above and below the beam that is within the foundation, and the flexural rigidity of the foundation beam itself. By changing the values of these three constants, elastic foundations of a wide variety may be produced or, conversely, the constants may be adjusted in such a manner as to represent approximately the characteristics of any given elastic supporting medium.

In the paper a general procedure is presented from which solutions can be derived for the bending of beams on such foundations under any loading or end conditions. The method is illustrated by examples showing the range of pressure distributions that may occur under beams supported on foundations of this type.

IN dealing with problems of bending of beams which are supported elastically along their entire length, it is usually assumed that the supporting medium is provided either by a series of independent springs, or by a completely continuous elastic body. Solutions for a large variety of problems were developed in the past on the basis of either of these two assumptions.† There remains an obvious need, however, for a method of analyzing the intermediate cases, where the foundation material may exhibit an arbitrary and partial degree of continuity. The aim of the present paper is to propose a method of solution for problems of this kind.

A partially continuous foundation will be assumed in this analysis as composed of a bending resistant beam, imbedded between two layers of otherwise independent elastic springs. A foundation of this type can be characterized by three elastic constants, the k_1 and k_2 spring constants (lb./in. per inch) of the two layers, and the flexural rigidity EI_2 of the beam within the foundation. If a trial load q lb./in. is placed along a length b on the surface of such a composite foundation, the resulting deflection line may also be defined by three data, namely, by the amount of local deflection δ_1 within the loaded region, by the maximum deflection ordinate δ_2 of the continuous part of the displacement curve, and by the distance d at which displacements vanish [Fig. 1(a)]. The three characteristic constants of the foundation, k_1, k_2, and EI_2, can be calculated from the observation data, δ_1, δ_2, and d, on the basis of the following relationships in the known solution of a single beam on an elastic foundation without continuity: $\delta_1=q/k_1$, $\delta_2=qb(\lambda_2/2k_2)$, and $d=3\pi/4\lambda_2$, where $\lambda_2=(k_2/4EI_2)^{\frac{1}{4}}$.

If a load carrying beam of flexural rigidity EI_1 is placed on a foundation defined by these three constants, k_1, k_2, and EI_2, as shown in Fig. 1(b), the differential equations of bending may be derived as follows: denoting the deflection ordinates of the upper and the lower beam by y_1 and y_2, respectively, we find that the pressure in the foundation under the upper beam is $p_1=k_1(y_1-y_2)$, and under the lower beam $p_2=k_2y_2$, while the resultant pressure acting on the lower beam is $p_2-p_1=(k_1+k_2)y_2-k_1y_1$. Since these pressures are continuously distributed along the two beams, we have from the flexural theory:

$$EI_1(d^4y_1/dx^4)=-p_1=-k_1(y_1-y_2) \qquad \text{(a)}$$

and

$$EI_2(d^4y_2/dx^4)=-(p_2-p_1)=-(k_1+k_2)y_2+k_1y_1. \qquad \text{(b)}$$

The pressures in these cases are considered positive when accompanied by positive (downward) deflections. From (a) we have

$$y_2=\frac{EI_1}{k_1}\frac{d^4y_1}{dx^4}+y_1 \qquad \text{(c)}$$

or

$$\frac{d^4y_2}{dx^4}=\frac{EI_1}{k_1}\frac{d^8y_1}{dx^8}+\frac{d^4y_1}{dx^4}. \qquad \text{(d)}$$

On substituting these expressions into (b), y_2 will cancel out, and we have the differential equation of the elastic line of the upper beam

$$(d^8y_1/dx^8)+2\alpha(d^4y_1/dx^4)+(\alpha_2-\beta_2)y_1=0,$$

where

$$\alpha=[k_1(I_1+I_2)+k_2I_1]/2EI_1I_2$$

and

$$\beta=[\alpha^2-(k_1/EI_1)(k_2/EI_2)]^{\frac{1}{4}}.$$

* Paper presented at the VII International Congress of Applied Mechanics, London, England, September 5–11, 1948.

† See section on references at the end of this paper.

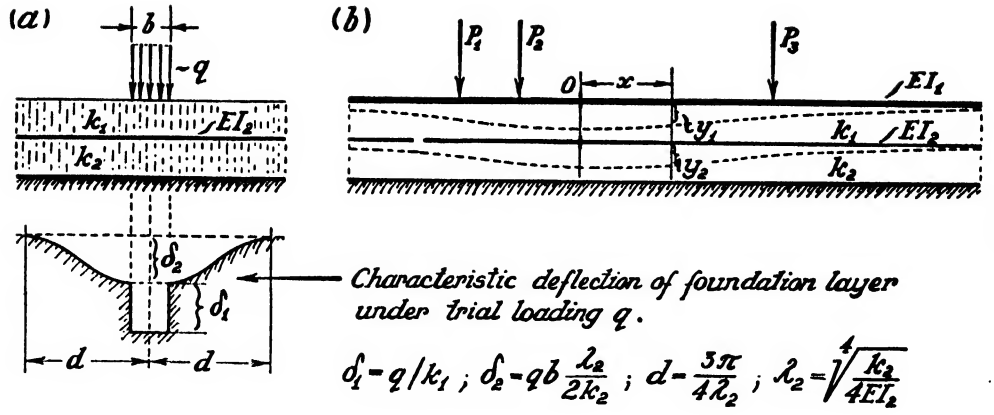

FIG. 1. Foundation layer with an arbitrary degree of continuity.

The general solution of (e) can be written in the form:

$$y_1 = e^{\lambda_1 x}(C_1\cos\lambda_1 x + C_2\sin\lambda_1 x) + e^{-\lambda_1 x}(C_3\cos\lambda_1 x + C_4\sin\lambda_1 x) + e^{\lambda_2 x}(C_5\cos\lambda_2 x + C_6\sin\lambda_2 x) + e^{-\lambda_2 x}(C_7\cos\lambda_2 x + C_8\sin\lambda_2 x), \quad (1)$$

where

$$\lambda_1 = [(\alpha+\beta)/4]^{\frac{1}{4}} \quad \text{and} \quad \lambda_2 = [(\alpha-\beta)/4]^{\frac{1}{4}}.$$

Substituting the solution from (1) into (c), we have the expression for the elastic line of the beam within the foundation:

$$y_2 = [1-(\alpha+\beta)(EI_1/k_1)][e^{\lambda_1 x}(C_1\cos\lambda_1 x + C_2\sin\lambda_1 x) + e^{-\lambda_1 x}(C_3\cos\lambda_1 + C_4\sin\lambda_1 x)] + [1-(\alpha-\beta)(EI_1/k_1)] \times [e^{\lambda_2 x}(C_5\cos\lambda_2 x + C_6\sin\lambda_2 x) + e^{-\lambda_2 x}(C_7\cos\lambda_2 x + C_8\sin\lambda_2 x)]. \quad (2)$$

Expressions for the slope $\theta = dy/dx$, bending moment $M = -EI(d^2y/dx^2)$, and shearing force $Q = -EI(d^3y/dx^3)$ may be obtained for each of the above beams by differentiating the corresponding equation of the elastic line, (1) or (2), respectively.

In applying the above general solutions to the analysis of beams of finite length, the scheme illustrated in Fig. 2 may be the most conveniently used. Here it is first assumed that the beam within the foundation is severed at A and B, resulting in relative displacements and rotations between the severed ends, as the upper beam is loaded. The continuity of slope and deflection in the lower beam is then re-established by the application of end forces P_0 and moments M_0 in the manner shown in the figure.

In using this method of calculation, one needs to know the particular solutions of the elastic lines corresponding to each of the loading cases shown in Fig. 2. The integration constants, C_1 to C_8, in the general solutions (1) and (2) were determined from the prevailing end conditions in each of these particular cases of loading, giving the following results.

Concentrated load P, centrally applied at the upper beam (Fig. 3).

$$C_1 = A\left[\frac{\cosh^2\lambda_1 c + \cos^2\lambda_1 c}{\sinh 2\lambda_1 c + \sin 2\lambda_1 c} - \frac{1}{2}\right]$$

$$C_2 = A\left[\frac{1}{2} - \frac{\sinh^2\lambda_1 c + \sin^2\lambda_1 c}{\sinh 2\lambda_1 c + \sin 2\lambda_1 c}\right]$$

$$C_3 = A\left[\frac{\cosh^2\lambda_1 c + \cos^2\lambda_1 c}{\sinh 2\lambda_1 c + \sin 2\lambda_1 c} + \frac{1}{2}\right]$$

$$C_4 = A\left[\frac{1}{2} + \frac{\sinh^2\lambda_1 c + \sin^2\lambda_1 c}{\sinh 2\lambda_1 c + \sin 2\lambda_1 c}\right]$$

$$C_5 = -B\left[\frac{\cosh^2\lambda_2 c + \cos^2\lambda_2 c}{\sinh 2\lambda_2 c + \sin 2\lambda_2 c} - \frac{1}{2}\right]$$

$$C_6 = -B\left[\frac{1}{2} - \frac{\sinh^2\lambda_2 c + \sin^2\lambda_2 c}{\sinh 2\lambda_2 c + \sin 2\lambda_2 c}\right]$$

$$C_7 = -B\left[\frac{\cosh^2\lambda_2 c + \cos^2\lambda_2 c}{\sinh 2\lambda_2 c + \sin 2\lambda_2 c} + \frac{1}{2}\right]$$

$$C_8 = -B\left[\frac{1}{2} + \frac{\sinh^2\lambda_2 c + \sin^2\lambda_2 c}{\sinh 2\lambda_2 c + \sin 2\lambda_2 c}\right]$$

where:

$$A = \left[\frac{k_1}{EI_1} - \alpha + \beta\right]\frac{P}{EI_1}\,\frac{1}{16\beta}\,\frac{1}{\lambda_1^3}$$

and

$$B = \left[\frac{k_1}{EI_1} - \alpha - \beta\right]\frac{P}{EI_1}\,\frac{1}{16\beta}\,\frac{1}{\lambda_2^3}.$$

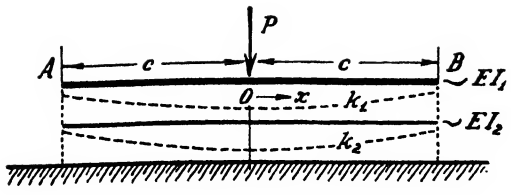

FIG. 3. Particular solution to problem shown in Fig. 2.

Lower beam subjected to equal concentrated end forces P_0 (Fig. 4).

$$C_1=C_3=-\frac{P_0}{EI_2}\frac{k_1}{EI_1}\frac{1}{4\beta\lambda_1^3}\frac{1}{}\frac{\cosh\lambda_1 c\cos\lambda_1 c}{\sinh 2\lambda_1 c+\sin 2\lambda_1 c}$$

$$C_2=-C_4=-\frac{P_0}{EI_1}\frac{k_1}{EI_1}\frac{1}{4\beta\lambda_1^3}\frac{1}{}\frac{\sinh\lambda_1 c\sin\lambda_1 c}{\sinh 2\lambda_1 c+\sin 2\lambda_1 c}$$

$$C_5=C_7=\frac{P_0}{EI_2}\frac{k_1}{EI_1}\frac{1}{4\beta\lambda_2^3}\frac{1}{}\frac{\cosh\lambda_2 c\cos\lambda_2 c}{\sinh 2\lambda_2 c+\sin 2\lambda_2 c}$$

$$C_6=-C_8=\frac{P_0}{EI_2}\frac{k_1}{EI_1}\frac{1}{4\beta\lambda_2^3}\frac{1}{}\frac{\sinh\lambda_2 c\sin\lambda_2 c}{\sinh 2\lambda_2 c+\sin 2\lambda_2 c}.$$

Lower beam subjected to equal concentrated end moments M_0 (Fig. 5).

$$C_1=C_3=\frac{M_0}{EI_2}\frac{k_1}{EI_1}\frac{1}{4\beta\lambda_1^2}\frac{1}{}\frac{\sinh\lambda_1 c\cos\lambda_1 c-\cosh\lambda_1 c\sin\lambda_1 c}{\sinh 2\lambda_1 c+\sin 2\lambda_1 c}$$

$$C_2=-C_4=\frac{M_0}{EI_2}\frac{k_1}{EI_1}\frac{1}{4\beta\lambda_1^2}\frac{1}{}\frac{\sinh\lambda_1 c\cos\lambda_1 c+\cosh\lambda_1 c\sin\lambda_1 c}{\sinh 2\lambda_1 c+\sin 2\lambda_1 c}$$

$$C_5=C_7=-\frac{M_0}{EI_2}\frac{k_1}{EI_1}\frac{1}{4\beta\lambda_2^2}\frac{1}{}\frac{\sinh\lambda_2 c\cos\lambda_2 c-\cosh\lambda_2 c\sin\lambda_2 c}{\sinh 2\lambda_2 c+\sin 2\lambda_2 c}$$

$$C_6=-C_8$$

$$=-\frac{M_0}{EI_2}\frac{k_1}{EI_1}\frac{1}{4\beta\lambda_2^2}\frac{1}{}\frac{\sinh\lambda_2 c\cos\lambda_2 c+\cosh\lambda_2 c\sin\lambda_2 c}{\sinh 2\lambda_2 c+\sin 2\lambda_2 c}.$$

Semi-infinite beam on a simple elastic foundation loaded by concentrated end force P_0 and moment M_0 (Fig. 6). Equation of elastic line:

$$y=\frac{2P_0\lambda}{k_2}e^{-\lambda x}\cos\lambda x-\frac{2M_0\lambda^2}{k_2}e^{-\lambda x}(\cos\lambda x-\sin\lambda x),$$

where $\lambda=[(k_2/4EI_2)]^{\frac{1}{4}}$.

The wide range in the pressure distribution types which may be covered by this theory is illustrated in Fig. 7, where a centrally loaded beam of length $2c=280$ in. and flexural rigidity $EI=250\times10^6$ lb. in.^{2} is placed on foundations with increasing degree of continuity. On the left side of the figure the characteristic deflection curves are shown for each of the three types of foundation, as they are subjected to a trial load of $q=10$ lb./in. distributed along a length of 10 in.

The first type of foundation lacks continuity entirely, and its spring constant can be calculated through dividing the applied trial load q by the observed local deflection ordinate $k=10/0.75=13.33$ lb./in.^{2}. The second type of foundation is characterized by a local deflection of $\delta=0.25$ in. and a continuous deflection curve of maximum ordinate of $\delta=0.50$ in. and wave-length $d=50$ in., which define the following elastic constants for the foundation layer: $k_1=20$ lb./in.^{2}, $k_2=8.44$ lb./in.^{2}, and $EI_2=0.476\times10^8$ lb. in.^{2}. The third type of foundation is assumed to have the greatest degree of continuity, with two-thirds of the maximum deflection being of the continuous type, $\delta_1=0.25$ in. and $\delta_2=0.50$ in., and the effect of continuity being observable up to a distance of $d=100$ in. from the center of application of the trial load, which define the following elastic constants for the foundation layer: $k_1=40$ lb./in.^{2}, $k_2=2.36$ lb./in.^{2}, and $EI_2=1.90\times10^6$ lb. in.^{2}.

The pressure distribution under the loaded beam for each of the average pressure $p_0=P/2c$. It is to be noted that the flexural values of the loaded beam ($2c=280$ in., $EI_1=250\times10^6$ lb. in.^{2}) and the total compressibility of the foundations ($\delta_1+\delta_2=0.75$ in.) were the same in each case, thus the pronounced difference in the resulting pressure distributions was due solely to the different degrees of continuity in the material of the foundation.

The outlined method of analysis may be applied to any elastic supporting medium (subsoils, elastic layers, packing or gasket materials etc.) which exhibits a partly local and partly continuous deflection curve when tested under localized pressure. Though in the paper

only one-dimensional problems were considered, when beam and foundation are of the same constant width, the same principle may be readily extended to the analysis of corresponding two-dimensional plate problems.

Microwave Frequency Dividers

HAROLD LYONS
National Bureau of Standards, Washington, D. C.
August 8, 1949

IN order to extend the range of application of microwave techniques it is becoming more and more important to be able to carry out the operation of frequency division in the microwave region just as at lower frequencies. Such needs are felt, particularly, in connection with spectroscopic or atomic clocks and frequency standards which usually use spectrum lines in the neighborhood of 3000–20,000 Mc or higher.[1] It is therefore necessary to look for a frequency division principle which uses components and techniques that are practicable in the microwave range.[2]

One could inject a signal to be divided into an oscillator operating at a sub-multiple of the injected frequency and lock it in.[3] This well-known principle has obvious disadvantages. If control is lost the lower frequency oscillator will run free. A frequency divider which avoids this difficulty and which is widely used at low frequencies, e.g., in precision quartz-crystal clocks, is the regenerative modulator type.[4] This circuit also works well even in the presence of high noise levels and distorted input signals. It can be designed so that the output will be linearly dependent on the input and maintain a constant phase angle with respect to it. It can generate both sub-multiple and other fractional frequency ratios. Such a circuit to divide down from 9300 Mc to 3100 Mc has been built and tested.[5] A block diagram is shown in Fig. 1. Here it is seen that the 9300 Mc signal is applied to a mixer; to the mixer is also applied a signal at 6200 Mc. This may be a noise component or transient generated by turning the circuit on. The 6200 Mc signal beats with the 9300 Mc input signal to give an output of 3100 Mc. This is amplified by means of the Sperry 2K35 klystron amplifier tubes, and then fed to a Sperry 2K46 klystron multiplier which is tuned to double the input signal to 6200 Mc. After multiplication the signal is amplified at 6200 Mc by means of a Sperry SAC-19 klystron amplifier and fed back to the mixer. If the gain around the feedback loop is great enough, the output signal at 3100 Mc will be maintained independently of the phase shift in the feedback loop. No output will appear unless there is an input signal since the 3100 Mc beat note can only be obtained in this way. If the gain is not high enough in the regenerative circuit it may be necessary to start the operation by injecting some sort of transient. In the circuit shown this was not necessary. Since no attempt was made in this first circuit to design a very efficient mixer, it may not be necessary to use all of the amplification shown in Fig. 1. In principle, the 2K46 frequency multiplier could be replaced by any nonlinear modulator device, such as a crystal rectifier if enough gain were available and the signal level high enough.

Among numerous tests conducted, the input, intermediate, and output frequencies were measured and found to track each other and it was also shown by the insertion of wave-guide filters that no other output signals were present except those in the 3000 Mc range. The output signal was taken from the middle cavity of one of the 2K35 tubes. A definitive test of the accuracy of frequency division was made as follows. The 9300 Mc input signal was fed to a spectrum analyzer where it was viewed on the scope as a pip. The output signal was monitored by means of a frequency meter and second spectrum analyzer. In addition it was fed to a crystal multiplier which multiplied by three and then fed to the same spectrum analyzer as the input frequency. If the output frequency times three is exactly equal to the input frequency, the two pips on the scope should coincide. The two individual pips could be identified by first displaying one and then the other by control of their intensities by means of attenuators. When the two pips were superimposed they blended smoothly into one larger pip; this was done under conditions of highest dispersion in the spectrum analyzer. No beating of the two signals whatsoever could be discerned nor any shift or change in shape of the pulses. If it is assumed rather arbitrarily that a beat note of approximately one cycle per second could be observed, this means that the output frequency times three was equal to the input frequency with an accuracy of at least one part in 10^{10}. In this type of test no difficulty results if the input-oscillator-frequency slowly drifts back and forth since the output frequency drifts with it. It is clear that direct frequency calibrations of extreme accuracy would be necessary to obtain a test with the sensitivity of the one just described.

Since another klystron multiplier tube, the Sperry 2K47, is commercially available and multiplies from approximately 270 Mc up to the 3000 Mc range, frequency dividers could be built to go down to as low a frequency as desired. It is important to note that in this type of circuit it is not necessary to have amplifiers available at the input frequency but only at a lower frequency, essentially a divided frequency. Since klystron multipliers are very efficient and much easier to make than amplifiers, a multiplier tube and frequency divider dividing down from the 24,000 Mc region, rich in spectrum lines, should be possible.

Since amplifiers in this type of circuit are only needed at the divided frequency, some interesting possibilities are opened up by consideration of circuits of the type shown in Fig. 2. In this circuit we make the regenerative-modulator divider provide its own input by providing a second regenerative channel. In this case, if there is enough gain, the circuit should oscillate and divide in frequency at the same time. A more general arrangement allowing more flexibility in the choice of frequencies which can be used with any given set of tubes is shown in Fig. 3. Figures 2 and 3 show a proposed application to an atomic oscillator and atomic clock.[6] Here by atomic oscillator we mean a self-excited or feedback oscillator, the frequency of which is directly controlled by an absorption cell. This is in contra-distinction to the stabilized servo mechanism or frequency discriminator type of spectrum-line controlled oscillators.[1,6] To make an atomic clock it is then necessary to divide down by means of straight frequency division from the atomic oscillator to a frequency low enough to drive the usual synchronous motor type of clock. Two types of atomic oscillators in which the

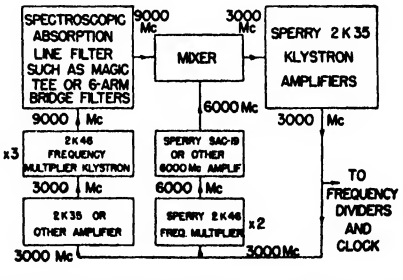

FIG. 2. Proposed combination atomic oscillator and frequency divider, using amplifiers at divided frequencies, applied to an atomic clock.

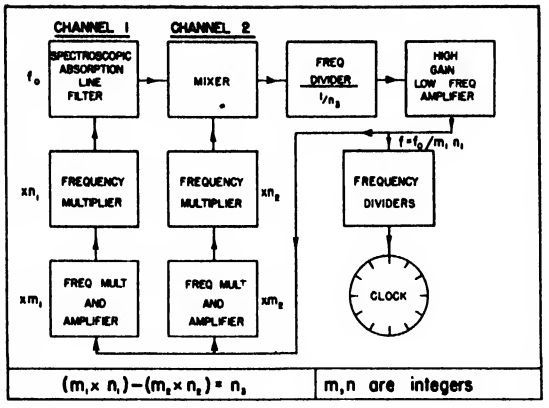

FIG. 3. General and more flexible block diagram of atomic clock using combination oscillator and divider.

feedback frequency is controlled by means of spectroscopic circuits have been described.[1,2,5] Here the spectroscopic filter is based on the use of a magic-tee or a six-arm, wave-guide Wheatstone bridge in which an absorption cell containing ammonia or other absorbing gas at low pressure determines the frequency which will be transmitted by the filter. As shown in Fig. 3, this spectroscopic filter transmits an input frequency to the regenerative modulator only at the frequency of the spectrum line used in the filter. This, therefore, controls the frequency of the oscillator and similarly that of the divided frequency. However, as compared to the atomic oscillators previously described, in this method not only is frequency division carried on simultaneously with controlled oscillation, but an amplifier at the spectrum line frequency is no longer needed.

Although it is very desirable to go back up to the 3,3 line of ammonia at approximately 24,000 Mc, and we are attempting development and procurement of suitable multiplier and amplifier tubes for this purpose, an atomic clock could be developed using a spectrum line in the 9000 Mc range using available amplifier and multiplier tubes and the circuit shown in Fig. 2. For this purpose the various deuterated species of ammonia were prepared and spectrum lines searched for in order to provide a strong absorption line at a lower frequency. Although this work is still incomplete, about 30 lines have been found in the range between 3000 and 10,000 Mc.[5] Such spectrum lines can be used to make a clock following the circuit shown in Fig. 2 or simply used in a separate atomic oscillator driving a frequency divider.

Particle Size of Evaporated Gold

P. G. WILKINSON AND L. S. BIRKS
U. S. Naval Research Laboratory, Washington, D. C.
October 5, 1949

MANY observers have noted that the gold on shadowed electron micrographs granulates when exposed to an intense beam of electrons. It has been generally assumed that before electron bombardment, the gold was a smooth continuous film. Picard and Duffendack[1] published micrographs of gold evaporated at 10^{-6} mm pressure in which the gold appeared as discreet particles. From work[2] we have done on correlating electrical resistance properties of gold with microstructure, we believe that such is generally the condition of evaporated gold except when contaminated by the presence of tungstic oxide. In the usual bell jar conditions for gold shadowing electron micrographs at about 10^{-3} mm pressure, the deposit contained about five percent tungsten by analysis. This gave a characteristic matte background which was observed no matter how careful the operator was to use low beam intensity and fast exposure. When the percentage of tungstic oxide was reduced either by pumping to lower pressure or by flushing the system during evaporation with a few microns of purified nitrogen, free of oxygen, the gold appeared as discreet particles, similar to those observed by Picard and Duffendack. Such deposits showed no tungsten by chemical analysis. Figure 1

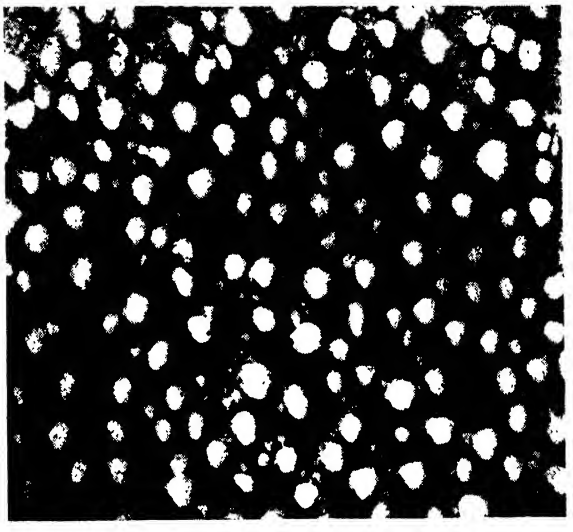

FIG. 1. Gold evaporated at 10^{-6} mm pressure and shadowed with tungstic oxide.

proves the existence of discreet gold particles before electron bombardment. The gold was evaporated at 10^{-6} mm pressure and then shadowed with tungstic oxide before it was placed in the microscope. The shadows could not have appeared if the granulation had taken place in the electron microscope.

Figure 1 is typical of all the tungsten-free gold deposits we have observed.

* Brittle fracture occurred 0.005 in. in excess of these values, for the respective specimens.

the fracture depth (x), and the applied dynamic load. Specimens were held thermostatically at temperatures between 0°F and 50°F so that strain ageing would be small, and deformation was effected very slowly at a constant rate. The essential features of the apparatus have been described elsewhere.[1] At the higher temperatures the specimens fractured in a controlled (ductile) manner, but at the lower ones many ultimately underwent uncontrolled (brittle) fracture during test; however, temperature did not affect the data measureably.

When plotted against s, the data for ductile and pre-brittle specimens were identical. But when plotted against x, the data clearly identified the pre-brittle specimens as different from the ductile ones which were chemically and metallurgically identical with them. As Table I shows (in terms of derivatives), brittle fracture was preceded in the pre-brittle phases by excessive fracture depths and by deficient (in terms of x) energy absorption (see columns 3 and 4, respectively). The three brittle specimens reported in Table I are representative of the many others observed.

Column 5 in Table I refers to the function

$$G=1+de/dw. \quad (1)$$

G. R. Irwin has suggested[2] that a controlled fracture should become uncontrolled when $G\rightarrow 0$, by extending the concepts of A. A. Griffith.[3] Although the present data are not sufficiently precise to provide an ultimate test of Irwin's suggestion, they are in entire accord with it as far as they go, and to that extent serve to emphasize the significance of energy partition in macrofracture phenomena.

* The experimental portions of this work were carried out in the research laboratories of The University of North Carolina under the provisions of Contract No. N6-ori-227 (and Amendment I) of the ONR with the University. Dr. P. E. Shearin and Mr. R. M. Trimble provided material assistance.

A Low Temperature Replica Method for Electron Microscopy

C. E. HALL
Massachusetts Institute of Technology, Cambridge, Massachusetts
September 6, 1949

A REPLICA method has been tested which appears to be of value for the electron microscopy of aqueous substances while they are in the frozen state. The apparatus employed is shown diagrammatically in Fig. 1. The specimen, A, on glass is supported in a vacuum chamber in contact with a copper block, B, which is pre-cooled to liquid air temperature. The block is suspended from a glass rod and can be set at any desired angle by means of a conical vacuum plug. When a vacuum has been obtained, the temperature of the specimen is temporarily raised to about −60° to −90°C with radiant heat from an external microscope lamp in order to sublime ice crystals which may have condensed on the specimen from the atmosphere and also to secure a surface etch. In the absence of an intense source of radiant heat, the conductivity of the supporting glass is sufficient to maintain the specimen at a temperature close to that of the cold sink. After the etching procedure, the specimen is shadowed with Cr and a supporting film of Si evaporated from a BeO crucible[1] is deposited on the surface at normal incidence. (Although Si was used on these experiments, SiO has subsequently proved more convenient for evaporated films since it does not attack tungsten.) Finally, the cold block is removed from the vacuum, the glass plate is detached and the surface film is floated on water after the specimen has warmed to room temperature.

In order to test the feasibility of the method a dilute aqueous suspension of silver halide particles from a photographic plate was used as a test object. Silver halide was removed by floating the replica film on sodium hyposulfite. A micrograph of such a film is shown in Fig. 2. Although the etch was too light to cause the large particles to project far above the surface their outline may be discerned. The surrounding surface of frozen, dilute gelatin displays a crater-like structure, the significance of which is not understood at present. No evidence of gross ice crystals has been observed within quick-frozen specimens.

The micrograph in Fig. 3, for which the etching procedure was omitted, shows ice crystals condensed from air on the surface of frozen distilled water. The micrograph demonstrates the feasibility of obtaining replicas of ice surfaces in this manner and also emphasizes the necessity for either carefully shielding the cold specimen surface or removing the condensed moisture by sublimation before the process is employed.

Since the method depends on the immobilization of a water surface in a vacuum, it is of interest to estimate the rate at which water will sublime from a specimen. The rate of sublimation can be computed[2] for a given temperature from a knowledge of the equilibrium vapor pressure of ice which is tabulated[3] to −98°C and extrapolated values may be obtained with the aid of Clapey-

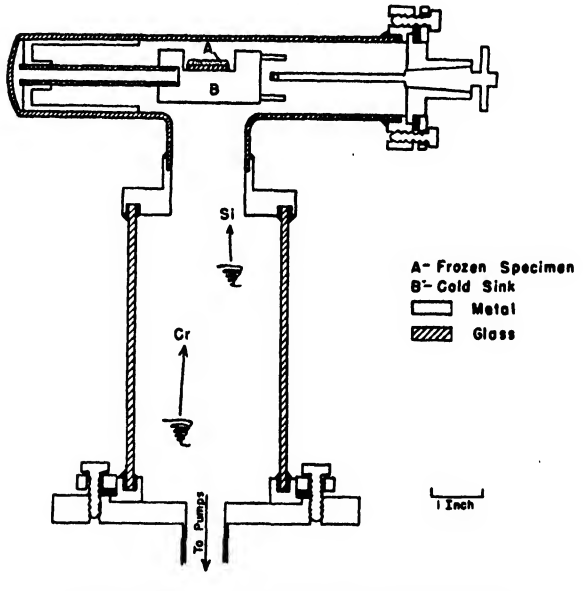

FIG. 1. Apparatus for low temperature replica method.

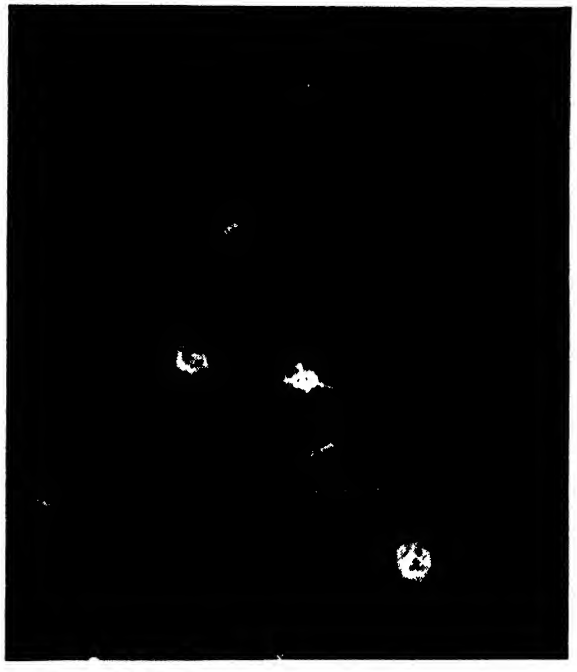

FIG. 2. Low temperature replica of surface of a frozen dilute suspension of silver halide particles.

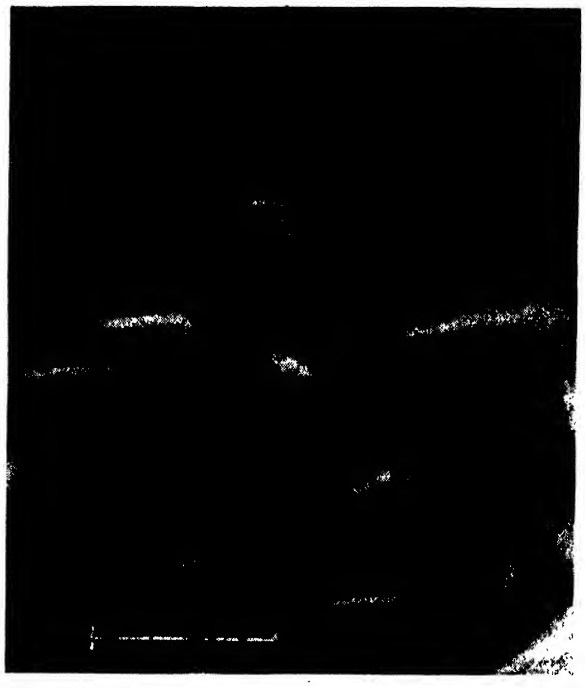

FIG. 3. Low temperature replica of ice crystal condensed on frozen distilled water surface, shadow-cast with Cr, but not etched.

ron's equation.[4] The vapor pressures together with the computed rates at which an ice surface would recede in a perfect vacuum at various temperatures of interest are listed in Table I. It is apparent from the table that if the surface is to be maintained over periods of several minutes, the temperature should be in the range −120°C or lower, and that for the etching procedure, the rate of sublimation is reasonably rapid at about −90°C and higher.

TABLE I.* Estimated rate of recession of an ice surface in a vacuum.

Temperature °C	Vapor pressure dynes cm^{-2}	Rate of recession A sec.$^{-1}$
−90	9.3×10^{-3}	140
−100	1.4×10^{-3}	23
−110	1.6×10^{-4}	2.6
−120	1.3×10^{-5}	0.2
−130	7.7×10^{-7}	0.01

* Vapor pressure at −90°C from *Handbook of Chemistry and Physics*; other values calculated from Clapeyron's equation assuming latent heat of sublimation 675 calories per g.

With reasonable assumptions concerning the conductivity between specimen and cold sink, estimates can be made of the rise in specimen temperature due to radiant heat from the hot evaporation filaments and due to heat released through deposition of evaporated shadowing and film materials. Such estimates indicate that under typical conditions the temperature rises about 2°C from radiant heat and is also of negligible magnitude due to condensing Si or shadowing metal. Heat is also absorbed during transfer from liquid air to the vacuum chamber by condensation of moisture from the air and conduction to the atmosphere. When the operation was performed with reasonable speed, the temperature of the block (measured with a platinum resistance thermometer) had usually risen to about −145°C by the time the pressure in the vacuum chamber had reached the point where the oil diffusion pump became effective. The temperature rose at the rate of about 1°C per minute beyond this point. Clearly, in order to complete the process before the specimen warms to a temperature where an ice surface becomes unstable, it is necessary to transfer the cold block rapidly to the vacuum chamber and attain a working vacuum in the shortest possible time. Probably it would be advantageous if thermal contact between specimen and sink could be decreased or broken during the etching procedure to reduce undesirable heating of the cold sink.

Plasma Oscillator

GOTTFRIED WEHNER,
Wright Field, Dayton, Ohio
August 15, 1949

EXPERIMENTS with a stabilized low pressure arc discharge[1] resulted in the discover of a new kind of r-f oscillator. This oscillator is similar to a klystron, whose resonance circuits are formed inside the plasma by thin oscillation layers.[2]

Cathode is either a mercury arc cathode with auxiliary anode or an oxide cathode. The grid completely separates the anode space from the cathode space and has a mesh width (depending on the gas pressure), which makes it possible to stabilize the discharge between fired and unfired operation.[3] The increased voltage drop of such a stabilized discharge is concentrated near the grid.[4] Electrons reaching this region from the cathode side are accelerated into the anode space and form a beam of fast electrons, provided the gas pressure is low (<5 micron) and the mean free path is large compared to the electrode distances.

When another electrode (a plate facing the grid and called repeller) is inserted in the beam and the anode arranged outside the beam, oscillations arise with a well-defined frequency, which are tunable between 1000 and 4000 mc by changing anode voltage and anode current. The grid and repeller (both near cathode potential) are covered with dark sheaths between which the bright anode plasma at high potential is located.

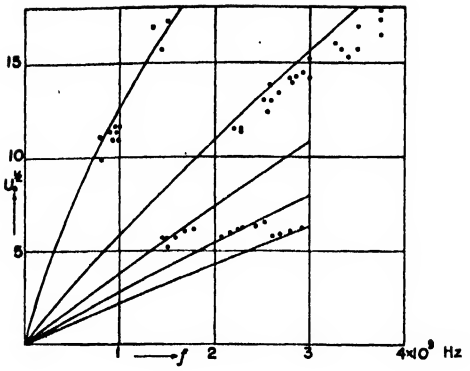

FIG. 1. Velocity *vs.* frequency diagram. Pressure 6 micron.

The investigation of the beam velocity distribution by means of a movable probe resulted in the discovery of a thin r-f velocity modulating layer inside the plasma near the grid ion sheath.[6] Often a second layer is found near the repeller ion sheath. In a suitable arrangement these oscillation layers can be seen as slightly darker zones inside the bright plasma.

Probe measurements showed that the plasma density N is not uniform along the anode space but decreases from the center in direction of the grid as well as of the repeller. Just near the oscillation layer N has a value which is connected with the observed frequency f by Langmuir's equation $f=9000N^{\frac{1}{2}}$. This density distribution provides an infinite number of resonance circuits in line with increasing resonance frequencies to the center. Hence only in one or two layers does the plasma density fit to one frequency. The repeller provides either the second oscillation layer (catcher) or the reversion of the beam when the tube oscillates as a reflex klystron.

Figure 1 shows the beam velocity *vs.* frequency diagram of a sealed-off all metal tube with an electrode arrangement according to Fig. 2. Without changing or matching any resonance circuit,

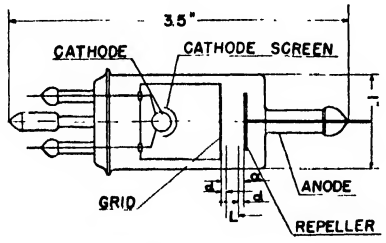

FIG. 2. Sealed-off plasma oscillator tube.

merely by changing anode voltage and anode current the frequency can be changed between 800 to 4000 mc. Oscillations occur along different modes. In case of higher pressures when reflex excitation due to the limited free path of the beam electrons does not exist, these modes are easy to calculate by transit time relations. Identifying the plasma edges near grid and repeller with the oscillation layers and assuming that the two oscillation layers oscillate in opposite phase, excitation should be possible if the transit time t_0 of electrons with the velocity v_0 through the drift space L equals:

$$t_0=\tfrac{1}{4}f\times(4n+1) \quad n=0,1,2,\cdots.$$

Setting

$$f=9000N^{\frac{1}{2}}$$
$$L=a-2d \text{ (Fig. 2)}$$
$$d=550U_0^{\frac{3}{4}}/N^{\frac{1}{2}}\,^{6,7}$$
$$v_0=6\ 10^7U_0^{\frac{1}{2}}$$
$$L=v_0t_0$$

the following relation may be derived:

$$(n+\tfrac{1}{4})\ 6\ 10^7U_0^{\frac{1}{2}}+10^7U_0^{\frac{3}{4}}=af.$$

This is shown with $a=0.6$ cm (Fig. 2) in the curves of Fig. 1. Beside these modes at lower pressures several other modes are detectable. They belong, as can be shown, to an excitation which is similar to the reflex klystron.

Wave-Lengths Suitable for X-Ray Microscopy of Biological Specimens

J. L. FARRANT
Division of Industrial Chemistry, Commonwealth Scientific and Industrial Research Organisation, Melbourne, Australia
September 6, 1949

AN x-ray microscope has recently been developed by Kirkpatrick and Baez[1] based on Compton's observation,[2] in 1922, that x-rays incident upon surfaces at glancing angles less than certain small critical angles undergo total specular reflection in accordance with the theory of Drude and Lorentz. The x-ray beam is focused by successive reflections at small glancing angles of incidence from two concave mirrors, having spherical, elliptical or cylindrical cross sections, and set up so that the normals to the two surfaces are mutually perpendicular. In this way one mirror exercises a focusing function for rays in a particular plane, while the other focuses the rays in a plane normal to the first. Kirkpatrick has suggested additional mirrors to reduce the spherical aberration and anamorphotism of the image inherent in the two-mirror system and calculates by means of the theory of Drude and Lorentz that diffraction limits the resolution to about 70A, this limit being independent of the wave-length of the radiation used.[1] In exploratory work with wave-lengths of the order of 1.5A at glancing angles of incidence of less than 30 minutes upon spherical mirrors coated with platinum and gold, Kirkpatrick and his colleagues have already obtained a resolving power of 2 microns.

Radiation of wave-length 1.5A has the advantage of being penetrating enough to allow the specimen to be imaged while in air at normal pressure, provided the absorption of radiation along the path between the mirrors and the image is diminished by the employment of a hydrogen or helium atmosphere.[1] On the other hand only the coarser details of comparatively thick specimens will absorb sufficiently to yield adequate image contrasts, since the "Half-Value Layer (H.V.L.) of organic substances (e.g., cellulose of density 1.3 g/cc) for a wave-length of 1.5A is approximately 0.7 mm, and even for an element of as high an atomic number as copper the H.V.L. is 15 microns. An additional limitation is that such wave-lengths restrict the angle of glancing incidence to a maximum of about 30 minutes, so that images are produced under conditions of extreme obliquity resulting in large aberrations.

In view of these limitations it is suggested by the writer that the realization of a microscope of this type suitable for the examination of bacteria and other organic specimens will entail the use of longer, more absorbable wave-lengths. Besides giving more adequate contrast the use of longer wave-lengths offers the additional advantages that (a) the degree of polish and accuracy of figure of the mirrors would be less critical, (b) the increased critical glancing angle of reflection would allow a greater numerical aperture with consequent increased speed of the optical system and (c) the larger aperture would allow more accurate focusing of the specimen with visible light before making the exposure with x-rays. It is also possible that conditions of less

TABLE I. Limits of resolution set by diffraction.

Mirror material	Wave-length (angstrom units)	$i_c \times 10^3$ (radians)	$d = \lambda/(2i_c)$ (angstrom units)	Observer
Platinum	2.0	14.1	70	E. Dershem[a]
Platinum	7.0	35.5	100	E. Dershem[a]
Gold	8.32	39.0	110	C. B. O. Mohr[b]
Glass	8.32	23.0	180	C. B. O. Mohr[b]
Glass	13.3	37.8	180	C. B. O. Mohr[b]
Glass	44.5	80.0	280	E. Dershem[c]

oblique reflection would reduce aberrations, but more work on oblique optics is needed to decide this point.

According to the Drude and Lorentz theory the resolving power of the instrument is independent of the wave-length of the x-rays used.[1] However, the high absorption of long wave-length x-rays results in a less sharply defined critical angle and some of the radiation is specularly reflected at large glancing angles. Hence the Drude and Lorentz theory is inadequate here and even the application of the Fresnel expressions is not completely satisfactory. A closer agreement with experiment is given by the wave-mechanical treatment developed by Hönl,[3] but probably the best estimate of the resolution possible with long wave-lengths is obtained from actual experimental data, even though little information for monochromatic radiation has been published. In Table I is cited the limit d set to the resolution by diffraction, calculated by Kirkpatrick's formula $\lambda/2i_c$ from experimental values of the glancing angle of incidence i_c at which the reflected intensity I is half the intensity I_0 reflected at grazing incidence. The deterioration of resolution at long wave-lengths is not great.

Several investigators[4, 5] have found that mirrors composed of light elements are more efficient than heavy metals as reflectors of x-rays of wave-lengths greater than about 8A, and claims have been made for specular reflection of some of the radiation incident at surprisingly large glancing angles. The first observations of this nature were made by Holweck[6] in 1923, but perhaps the most interesting investigations are those of Laby, Bingham and Shearer,[7, 8] who examined the reflection of x-rays of wave-length 44.5A ($CK\alpha$) from several substances. At a glancing angle of 6 degrees soda-glass reflected 46 percent of the incident radiation and even at 20 degrees the reflected intensity was 18 percent. The radiation was focused with a concave soda-glass mirror at a glancing angle of incidence of 45 degrees to obtain a diffuse image of the focal spot. The observations made must be accepted with the reservation that part of the effect was due to general long wave-length radiation from the carbon anode employed, but a spectral analysis of the radiation revealed that it consisted largely of the carbon $K\alpha$-line. Although they realized their work established that concave gratings of considerable aperture could be used in this region, these workers unfortunately did not further explore the field of x-ray optics. These and other observations set out in Table II suggest that possibly mirrors of some materials would reflect sufficient of the very long wave-length radiations at close enough to normal incidence to allow the reflecting microscope of Burch[1] with its relatively large aperture to be used in that region.

TABLE II. Observations on the specular reflection of very long wave-length x-rays.

[c] S. D. Gehman, Phys. Rev. 33, 141 (1929).

Work on the specular reflection of x-rays seems to have practically ceased about 1932, but the attractions of x-ray optics are sufficient incentive to reopen investigation of this field. The modern techniques of vacuum evaporation and electron microscopy should greatly facilitate the preparation of mirrors and the examination of the smoothness of their surfaces.

An appreciation of the wave-lengths required to yield adequate image contrast for bacterial and organic specimens is given by the fact that the H.V.L.'s in organic substances for the $K\alpha$-radiations of aluminum (8.3A) and carbon (44.5A) are 5 and 1.4 microns respectively. The corresponding H.V.L.'s for air at N.T.P. are 4.5 and 1.0 mm, so probably the specimen could be imaged while placed in a thin cell filled with air or a lighter gas and sealed off from the x-ray tube and the optical system by thin, small diameter, vacuum-tight windows of collodion or beryllium. Radiation damage to specimens may however restrict the use of the longer wave-lengths.

The low intensity difficulty can be avoided to some extent by using visible light to search and roughly focus the field, while the photography of the image at low magnification with fine-grained plates should reduce exposure time somewhat. Application of the recently-developed x-ray image-intensity multiplier[9] may resolve this difficulty. The obvious advantages of the x-ray microscope are as follows: (i) Thicker specimens may be examined without the use of extremely high potentials. (ii) It may not be necessary to desiccate the specimen by placing it in vacuum. (iii) By choice of appropriate wave-lengths it should be possible to locate specific elements in the specimen. (iv) The x-ray microscope should be capable of use as an x-ray diffraction camera yielding focused diffraction patterns which would be of considerable value, particularly in the investigation of long spacings.

Thin Films Peeled from Teflon

C. K. JONES
Thomson Laboratory, General Electric Company, West Lynn, Massachusetts

July 28, 1949

THERE are many occasions when one has need of thin films of specific materials. These are cometimes difficult to prepare. The method described below was used to prepare films for x-ray absorption measurements.

A thin film of a barium compound was required with a negligible amount of foreign matter of high atomic weight. The specific compounds used were $BaCO_3$, BaF_2 and $BaSO_4$ but the method is equally applicable for a wide variety of such compounds.

The compound in question was mixed with General Electric Sleeving Lacquer #1548 in the ratio of one part compound to two parts lacquer by weight in a ball machine for two hours. A strip of Teflon, a vinyl polymer of the formula

$$\left[\begin{array}{cc} F & F \\ | & | \\ -C- & -C- \\ | & | \\ F & F \end{array}\right]_n,$$

which is attached only by liquid sodium, two inches wide, six inches long, and forty mils thick was mounted on a brass frame. The Teflon was then dipped into the mixture and withdrawn at a slow rate, the optimum being such that the rate of run back is equal to the rate of withdrawal. A Fisher-Payne dip coater is very useful for this purpose. The films were allowed to dry and

then peeled off. In removing the film, lifting at one end was found to be preferable to pulling the film back over itself.

Films prepared in this manner contained sixty percent compound, were as thin as ½-mil thick, and were sufficiently strong to be handled with ease. The thickness of the film could be varied by the dilution of the lacquer. The films were found to vary over a film and between films of roughly one percent.

High Strength Ceramics for High Temperature Use

RESULTS of recent tests at the National Bureau of Standards have shown that several ceramic bodies previously developed by the Bureau have marked superiority, in both strength and creep characteristics at 1800°F and above, over the best available high temperature metal alloys. Laboratory data indicate that these ceramic bodies, especially designed for use in jet engines and gas turbines, possess special properties required at the elevated operating temperatures of these power plants.[1]

The revolutionary developments during the past 30 years, particularly the last 10 years, in both design and efficiency of power plants have emphasized the need for materials of great strength and durability at very high temperatures. This is a natural consequence of the fact that, in any device for the conversion of heat energy into work, the efficiency of that device may be increased by increasing the temperature differential between the beginning and end of the conversion.

Because design engineers projected their plans into regions of temperature and stress far beyond the potentialities of known metallic alloys, a survey of non-metallic compounds, especially the oxides, silicates, carbides, and related combinations peculiar to ceramics became necessary. Little data existed in the literature upon which to base specific designs for the application of ceramics in power plants such as the gas turbine. Some work has been done on feldspathic bodies, which contain a bond of glass and, consequently, have limited use at elevated temperatures. Several reports were also available in the German literature on small specimens of simple oxide bodies with extraordinary resistance to mechanical stress at temperatures above 1800°F. These bodies had been matured, experimentally, at such high temperatures (about 3450° to 3550°F) that their successful production commercially in the United States seemed to be only a remote possibility.

Therefore, when the National Bureau of Standards was requested, by the National Advisory Committee for Aeronautics in 1944, to obtain engineering data on ceramic bodies in tension at elevated temperatures, it was thought advisable to begin the work on bodies which could be produced with available industrial facilities. Leading ceramic concerns were requested to submit specimens for preliminary tests of bending at elevated temperatures and of resistance to thermal shock. Also, six promising bodies were selected from a number developed at the National Bureau of Standards during a previous investigation. These tests, involving bending strength at 1800°F and relative resistance to thermal shock, showed the oxide bodies developed at the Bureau to have superior quality over those then available from commercial concerns. A comprehensive investigation was begun on the high temperature strength and creep in pure tension of six NBS oxide bodies.

For test purposes specimens round in cross section and approximately 0.3 in. in diameter throughout the gauge length were prepared. The adapters for applying the stress were 8½ in. long, 1 5/16 in. in diameter, and were made of one of the bodies under test. Ceramic adapters were used because calculations based on the data available indicated that high temperature alloys would not have sufficient strength at the maximum temperatures and stresses likely to be obtained in some of the tests. Both adapters and test specimens were fabricated under contract by a co-operating industrial concern, using hydrostatic pressure applied by means of rubber molds. The strain gauges, similar in design to those used at the National Bureau of Standards for measuring creep of metals, were fabricated from 90 percent platinum, 10 percent rhodium tubing, and wire.

TABLE I. *Stress-temperature data on four high strength ceramic bodies.*

Temperature (°F)	Maximum stress lb./in.² NBS ceramic bodies No. 358	No. 353	No. 151	No. 4811C
1500	13,000	13,000	12,000	14,000
1700	14,000	13,000	13,000	14,000
1800	17,000	18,000	18,000	18,000
1900	8000	4000	15,000	16,000
2100	...	...	...	6000

Four thermocouples mounted in the vicinity of the specimen provided temperature measurements at the ends and at the center of the gauge length and actuated the temperature controlling and recording instruments. The specimens were heated in conventional wire-wound furnaces equipped with viewing windows to permit the periodic measurement of strain using a Gaertner extensometer-viewing microscope. Loads were applied to the specimen through a lever system.

Four general methods of test were followed, the first two of which may be described as "step testing."

Method 1.—The specimen was heated gradually to the test temperature and a stress considered to be well below the tensile strength of the specimen was applied. After observing length changes for some predetermined time, the stress was increased. Length changes were observed again, whereupon another increment of stress was applied. This was repeated until rupture occurred. It was customary to increase the stress in increments of 1000 lb./in.² at about one-week intervals.

Method 2.—The original temperature and load conditions were essentially as described for Method 1. In this method, however, the load remained constant and the temperature was raised, usually in 100°F steps at about one-week intervals. In some cases, the specimen had not ruptured after prolonged holding at 1800°F. When this occurred in a furnace in which the temperature could not be raised safely above 1800°F, the test was continued by increasing the load in steps while maintaining the 1800°F temperature.

Method 3.—After holding the specimen at 1800°F under a stress of 4000 lb./in.² for 48 hr., stress was increased at the rate of about 1200 lb./in.²/min. to failure. The load was increased by flowing shot into a bucket.

Method 4.—The specimen was held at constant stress and constant temperature to failure, the purpose being to obtain curves of stress against rupture time which could be compared with similar curves for metal alloys.

In general, each combination of stress and temperature was maintained for about 160 hr., or one week. Conditions were then changed by an increment of either stress or temperature, until failure, for a total of 109 tests. Strengths in tension up to 18,000 lb./in.² at 1800°F, and 15,000 lb./in.² at 1900°F were observed. Above 1900°F, however, the strengths drop off rapidly to an average of about 5000 lb./in.² at 2000° to 2200°F.

Resistance to creep also decreases rapidly, for the particular porcelains tested, when temperatures are raised above the range 1800° to 1900°F. Results show that even the comparatively low stress of 6000 lb./in.² has caused more than a tenfold increase in the rate of creep at 2050°F compared to the rate at 1800°F,—and the porcelains on which these tests were made are the most resistant to creep of any investigated. Maximum observed creep rates, for all of the bodies tested, may be summarized as ranging from about 0.0001 to 0.0002 percent per hour at 1700°F for the range of stresses used; from 0.0002 to 0.0008 percent per hour at 1800°F and a stress of 16,000 lb./in.²; and from 0.0030 to 0.0040 percent per hour at 1900°F and 10,000 lb./in.² stress. The maximum stress at rupture for the four NBS ceramic bodies at various temperatures is given in Table I.

Data obtained from the Bureau's tests have revealed that some of the NBS oxide bodies are capable of effectively withstanding high temperature conditions far better than any other material now in use. In fact, an experimental gas turbine, using blades fabricated from the oxide body of the most promising strength and creep characteristics, has been operated successfully in the Cleveland Laboratory of the National Advisory Committee for Aeronautics.

PROGRAM

Proceedings of the Electron Microscope Society of America

Chairman: L. MARTON

THE annual meeting of the Electron Microscope Society of America was held at the National Bureau of Standards in Washington, D. C., October 6–8, 1949. Titles and abstracts of the papers presented are given below.

1. The Temperature of Electron Microscope Specimens. G. D. SCOTT AND FRANCES DAWES, *Department of Physics, University of Toronto, Toronto, Ontario.*—It is well known that with the high current densities of the illuminating beam obtainable with a self-biased gun, electron microscope specimens often undergo marked changes. Frequently these changes can be attributed to elevated temperatures. This paper is a discussion of the equilibrium between the energy absorbed by a particle from the electron beam and that which is either radiated to the walls of the surrounding chamber or conducted to the supporting substrate. For the case of an opaque particle on a Formvar film it can be shown that under possible conditions of contact between particle and film, conduction becomes negligible and hence the equilibrium temperature as determined by radiation alone can be 1000°C or more. As there is no mechanism by which the film can absorb any large fraction of the energy either directly from the beam or from the radiation emitted by the adjacent particle, the film itself remains at nearly ambient temperature. The high temperature gradients at the points of contact may, of course, cause instability and ultimately rupture of the film. The temperature conditions of electron microscope specimens are thus seen to be in marked contrast to those which can exist in macroscopic experiments.

2. Vibration Studies: Related to Electron Microscopy. F. A. HAMM AND F. C. SNOWDEN, *General Aniline and Film Corporation, Easton, Pennsylvania.*—This investigation has provided information which is useful as a convenient guide for properly locating the instrument and for high resolution electron microscopy where vibration is a problem. The scheme involves the measurement of an oscillographic trace whose amplitude is proportional to the voltage generated by a piezoelectric crystal pick-up. The essential steps in the calibration and a brief description of the circuit characteristics are given. Electron micrographs relating image shifts with mechanical displacements of the instrument are illustrated. At present these results are only semiquantitative.

3. Performance Tests on the RCA Model EMC Electron Microscope. S. G. ELLIS, *RCA Laboratories, Princeton, New Jersey.*—A standard EMC electron microscope was tested to find the factors which limited its performance. These factors were drifting of the specimen due to thermal motions of the specimen stage and objective lens asymmetry. When these had been reduced, the instrument demonstrated a resolution of approximately 50A. The resolution was now limited by the angular aperture of the illumination. Some of the techniques employed will be described.

4. On the Testing of Electron Microscope Objectives. JAMES HILLIER AND HENRY FROULA,* *RCA Laboratories, Princeton, New Jersey.*—A method of obtaining a quantitative evaluation of electron microscope objectives is described. The axial distance between the line foci produced by an asymmetrical objective is used as a measure of its asymmetries. Using a carefully compensated objective and a carbon black specimen (filmless mount), a photographic chart has been assembled showing the Fresnel fringes in images defocused by known amounts in the range $+100\mu$ to -100μ. These were obtained under standardized conditions of operating of the microscope. To test a lens a single micrograph of a similar specimen is taken near focus and under approximately the same conditions and an enlargement made at the same magnification as the chart. The fringes in the directions of maximum and minimum defocusing are then compared with those of the chart. In this way the amount of defocusing in the two directions can be accurately estimated. The difference between these values is the axial separation of the line foci for the lens tested. It is shown that a separation of $\frac{1}{2}\mu$ can be detected. Preliminary estimates indicate that separations of less than 1μ are necessary for the highest resolution. Lenses with separations greater than $10–15\mu$ are what would be generally considered as unsatisfactory.

* Permanent address: Department of Engineering, University of California, Los Angeles, California.

5. A Technique for the Comparison of Identical Surface Areas in the Light and Electron Microscopes. ERNEST F. FULLAM AND RUTH H. PETCHER, *Knolls Laboratory, General Electric Company, Schenectady, New York.*—To facilitate the interpretation of electron micrographs of surfaces, particularly metals, it is desirable to compare identical areas, at the same magnification, in the light and electron microscopes. The principle difficulty involved is in locating the identical area of the sample in each instrument. This has been done quite successfully by Bryner[1]; however, a simpler and more rapid technique would be more desirable. The proposed simplified technique consists of polishing and etching the metal sample in the usual way. Immediately following the etch an acute angle is scribed lightly on the surface, under the light microscope with a sharpened needle, enclosing or adjacent to the desired area. The needle is placed on the sample by an arm attached to the fine focusing mechanism from another microscope. This insures a very light contact with the metal to minimize the production of a cold-worked structure. The line width is three to ten microns. The angle is reproduced in a nitrocellulose replica cast on and stripped from the surface. This first replica is coated with a thin double film of beryllium and quartz. Quartz films alone do not have sufficient strength. A "Lektromesh" specimen screen with a four-mil hole drilled in its approximate center and polished is cemented to the replica with the apex of the angle visible in the center of the hole. The hole is necessary in order to locate quickly the angle in the electron microscope and to provide sufficient identifiable area adjacent to it for study without the interference of the screen wires. This placing operation is carried out under a dissecting microscope through which the angle in the replica is easily visible. After washing away the nitrocellulose replica by condensation of amyl acetate vapors on it, the remaining thin replica film over the drilled screen is ready for the microscope. Using the apex of the angle as a reference point, many areas adjacent to it may be easily recognized in both the light and electron microscopes even though the surface has no distinctive natural structure that may be readily identified.

[1] J. S. Bryner, "Correlation of optical and electron microscopy," Metals Tech. 15, No. 4 (June 1948).

6. A Centerable Condenser Aperture for the RCA Model "B" Electron Microscope. F. F. MOREHEAD, *American Viscose Corporation, Marcus Hook, Pennsylvania.*—A modification of the regular condenser aperture that may be centered while the instrument is in operation is described. (5 min.)

7. Permanent Magnet Lenses. JOHN H. REISNER, *RCA Victor Division, Radio Corporation of America, Camden, New Jersey.*—Permanent magnets have been successfully utilized to energize magnetic lens pole pieces for high resolution electron microscopy at direct magnifications of 7000 times with 30-kilovolt electrons, and 5000 times at 50 kilovolts. Stray magnetic fields which have previously limited high magnification and high resolution have been minimized by using two circuit gaps in parallel, and by surrounding the assembly with a magnetic shield connected to the external pole pieces of the two gaps. Magnetomotive forces of 1400 gilberts have been obtained. A single magnet or magnets in bucking arrangement, as well as configurations involving magnets disposed either radially or parallel to the optical axis of the lens, have been successfully utilized. The effects of various magnetic circuit parameters on the design and operation of the lens system have been studied.

8. Beam Deflection Focusing Device. HAROLD T. MERYMAN, *Naval Medical Research Institute, Bethesda, Maryland.*—A beam deflection device operating on an electromagnetic principle has been adapted to the RCA EMU electron microscope. Design and principle of the device will be discussed and its performance demonstrated with micrographs.

9. Motion Pictures of Electron Microscope Images. JOHN H. L. WATSON AND LUTHER E. PREUSS, *Edsel B. Ford Institute for Medical Research, Detroit 2, Michigan.*—The feasibility of taking motion pictures of electron microscope images has been considered on occasion, but the lack of informative, moving subjects has made the project impractical. Lately the technique has been developed as a tool for studying the effects of electron bombardment upon matter[1] and particularly upon tungsten oxide[2] and other tactoid structures. It may be used also to study reticulation of thin metal films under electron bombardment, contamination of microscope specimens due to the electron beam, and for observing the effects of bombardment upon biological and bacteriological specimens. The technique is described and several films are shown illustrating the results. It is found that intensity in the microscope is quite adequate and that contrast is good. Resolution is inferior to stills taken in the normal way, but images are interpreted from "moving micrographs," in conjunction with stills, somewhat more easily by virtue of (1) object movement which often gives a three-dimensional impression, (2) the control of the film which allows the reactions to be observed at a range of speeds and to be studied at close hand repeatedly, and (3) the increased number of single micrographs which are taken in a run and which, because of their number and the speed with which they are taken, are likely to contain more complete information than are a few isolated stills. (20 min.)

Papers on Sectioning

Chairman: T. F. ANDERSON

10. Improved Sectioning Technique for the Electron Microscope. RICHARD F. BAKER AND DANIEL C. PEASE, *School of Medicine, The University of Southern California, Los Angeles, California.*—Some refinements in a previously described technique[1,2] are described. These include a reliable method of flattening and mounting sections, also a standardized method of knife sharpening. A comparison of fixing agents has been made, using liver and nervous tissue, which indicates the superiority of osmic acid for general use. Perfusion is compared with fluid and vapor immersion as a means of introducing the fixative to the tissue. A discussion of resolving power limitations in thin section microscopy is given. (20 min.)

[1] D. C. Pease and R. F. Baker, Proc. Soc. Exper. Biol. and Med. 67, 470 (1948).
[2] R. F. Baker and D. C. Pease, J. App. Phys. 20, 480 (1949).

11. Ultra-Microtomy by a New Method. SANFORD B. NEWMAN, EMIL BORYSKO, AND MAX SWERDLOW, *National Bureau of Standards, Washington, D. C.*—Polymerization of *n*-butyl methacrylate monomer is used as a rapid and simple means for embedding fixed biological material. The solid resin provides an optically clear matrix for cutting very thin sections, one at a time, with a slightly modified conventional rotary microtome. Advance of the embedded specimen toward the knife is obtained from the thermal expansion of a brass specimen holder. These ultra-thin sections have uniform thickness, large area, and integrity of tissue structure. They are suitable for producing transmission images at the higher magnifications of the conventional light, phase-contrast, and electron microscopes. Metallic shadowing of the sections provides greater contrast as well as a three-dimensional aspect to the structural details of the tissue. (20 min.)

12. Electron Microscopy of Renal Morphology. JOHN J. KELSCH AND JOAN BARDET, *Interchemical Corporation, New York, New York.*—The high speed microtome, developed at Interchemical Corporation Research Laboratories, and described by Fullam, Gessler, Grey, Kelsch, and Schuster has been redesigned. The knife is set in a rotatable holder to facilitate the adjustment of the critical clearance angle, which must vary for different materials. The wheel is heavier, and is balanced at three points. The knife edge is at a 45 degree angle to the radius of the wheel to give a slicing action in contrast to the chopping action of the previous model. Cutting speed has been reduced to *ca.* 10,000 r.p.m., and feed speed reduced to 0.5 mm/min. Utilizing the improved high speed microtome, a study of the renal morphology of the mouse was undertaken. The structure of the renal tubules as seen in 0.1μ-sections in the electron microscope is demonstrated, and a series of sections through the cortex and medulla is shown.

13. Some Refinements of the Rotary Microtome Modified for Ultra-Thin Sectioning.* JAMES HILLIER, *RCA Laboratories, Princeton, New Jersey* AND MARK GETTNER, *Sloan-Kettering Institute, New York, New York.*—Using the reservoir described in the accompanying paper accidental distortions of the section by the blade are eliminated with the exception of uniform compression. This appears to be a function of the sharpness of the blade and the thickness of the section cut. Thus with a given blade the compression of each section, which can be easily observed through a low power microscope, provides a reliable indication of the thickness. By this means it has been possible to identify many sources of variations in the thickness of the sections. In the Spencer rotary microtome static friction in the horizontal ways is largely eliminated by the introduction of a 300-micron horizontal excursion of the specimen block during each cutting cycle. This motion must be reproduced to within 0.01 micron if sections of uniform thickness in the 0.05- to 0.1-micron range are to be cut. Static friction in the horizontal ways which has an opportunity to occur during two extremely short intervals in each cutting cycle and is one of the major causes of thickness variation has been reduced by a spring which supports most of the weight of the horizontal member. Variations in the thickness of the

lubricating film in the rear vertical way and on the advance plate constitute a second important source of thickness variations. A definite improvement in performance has been obtained by keeping the thickness of this film to a minimum and by running the mechanism more or less continuously for one-half to one hour before cutting. The third source of variations that has been identified includes vibrations originating in the rachet and other parts of the advance mechanism, from irregularities of hand operation and from accidental table and room vibrations. Laying a finger lightly on any part of the microtome will cause as much as a 0.05-micron variation. The addition of a motor drive has so improved the operation that the variation in 0.02-micron sections cannot be detected visually. It is presumed they are below 40A.

* This work was sponsored in part by the U. S. Navy under Contract N6-ori-99 Task Order I and in part by RCA Laboratories.

14. Serial Sections for Electron Micrography.* MARK GETTNER, *Sloan-Kettering Institute, New York, New York,* AND JAMES HILLIER, *RCA Laboratories, Princeton, New Jersey.*—When a rotary microtome is modified[1] to cut sections of thickness less than 0.2 micron, serial sections cannot be cut in the usual fashion. The extremely low rigidity of such thin sections is not sufficient to overcome the friction between section and the facet of the knife resulting in a rolling and folding of the section. In the present work this has been overcome by the use of a reservoir attached to the blade and filled with a liquid. The height and surface tension of the liquid are adjusted until the meniscus reaches just to the cutting edge. The block and the clearance facet of the blade are kept dry. With this arrangement the sections float as they are being cut, the trailing edge of each section holding to the edge of the blade until the leading edge of the succeeding section attaches itself to it and pushes it on. In this way a chain of sections already flattened, spread and in sequence is obtained floating on the surface of the liquid from which it can be lifted and mounted by any of the usual techniques. The only distortion of the sections observed in this technique is a uniform compression which occurs when sections of less than 0.05 micron are cut or when the blade is dull. The use of different liquids and cutting speeds will be discussed.

* This work was sponsored in part by the U. S. Navy under Contract N6-ori-99, Task Order I and in part by RCA Laboratories.

15. A Technique for the Preparation of Grease or Solid Samples Dispersed in Grease-Like Media for Examination with the Electron Microscope. A. Y. MOTTLAU, *Standard Oil Development Company, Linden, New Jersey.*—The nature of grease as a dispersion of solid particles in oil is briefly discussed, and the value of the electron microscope in studying this solid phase is pointed out. The requirements of a satisfactory grease specimen mounting technique are outlined and a new technique fulfilling these requirements is described. Electron micrographs are presented which demonstrate the usefulness of the technique in disclosing pertinent information on grease structure. The factors involved in the preparation of powder specimens for electron micrography are discussed in relation to the adoption of a modification of the grease mounting technique for this purpose. The modified technique for powders is outlined and illustrated with micrographs.

16. Replication of Frozen Liquids by Vacuum Evaporation. HAROLD T. MERYMAN, *Naval Medical Research Institute, Bethesda, Maryland.*—Silicon monoxide replicas of frozen liquids have been made with particular attention to water. The size and shape of single crystals of ice frozen at various speeds can be demonstrated. The ices have been studied by replication of the surface immediately following freezing, following evaporation from the surface, and of the interior of a fractured crystal. The method has been applied to replication of wet biological specimens and its advantages and limitations will be discussed.

17. Measurement of Cellulose Particle Length by the Electron Microscope. F. F. MOREHEAD, *American Viscose Corporation, Marcus Hook, Pennsylvania.*—The technique for preparing cellulose films from viscose thin enough to examine directly in the electron microscope is described. A difference in particle size on the two sides of cellulose film cast as described on glass is reported and an explanation offered. The average particle length when corrected proportionally to the "skin" and "core" of two types of viscose rayon is compared with the lengths obtained from the measurement of "crystallites" observed after acid hydrolysis plus ultrasonic disintegration. Good agreement is found when the latter are corrected for recrystallization during hydrolysis. The length of the crystalline and amorphous areas of a number of cellulose fibers are calculated from the lengths of the hydrolysis crystallites as measured by the electron microscope. From the calculated results the ratio of the crystalline and amorphous lengths and the number of crystalline plus amorphous lengths per chain is obtained. (15 min.)

18. Reproducibly Representative Specimen Fields in Electron Microscopy. ROBERT C. BACKUS AND ROBLEY C. WILLIAMS, *University of Michigan, Ann Arbor, Michigan.*—Representative specimen fields are highly desirable in electron microscopy whenever one attempts to do precise qualitative or quantitative work. Developments leading toward such fields have been made in the past, but they have not been extensive, nor has there apparently been any adequate appreciation of the unique usefulness of representative fields. The method of producing representative fields by spraying has been extensively developed, and its advantages investigated. The qualitative advantages are the short drying time of spray droplets and the establishment of ideal conditions for both a precise qualitative assay of a single specimen and for a comparison of two or more specimens. The primary quantitative advantage is that counts can be made of the number of specimen particles per unit volume of suspension, by the use of reference particles. The suspending medium should be wholly volatile, in order to realize these advantages, and a volatile, electrolyte-containing buffer has been developed and tested.

19. Determination of the Weight of the Bushy Stunt Virus Particle by Electron Microscopy. ROBLEY C. WILLIAMS AND ROBERT C. BACKUS, *University of Michigan, Ann Arbor, Michigan.*—A method has been developed for determining the weight of macromolecules by counting them directly in electron micrographs. This paper describes the method and the results for the case of the bushy stunt virus particle. The number of virus particles per unit volume of a suspension is determined by counting the virus particles mixed with a known concentration of reference particles, as they appear in representative fields formed by the method described in the preceding abstract. The dry weight of the virus particle in a known volume of the suspension is measured, and hence the weight of a known number of particles is ascertained. Simple division yields the weight of a single particle. In the case of a highly purified suspension of the bushy stunt virus this method has yielded a particle weight of $9.4 \pm 0.7 \times 10^6$.

20. Electron Metallography of Cast Irons. CHARLES H. GEROULD, *The Dow Chemical Company, Midland, Michigan.*—A preliminary report is given on the metallography of cast

irons with emphasis on the formation and distribution of graphite. Electron micrographs are shown comparing typical normal cast iron with malleabilized, magnesium-treated, magnesium-overtreated, and cerium-treated cast irons showing graphite distribution and its relation to properties. Polystyrene-SiO replicas have been used in this work after the etched metal surface has been cleaned by stripping collodion from the surface.

21. **Quantitative Metallography with the Electron Microscope.** ALFRED L. ELLIS AND F. K. IVERSON, *International Harvester Company, Chicago, Illinois.*—An investigation of the carbide particle size and distribution in five heats of annealed SAE 52100 steel revealed that between 50 and 75 percent of the carbide particles are smaller than 0.5 micron. Since carbide particles smaller than 0.5 micron are difficult to measure at magnifications normally used for lineal analysis (1000×), it was considered desirable to develop an accurate quantitative method using the electron microscope. The accuracy of the replica method was first checked by examining the same carbide particles in the light and electron microscopes. A method was then developed for determining the percentage of carbide from electron micrographs. A statistical analysis of this method revealed that ten plates of five exposures each are required for accuracy within ±0.5 percent of the mean with 95 percent probability. However, only two plates are required for accuracy within approximately ±1 percent of the mean with 65 percent probability. The method of sampling and the statistical data will be presented. The method was applied to determination of the percentage of carbide in heat-treated steels.

22. **Electron Metallography of Cemented Carbides.** W. L. GRUBE, *General Motors Corporation, Detroit, Michigan.*— In the evaluation of quality and in the correlation of metallurgical properties with the performance of cemented carbide tools various metallographic examinations are utilized. Light-microscopical examinations of this type of material furnish information concerning inherent porosity, bonding, grain size, and grain size distribution. Electron-microscopical examination of cemented carbides has extended the study of the above-listed properties and has also made possible a study of microstructure heretofore unresolved. The metallurgical properties of cemented carbides which have been studied by electron microscopy are: (1) differential etching of binder metal, tungsten carbide, and alloy carbide phases, (2) grain size (below two microns), (3) binder metal distribution, (4) segregation, (5) boundary phenomena between carbide grains, and (6) submicroscopic voids. The electron microstructure of specific samples of commercial carbide tools and its relationship to tool performance is discussed. The replica techniques used in the course of the examinations are also presented.

23. **Electron Diffraction Studies of Thin Iron and Chromium Films.** LELAND L. ANTES, *The University of Texas, Austin, Texas.*—The formation of air compounds on vacuum-deposited iron and chromium films at room temperature is discussed. When the thickness of the iron films is close to 10A, the conversion of the iron is nearly complete in a few minutes. The reaction of chromium with air is quite similar. The electrical resistance change of thin chromium films is discussed. The talk will be illustrated by slides.

24. **Electron Microscopy of Enamel and Dentin.** DAVID B. SCOTT AND RALPH W. G. WYCKOFF, *National Institutes of Health, Bethesda, Maryland.*—The fine structure of enamel and dentin has been studied through use of shadowed collodion replicas of etched ground sections of teeth. Of special interest are the fibrous components of the dentin, which include the thin-walled dentinal fibers and their branches, fibers apparently within the dentinal fibers, collagenous fibrils, and ultra-fine fibers in the matrix.

25. **Studies of the Action of Sodium Fluoride on Human Enamel by Electron Microscopy and Electron Diffraction.** DAVID B. SCOTT AND RALPH W. G. WYCKOFF, *National Institutes of Health, Bethesda, Maryland,* AND ROBERT G. PICARD, *RCA Victor Division, Camden, New Jersey.*—Slabs of enamel, cut parallel to tooth surfaces, were immersed in 2–4 percent NaF solutions for periods ranging from 4 min. to 30 days. Under the electron microscope an inhomogeneous apparently crystalline deposit was observed on replicas taken after 15–30 days; traces were seen after 2–7 days; under 2 days results were negative. Electron diffraction indicated that the deposit is CaF_2; the normal apatite pattern was replaced by that of CaF_2 after treatment as short as 3 min. When treated slabs were washed for prolonged periods in water the deposit was not seen microscopically, and the diffraction pattern reverted to that of the normal apatite. (15 min.)

26. **The Molecular Configuration in Seed Globulin Crystals.** C. E. HALL, *Massachusetts Institute of Technology, Cambridge, Massachusetts.*—A method for examining the surface structure of small protein crystals will be described. Micrographs have been obtained showing the molecular configuration at the surface of crystalline edestin and certain other seed globulins. It is concluded from the observations that the structure is face-centered cubic with $a = 114$A in the dry state. The edestin molecule appears as an approximately spherical particle about 80A in diameter. Small-angle x-ray powder patterns made by Dr. R. S. Bear show spacings consistent with the conclusions drawn from the electron microscope analysis.

31. Electron Microscope Study of Isolated Nuclei of Liver Cells from Laboratory Animals. JUAN J. ANGULO, *University of Havana, School of Medicine, Havana, Cuba,* AND JOHN H. L. WATSON,* *Edsel B. Ford Institute for Medical Research, Detroit 2, Michigan.*—Nuclei of liver cells from the Rhesus monkey, guinea pig, rat, mouse and the 16-day chick embryo were isolated by fractional centrifugation and examined without chemical fixation in the electron microscope. Structural details are seen and the identity with nucleoli of certain dense zones in the images is discussed. A relationship is noted between the number of these zones and animal species. Some zones show images which suggest the existence of a nucleolus wall but no evidence is found for the existence of a nucleolus membrane. The absence of a chemical fixation does not distort the nucleus structure and electron microscopy of unfixed, isolated nuclei seems to be superior in some ways to other techniques for electron microscope study of the nucleus.

* To give the paper.

32. An Electron Microscope Study of an Undescribed Orchid Virus. NELSON NEWTON AND DAVID W. ROSBERG, *Battelle Memorial Institute, Columbus, Ohio.*—In connection with phytopathological research on a heretofore unreported virus which produces mottled streak symptoms in orchid plants, electron microscope studies of both diseased and healthy plants have been made. Host range studies have shown the orchid to be the only plant capable of being infected with the virus. Purified and concentrated extracts from raw plant juice were prepared by alternate low (6460 g) and high (19,942 g) speed centrifugation. The material was finally suspended in a 0.05 M phosphate buffer at *p*H 7. Electron microscope examinations of platinum-shadowed specimens prepared from diseased and apparently healthy plants showed both crooked and straight rod-shaped particles present in the diseased material as well as in some of the apparently healthy extracts. Extracts from other apparently healthy plants were free of these rod-shaped particles. The straight rods were approximately 300×24 mμ, while the crooked rods were 400×21 mμ. This suggests that either two viruses or two different phases of the same virus were present. Buffer suspensions of the rod-shaped particles are opalescent and exhibit pronounced Tyndall cone phenomena. When examined with the polarizing microscope, intense streaming birefringence has been observed, comparable to that exhibited by tobacco mosaic virus.

33. Destruction of Bacterial Viruses by Osmotic Shock.* THOMAS F. ANDERSON, *Johnson Foundation, University of Pennsylvania, Philadelphia 4, Pennsylvania.*—The similar viruses, T2, T4, and T6 which appear in the electron microscope to have membranes surrounding the internal structures of the heads can be disintegrated by what might be termed "osmotic shock." If these viruses are incubated with 4M NaCl and the suspension then rapidly diluted with water, the viruses are inactivated, while little inactivation occurs if the suspensions are gradually brought to lower solute concentrations. Electron micrographs of slowly diluted preparations reveal normal virus particles, while micrographs of the former, rapidly diluted preparations reveal virus "ghosts"—empty head membranes with tails attached. Similar destruction of these viruses follows rapid dilution from solutions of ethylene glycol, glycine, glycerol, glucose, or sucrose. These results are compatible with the view that the membranes of the even-numbered viruses, like those of cells, are somewhat permeable to these solutes, but much more permeable to water molecules. Presumably, the virus heads swell when the osmotic pressure is suddenly reduced, and actually burst if the reduction is sufficiently large and sudden. Osmotic shocks which inactivate the even-numbered viruses have no detectible effect on the small viruses T1, T3, and T7 which appear in the electron microscope not to have membranes.

* This work was supported by Contract N6-ori-168 T.O. II between the ONR and the Trustees of the University of Pennsylvania.

34. "Crystalline" Virus-Like Bodies from Human Skin Papillomas. JOSEPH L. MELNICK, MAURICE J. STRAUSS, HENRY BUNTING, AND ERNEST SHAW, *Yale University School of Medicine, New Haven, Connecticut.*—Certain skin papillomas have been shown to be characterized by the presence of intranuclear inclusion bodies. Immediately following removal from patients, such papillomas were fractionated by differential centrifugation and examined in the electron microscope. As control samples, common warts, molluscum contagiosum lesions, and normal skin were studied. From the intranuclear inclusion body papillomas, spherical bodies were readily obtained. These were characterized by their arrangement into crystalline-like clusters or layers in which the average particle diameter was 52 mμ. When these particles were not in crystalline array, they averaged 68 mμ in diameter. In the electron microscope the crystalline arrangement was not unlike that previously noted for certain of the plant viruses. Control preparations of molluscum contagiosum lesions revealed characteristic brick-shaped elementary bodies. The common wart and normal skin preparations revealed no uniform particles, but merely amorphous scattered clumps of matter, collagen fibers, and spherical particles of varying diameter.

35. Plant Virus Growth Curves as Determined by Use of the Electron Microscope. RUSSELL L. STEERE, *University of Michigan Ann Arbor, Michigan.*—Using uniform Dow latex polystyrene particles and applying the spray technique developed by Backus and Williams, we have been able to follow the increase in extractable virus content of plants following inoculation. The procedure involves clarification and dilution of the plant juices, addition of a constant amount of latex and thorough mixing, taking the electron micrographs, and obtaining the ratio of virus particles to latex particles in numerous drop patterns. This procedure is followed for each sample throughout the early development of the virus in the plant host. A comparison of the virus-latex ratio throughout the period results in what might be called a virus growth curve.

36. The Multiplication of Insect Viruses as Organisms. G. H. BERGOLD, *Laboratory of Insect Pathology, Sault Ste. Marie, Ontario.*—Electron micrographs of purified preparations of four different insect viruses indicate the presence of morphologically different forms, which are probably stages of multiplication. The virus first appears as a minute spherical body. This body increases in size and the virus appears as an elongated curved body surrounded by a membrane. Later the virus particle straightens out, ruptures the membrane and appears as a rod-shaped particle characteristic of insect viruses. One may assume that the rod-shaped virus particle contains several smaller sub-units each of which develops into a rod. The complicated nature of multiplication indicates that insect viruses are organisms with a relatively simple morphological structure of the mature rod.

37. The Electron Microscopy of Bacteriophage. RALPH W. G. WYCKOFF, *National Institutes of Health, Bethesda, Maryland.*—Several strains of the bacteriophages against colon bacilli have been under investigation to find out as much as possible about the mechanisms of their growth and multiplication. The electron microscopic results already obtained, to

be illustrated by a series of slides, show how these virus particles attack and destroy susceptible bacteria and make clear many steps in the process whereby they increase at the expense of these bacterial hosts. Reference is made to still incompletely understood aspects of bacteriophage proliferation, and to the bearing of these results on the more general problem of how viruses and other biological particles of macromolecular dimensions are produced in nature. (20 min.)

38. The Adaptation of Cytological Technique to Electron Microscopy. STUART MUDD AND ANDREW G. SMITH, *Medical School, University of Pennsylvania, Philadelphia, Pennsylvania.*—A limiting factor in the electron microscopic study of internal structures such as the nucleus in microbiological specimens has been inadequate contrast. Certain light cytological methods provide contrast but the light microscope has inadequate resolving power for dealing with the structure of the nucleus of bacteria. In the present study techniques of light cytology have been adapted to electron microscopy. The effect on contrast in the electron microscope of each step of the cytological processing has been determined. Technical details and the picture of the bacterial nucleus resulting will be presented.

39. The Effect of Certain Fixatives, Salts and Enzymes on Bacterial Cells with Respect to Chromatinic Structure and Contrast in Electron Microscopy. JON JONSEN AND ANDREW G. SMITH, *Medical School, University of Pennsylvania, Philadelphia, Pennsylvania.*—Bacterial cells which have been suitably fixed, treated with hydrochloric acid and stained show what has been referred to as chromatinic structure of a nuclear apparatus. Similar structures are produced after treatment with ribonuclease. In the present study the same structures were obtained with different salts on air-dried bacteria and bacteria fixed in Chabaud's fixative. Electron micrographs of similarly treated specimens will be shown and the results discussed together with a possible explanation of the salt effect. In addition, bacterial cells treated with osmium tetroxide vapor, Schaudinn's fixative, hydrochloric acid, desoxyribonuclease and trypsin will be presented.

40. A Fibrous Component of the Nerve Axon. FRANCIS O. SCHMITT, *Massachusetts Institute of Technology, Cambridge, Massachusetts.*—In a re-examination of the origin of the dense-edged fibrils (neurotubules) previously described by De-Robertis and Schmitt a study was made of giant fibers of the squid and the marine annelid, *Myxicola infundibulum.* Axons were isolated from the sheaths of formalin-fixed fibers and fragmented with a microblendor. Neurotubules were observed in the sheath of squid nerves from which the axoplasm had been removed before or after fixation; they were observed only occasionally in axon material (sheath contamination?). However, in some preparations no neurotubules could be found. More information is needed before the origin and composition of neurotubules can be stated conclusively. The most prominent feature of formalin-fixed axons is a fibrous component consisting of a reticulum of nodose fibrils 200–400A in width and of indefinite length. The nodes sometimes appear to be regularly spaced though a definitive periodicity has not been demonstrated. Squid axoplasm, extruded from freshly dissected fibers into water, disperses slowly, yielding fibrous structures ranging from relatively thick, rod-like bundles to very thin filaments. This fibrous protein, which may be concentrated by centrifuging at 10,000 g, is probably the chief fibrous component of the axon; its chemical properties are being studied. Even after brief blending, which fragments the fibrous bundles, diluted axoplasm yields nodose fibrils, after formalinization, which resemble closely those obtained from axons isolated from formalin-fixed fibers. The bearing of these results on the structure of the fresh axon will be discussed.

41. Morphologic Characteristics of the Oral Fusiform Bacilli as Revealed by the Electron Microscope. EDWARD G. HAMPP, DAVID B. SCOTT, AND RALPH W. G. WYCKOFF, *National Institutes of Health, Bethesda, Maryland.*—Pure cultures of seven strains of oral fusiform bacilli have been used. Shadowed preparations have been made from cultures of each strain at ages varying from 24 hours to 20 weeks. The morphologic characteristics of the organisms and the changes which occur with age have been studied.

Chairman: R. C. WILLIAMS

42. Use of Polystyrene Latex 580 G, Lot 3584 in Electron Microscopy. CHARLES H. GEROULD, *The Dow Chemical Company, Midland, Michigan.*—A review is presented of size determinations on this latex from 16 different laboratories, 12 of which show an average size of 2593A±40A. The four other determinations range upward to 3200A. Data are presented concerning latex dilution which indicates that particle diameter is not appreciably influenced by degree of dilution, size of drop added to specimen, drying speed, etc. Precautions in handling the latex are reviewed, including freezing, the danger of water evaporation from the undiluted latex, chemical and bacterial contamination, change of pH, over-heating in the electron beam, fusing due to insufficient dilution and contamination under electron bombardment. Electron micrographs are included which illustrate several of these dangers.

43. Particle Size and Density of Dow Latex 580 G—Measurements with the Ultracentrifuge. D. GORDON SHARP, *Duke University, Durham, North Carolina.*—Sedimentation velocity studies of the particles of Dow Latex 580 G suspended in physiological saline solution (0.9 percent NaCl) have been made in order that they may be used as a standard reference material in virus work. They sediment as a monodisperse system; less than 1 percent of the material differs ±2 percent from the mean sedimentation rate. The sedimentation constant is $S_{w20}^{\circ} = 1960 \times 10^{-13}$ sec.$^{-1}$ extrapolated to infinite dilution. Particle density was measured by observing sedimentation rate in media whose density was increased by addition of D_2O and of bovine serum albumin. Although some boundary instability was encountered near the point of zero sedimentation the particle density is estimated to be 1.054±.001, the same result being given by both albumin and D_2O indicating little or no hydration of the latex particles. This is in sharp contrast to the behavior of the heavily hydrated influenza virus, for example. From these data it is calculated that the particle size of Dow Latex 580 G is 252±2.5 mμ. It is therefore useful as a standard of size in electron microscopy and of sedimentation constant in the ultracentrifuge. It may also be used with the latter instrument to measure viscosity of samples too small to be measured otherwise.

44. The Apparent Size of Small Semi-Opaque Objects. RAYMOND A. KERN AND S. F. KERN, *Lilly Research Laboratories, Indianapolis, Indiana.*—It will be shown that the apparent size of small semi-opaque objects is a function of the conditions under which they are observed. Slides will be shown, demonstrating the apparent size differences of Dow's polystyrene balls 580 G, Lot 3584, as well as other small objects such as bacteriophage. A tentative explanation will be offered for these observed size variations.

45. A Removable Intermediate Lens for the RCA Model EMU. JAMES HILLIER, *RCA Laboratories, Princeton, New Jersey.*—An intermediate lens which can be introduced into the RCA Model EMU electron microscope without modifica-

tion of the column and with only a slight change in the electrical circuits is described. When used in conjunction with the highest power projection lens pole pieces, the new lens provides a full field at ten magnifications in the range 900 to 24,000. In addition, the new lens preserves the easy accessibility of the pole pieces for cleaning and adjustment. The distortion is less than with the single lens for all magnifications except the maximum and is very nearly zero for the lower magnifications. One value of the magnification is essentially independent of the accelerating potential and hence provides the possibility of achieving a permanent magnification calibration.

46. An Optical Method for the Thickness of Thin Films. G. D. SCOTT, *Department of Physics, University of Toronto, Toronto, Ontario.*—Tolansky* has discussed a method of measuring film thickness by multiple beam intereference using fringes of equal chromatic order in reflection. This method has proved very satisfactory for the accurate thickness determinations of films, evaporated metals and others, which are used in electron microscopy. The equipment consists essentially of a white light source and a spectroscope with calibrated wave-length scale. The preparation of the interference plates and the experimental arrangement will be discussed in detail. It has been found that ordinary microscope slides are superior to optically ground flats for the interference plates and their use makes it possible to reduce the fringe order to as low as *one* or *two*. The ease of observation and the accuracy of the measurements are thereby increased. The method can be applied to all types of stable films in thickness from 10A to several microns with areas of film less than one square mm. The measurements give the average metric thickness of the film and an accuracy of within ±5A is readily obtained.

* S. Tolansky, *Multiple Beam Interferometry* (Clarendon Press, New York, 1948).

47. A Technique for Studying the Electron Microstructure of Steel. D. M. TEAGUE AND L. H. ZIMMERMANN, *Chrysler Corporation, Detroit, Michigan.*—A brief history will be presented of the formation of the "Joint Committee on Electron Microstructure of Steel." The aims and scope of this group will be reviewed, together with sample and replica preparation methods. The second portion of the paper will be a discussion of a modified Formvar technique developed in our laboratories for studying the microstructure of steel. The salient features of the procedure are: (1) Deep etching of metal surface. This provides a strong Formvar film with good contrast. (2) Use of a soap monolayer on the metal surface to facilitate stripping. (3) Shadowing at a high angle—approximately 45°. This step improves detail, yet avoids certain difficulties of interpretation. The resultant electron micrographs correlate more readily with the experience of the metallurgist who will utilize the results. (15 min.)

48. Recent Advances in Electron-Microscopical Resinography. M. C. BOTTY, T. G. ROCHOW, AND F. G. ROWE, *Research Laboratories, American Cyanamid Company, Stamford, Connecticut.*—The general resinographic method of manifesting the electron-microscopical structure inside any solidified resin by replicating its fracture-surface was recently described.[1] The present paper will stress the description of the electronmicroscopical techniques and will exhibit micrographs of the *macromolecules* of single and composite resins as well as incorporations of pigments, fillers, and other modifiers.

[1] Anal. Chem. 21, 461-466 (1949).

49. Continuous Observations on the Formation of Metallic Films in the Electron Microscope. R. S. SENNETT AND T. A. MCLAUCHLAN, *University of Toronto, Toronto, Ontario.*—A number of different metals, including silver, gold, cadmium, and zinc, have been evaporated in a special specimen holder designed for the RCA type EMU instrument. Continuous observations have been made on the films during their formation, and micrographs of the same area have been obtained at a number of different stages during the evaporation. In all cases the first indication of a film was the appearance of a number of nuclei, and additional evaporation only increased the size of these aggregates without increasing their number. In zinc and cadmium films, the nuclei which first appeared had a regular crystalline form which was usually distorted during subsequent growth.

A Note on Collapsing Cylindrical Shells

THEODORE E. STERNE
Ballistic Research Laboratories, Aberdeen Proving Ground, Maryland
(Received May 23, 1949)

Expressions are obtained for the instantaneous dependence of pressure upon radius within a collapsing cylindrical shell of incompressible liquid when subjected to (a) neither external nor internal pressure or to (b) an external pressure but no internal pressure. Dynamical considerations suggest that very high pressures and radial velocities should be reached.

I.

DYNAMICAL considerations suggest that if an undisturbed cylindrical shell of liquid contracts radially, the velocity of the outer surface should tend to diminish and of the inner surface to increase, and that very high velocities and pressures should be reached. The author thinks that the collapse of a cylindrical liquid shell may bear some relation to details of the behavior of cylindrical and possibly of conical metal shells, caused to collapse by the detonation of external charges of high explosive. The collapse of such shells has already been considered, hydrodynamically, by Birkhoff, MacDougall, Pugh, and Taylor[1] without regard to such details as the instantaneous dependence of pressure upon radial coordinate.

II.

It is felt that the following brief treatment, which has been discussed with Professor Garrett Birkhoff, of an ideal case in which the liquid is incompressible and the collapse radial, without axial motion, may be of sufficient interest to merit a somewhat wider distribution and that it may also perhaps be regarded as a first step toward a detailed theoretical study of the collapse of a metal shell surrounded by an explosive charge.

III.

Consider a long liquid cylindrical shell with external and internal radii r_2 and r_3, respectively, and mass m per unit length. The quantity $r_0^2=r_2^2-r_3^2$ will be conserved as the cylinder contracts if, as is supposed, the motion is radial and the liquid incompressible. Let r_2/r_0 be denoted by x. Then the kinetic energy per unit length is

$$T=(m/2)r_0^2x^2\dot{x}^2\log[x^2/(x^2-1)],$$

and this is conserved if the shell is set contracting radially and left undisturbed. Any element of matter in the shell can be labeled by a Lagrange hydrodynamical coordinate μ defined as the mass, per unit of length, contained between the outside of the shell and a coaxial cylinder through the element. The velocity of any element of matter characterized by a particular value of μ is

$$\frac{\partial}{\partial t}r(\mu,t)=-\left(\frac{2T}{m}\right)^{\frac{1}{2}}\frac{1}{[\log^{\frac{1}{2}}x^2/(x^2-1)][x^2-\mu/m]^{\frac{1}{2}}}.$$

It can be seen from the preceding equation that the velocity of the internal surface approaches infinity as x approaches unity, and that the velocity of every other element of matter in the shell approaches zero as x approaches unity. It follows that during the undisturbed radial contraction of a cylindrical shell, the kinetic energy per unit mass tends to be more and more strongly concentrated toward the center as the contraction proceeds.

IV.

It may readily be shown that the pressure, zero at the outer and inner surfaces, has a maximum at

$$\mu/m=x^2-x^2(x^2-1)\log x^2/(x^2-1).$$

[1] Birkhoff, MacDougall, Pugh, and Taylor, J. App. Phys. 19, 563 (1948).

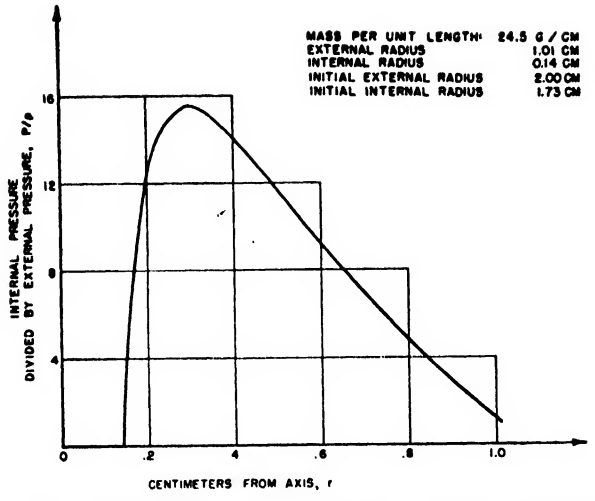

FIG. 1. The distribution of pressure in a radially contracting cylindrical shell of liquid, subjected to pressure over its outer surface.

The maximum pressure occurs at a place about midway between the surfaces when the shell is large, but moves toward the inner surface as the shell contracts. When the external and internal pressures are zero, the pressure is given generally throughout the cylindrical shell by the equation

$$P=\frac{1}{2\pi}\int_0^{\mu}\frac{1}{r}\frac{\partial^2 r}{\partial t^2}d\mu,$$

and has the value

$$P=\frac{T}{\pi r_0^2}\frac{1}{x^2(x^2-1)\log^2 x^2/(x^2-1)}\times\left[\log\frac{x^2}{x^2-\mu/m}-\frac{\mu}{m}\frac{x^2-1}{x^2-\mu/m}\log\frac{x^2}{x^2-1}\right].$$

Enormous pressures can be reached.

V.

If a constant pressure p is exerted on the external surface of the cylindrical shell, initially at rest, and zero pressure on the internal surface, then the resulting velocities and pressures can be calculated. The radial velocity of an element of matter in the shell is given by

$$\frac{\partial}{\partial t}r(\mu,t)=-\left(\frac{2\pi p}{m}\right)^{\frac{1}{2}}r_0\frac{(x_0^2-x^2)^{\frac{1}{2}}}{[\log x^2/(x^2-1)][x^2-\mu/m]^{\frac{1}{2}}},$$

where x_0 is the initial value of x, and the pressure in the shell is given by

$$P=p\left[1-\frac{\log x^2/(x^2-\mu/m)}{\log x^2/(x^2-1)}+\frac{x_0^2-x^2}{x^2(x^2-1)}\frac{\log x^2/(x^2-\mu/m)}{\log^2 x^2/(x^2-1)}-\frac{\mu}{m}\frac{x_0^2-x^2}{x^2(x^2-\mu/m)\log x^2/(x^2-1)}\right]$$

which has a maximum at

$$\frac{\mu}{m}=x^2-\frac{x^2(x^2-1)(x_0^2-x^2)\log x^2/(x^2-1)}{x_0^2-x^2-x^2(x^2-1)\log x^2/(x^2-1)}.$$

VI.

As an example of the application of the preceding general results, the following calculation may be of interest. If $p=10^{11}$ dynes/cm^2, if the initial value of the external radius r_2 is 2 cm, if r_0 is 1 cm, and if the liquid shell has the density of steel so that m is 24.5 g, then when $x=1.01$ the maximum pressure is at a value μ/m of 0.937 and is 15.6×10^{11} dynes/cm^2, which is sixteen times greater than the external pressure. The maximum velocity is then approximately 9.84×10^5 cm per sec., and is of course at the inner surface. In the preceding example the initial value of the internal radius is 1.73 cm and at the stage of contraction considered the external and internal radii are respectively 1.01 cm and 0.14 cm. The pressure is a maximum at 0.29 cm from the axis.

VII.

It seems intuitively plausible that the compressibility of any real liquid would probably cause the velocities and pressures to be less than they would be in an incompressible liquid. The elastic and plastic properties of a metallic shell would involve further departures from the ideal case of an incompressible liquid. The author is now unable to predict the magnitude of such departures. The magnitude may be limited, however, in cases of axially progressive collapse of the type considered by Birkhoff, MacDougall, Pugh, and Taylor.[1]

Steady-State Internal Temperature Rise in Magnet Coil Windings

CLAUDE L. EMMERICH*
Applied Science Research Laboratory, University of Cincinnati, Cincinnati, Ohio
(Received May 16, 1949)

The temperature distribution in an electric coil winding is determined by solving the differential equations which apply to the system approximately. The maximum and average temperature rises are given for several types of windings. A distinction is made between small and large temperature rise; the treatment of the former neglects local changes in resistivity and thermal conductivity caused by the increase in temperature. A correction factor is computed to obtain the actual temperature rise from the much simpler calculations for the maximum temperature rise which would occur if the resistance were independent of temperature. It is found that non-uniform windings, wound of several different wire sizes to minimize the resistance, exhibit the same temperature rise characteristics as conventional uniform windings of zero curvature.

INTRODUCTION

THE differential equation which applies to the steady-state temperature distribution in a magnet coil winding is Poisson's equation:

$$\nabla^2 T = -Q/K, \tag{1}$$

where T is the temperature at any point in the winding, Q is the rate with which heat is generated per unit volume per unit time, and K is the heat conducted per unit area per unit time per unit temperature gradient. The symbol ∇^2 denotes the Laplacian differential operator. In Cartesian coordinates, Eq. (1) would read

$$\frac{\partial^2 T}{\partial x^2}+\frac{\partial^2 T}{\partial y^2}+\frac{\partial^2 T}{\partial z^2}=-\frac{Q}{K}.$$

A coil winding is a heterogeneous structure, including metallic wire, surrounded by an insulating coating, and separated by insulating spaces. The term "insulating" refers qualitatively to both thermal and electrical properties. Thus, Eq. (1) as applied to magnet coils must represent a very complex system. However, for practical applications, it is sufficiently accurate to assume that the winding is a homogeneous body, with definite values of Q and K, averaged over the local discontinuities.

For a winding wound of one wire size, the value of Q is determined from the equation

$$Q=\rho A^2/(fL^2h^2), \tag{2}$$

where ρ = resistivity of the metal in the wire, ohm-inch; A = number of ampere-turns; f = space factor (cross-section area of metal divided by area of the winding Lh); L = length of winding, inch; h = thickness of winding, inch, $=b-a$ (see Fig. 1).

The value of K is not easy to predict from the physical constants of the coil. Moore[1] has made a theoretical investigation related to the problem of determining K; however, it appears that the theory has not yet been developed to give values of K more easily and accurately than experimental methods. Since K is an average of the thermal conductivities of the materials in the coil, it will be constant or variable according to the thermal characteristics of the wire and of the insulating materials of which the coil is composed. If the internal temperature rise in the winding is small, K may be assumed constant; and Q will also be nearly constant because the resistivity of the wire is not changed very much by a small change in the temperature.

Thus the solution of Eq. (1) is simplified considerably in the range of small temperature rises.

SMALL TEMPERATURE RISE

In particular, the small temperature rise conditions will be applied to a winding in the shape of a hollow cylinder (Fig. 1). If the winding is thin in comparison with its inside and outside diameters and its length, the curvature of the turns may be neglected, and the flow of heat may be assumed in the radial direction only, satisfying approximately the ordinary differential equation

$$(d^2T')/(dx^2)=-Q/K, \tag{3}$$

where x is the radial distance from the center line of the winding to the point whose temperature is T'. This equation will apply also approximately to a winding on a rectangular core.

Two sets of boundary conditions will be adopted as representing actual operating conditions of long magnet coil windings: (a) Core thermally insulated, outside surface at a fixed temperature T_s and (b) both core surface and outside surface at the same fixed temperature T_s.

These boundary conditions have been chosen in the interest of simplicity. It is evident that an actual coil does not operate under such conditions; however, to obtain a first approximation, some ideal cases should be considered. The deviations for actual coils may be judged from work reported in the literature.[2-4]

Using boundary conditions (a) in the solution of Eq. (3), the temperature distribution in the winding is found to be

$$\Theta'(x)=T'(x)-T_s=(Q/2K)(b^2+2ax-x^2-2ab), \quad (4)$$

where Θ' is defined as the temperature rise above the surface temperature T_s. The maximum temperature rise in the winding will occur at the inside surface ($x=a$), where

$$\Theta_m'=\rho A^2/(2fKL^2). \quad (5)$$

Equation (5) is plotted in terms of the dimensionless variable $2fKL^2\Theta'/\rho A^2=1$ in Fig. 2.

A useful criterion of internal temperature rise is the average temperature rise, obtained from a measurement of the increase in total resistance of the winding. The average temperature is defined as the temperature to which the entire coil would have to be raised in order

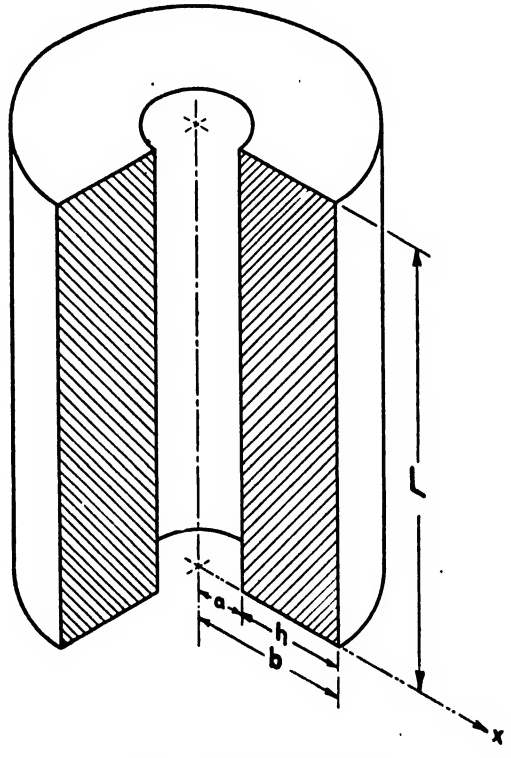

FIG. 1. Cylindrical winding.

to have the same increase in resistance as it actually has in the temperature field created by the heat generated in the winding. Expressed analytically, the average temperature rise is given by the equation

$$\Theta_{Av}=\left(\int\Theta dR\right)\Big/\left(\int dR\right), \quad (6)$$

where dR is the resistance of an elemental section of the winding whose temperature rise is Θ.

The temperature distribution as a function of the radius given by Eq. (4), together with the known distribution of resistance as a function of x, permits evaluation of the average temperature rise; which is found to be, for a winding with boundary conditions (a),

$$\Theta_{Av}'=\rho A^2/(3fKL^2). \quad (7)$$

This is plotted in Fig. 2 as $2fKL^2\Theta'/\rho A^2=\frac{2}{3}$.

For practical purposes it should be noted that the average and maximum temperature rises are in the ratio 2:3 for the thin cylindrical winding and small temperature rise.[5]

If boundary conditions (b) are applied to Eq. (3), the temperature distribution takes the form

$$\Theta'(x)=(Q/2K)(ax+bx-x^2-ab). \quad (8)$$

The maximum temperature rise will be the temperature rise at the center of the coil, where

$$\Theta_m'=\rho A^2/(8fKL^2). \quad (9)$$

In Fig. 2 this is plotted as $2fKL^2\Theta'/\rho A^2=\frac{1}{4}$.

The average temperature rise of the winding with boundary conditions (b) is

$$\Theta_{Av}'=\rho A^2/(12fKL^2) \quad (10)$$

plotted as $2fKL^2\Theta'/\rho A^2=\frac{1}{6}$ in Fig. 2.

For a thick, long, cylindrical winding, the assumption of negligible curvature, which led to the simple Eq. (3), cannot be applied. For this case, Poisson's Eq. (1) reduces to the ordinary differential equation

$$\frac{d^2T'}{dx^2}+\frac{1}{x}\frac{dT'}{dx}=-\frac{Q}{K}, \quad (11)$$

where x again denotes the radius of the point of temperature T'.

With boundary conditions (a), the temperature rise as a function of the radius is given by the expression

$$\Theta'(x)=(Q/4K)[b^2-x^2-2a^2\log_e(b/x)]. \quad (12)$$

The maximum temperature rise will occur at the inside of the winding, where

$$\Theta_m'=\frac{\rho A^2}{2fKL^2}\cdot\frac{r^2-1-2\log_e r}{2(r-1)^2}. \quad (13)$$

In this expression, $r=b/a$ is the thickness ratio of the winding, defined as the fraction outside radius divided by inside radius. Equation (13) will be found to represent actual conditions more accurately than the equation given for this case by Moore.†

Equation (13) may be represented by the following

[5] M. Jakob, Trans. A.S.M.E. 65, 593 (1943). Also M. Jakob and G. A. Hawkins, *Elements of Heat Transfer and Insulation* (John Wiley and Sons, Inc., New York, 1942), Chapter V.

† See reference 1, p. 98.

series expansion

$$\Theta_m' = \frac{\rho A^2}{2fKL^2}\left[\frac{(r+1)^2}{2(r^2+1)} - \frac{1}{3}(r-1)\left(\frac{r+1}{r^2+1}\right)^3 - \frac{1}{5}(r-1)^3\left(\frac{r+1}{r^2+1}\right)^5 - \cdots\right]. \quad (14)$$

The relation between $2fKL^2\Theta'/\rho A^2$ and r, as given by Eq. (13) is shown in Fig. 2 by the curve marked "Θ_m' uniform (a)." It is evident from this curve, as well as from the expansion (14), that for a thickness ratio of one, the special case of the thin winding is obtained. The other extreme, representing a winding in the shape of a solid cylinder, is seen to be approached as the thickness ratio becomes greater. For $r \to \infty$, Eqs. (13) and (14) reduce to the value

$$\Theta_m' = \tfrac{1}{2}\rho A^2/(2fKL^2). \quad (15)$$

which is just one-half of the expression for the maximum temperature rise of the thin winding [Eq. (5)]. It is indicated at the right edge of Fig. 2.

The average rise for the thick hollow cylinder with boundary conditions (a) can be determined from the temperature distribution $\Theta'(x)$ [Eq. (12)], and from the fact that the resistance of an elemental section of the hollow cylinder is proportional to the expression xdx. The average temperature rise is thus found to be

$$\Theta_{Av}' = \frac{\rho A^2}{2fKL^2}\cdot\frac{r^2-3+[4/(r^2-1)]\log_e r}{4(r-1)^2}. \quad (16)$$

Figure 2 shows this curve, marked "Θ_{Av}' uniform (a)."

The expansion of Eq. (16) is given by the following series

$$\Theta_{Av}' = \frac{\rho A^2}{2fKL^2}\cdot\frac{(r+1)^2}{(r^2+1)}\left[\frac{1}{4} + \frac{1}{3(r^2+1)^2} + \frac{(r^2-1)^2}{5(r^2+1)^4} + \cdots\right]. \quad (17)$$

If boundary conditions (b) are applied to the thick, long, hollow cylindrical winding [Eq. (11)], the temperature rise distribution will be found to be

$$\Theta'(x) = \frac{Q}{4K}\left(b^2 - x^2 - \frac{b^2-a^2}{\log_e(b/a)}\log_e\frac{b}{x}\right). \quad (18)$$

The radius x_m of the surface at which the maximum temperature rise occurs is found from the equation

$$x_m^2 = (b^2-a^2)/[2\log_e(b/a)].$$

The temperature rise at that surface will be

$$\Theta_m' = \frac{\rho A^2}{8fKL^2}\left\{\frac{2r^2}{(r-1)^2} - \frac{r+1}{(r-1)\log_e r}\left[1+\log_e\frac{2r^2\log_e r}{r^2-1}\right]\right\} \quad (19)$$

which is plotted in Fig. 2 as the curve marked "Θ_m' uniform (b)."

The average temperature rise with boundary conditions (b) is given by the equation

$$\Theta_{Av}' = \frac{\rho A^2}{2fKL^2}\cdot\frac{r^2+1-[(r^2-1)/\log_e r]}{4(r-1)^2} \quad (20)$$

shown in Fig. 2 by the curved marked "Θ_{Av}' uniform (b)."

In a non-uniform winding designed for minimum resistance,[6] the wire diameter varies as the square root

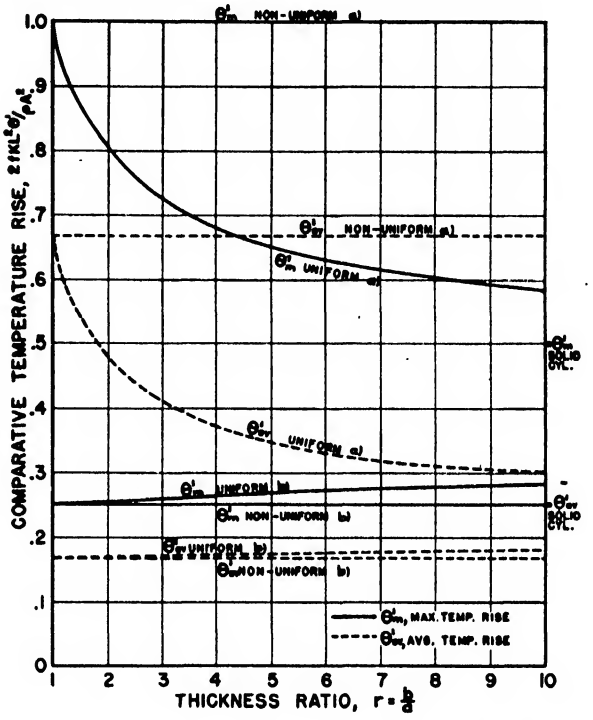

FIG. 2. Maximum and average temperature rise with constant resistivity.

of the radius of the turns in the winding. Thus the value of Q is given by the formula

$$Q = \rho A^2/[fL^2x^2(\log_e r)^2]. \quad (21)$$

Assuming small temperature rise conditions, both ρ and K are constant; hence the temperature field in a non-uniform cylindrical winding is represented by the equation

$$\frac{d^2T'}{dx^2} + \frac{1}{x}\frac{dT'}{dx} + \frac{1}{x^2}\cdot\frac{\rho A^2}{fKL^2(\log_e r)^2} = 0. \quad (22)$$

With boundary conditions (a), the temperature distribution is found to be

$$\Theta'(x) = \frac{\rho A^2}{2fKL^2(\log_e r)^2}\log_e\frac{b}{x}\log_e\frac{bx}{a^2} \quad (23)$$

[6] C. L. Emmerich, Am. Math. Monthly 55, 613 (1948).

which yields as the maximum temperature rise the value already found in Eq. (5). However, while Eq. (5) was found as the solution to the problem of the uniform winding of thickness ratio one only, the solution just determined is independent of the thickness ratio, hence representable by the straight line marked "Θ_m' non-uniform (a)" in Fig. 2.

Experimental data[7] indicate that the practical approximations to ideal non-uniform windings[8] exhibit the same temperature rise characteristics as the ideal windings. Thus the solution just determined for the ideal non-uniform windings is valid for practical work also.

The remarkable property that non-uniform windings exhibit the same temperature rise, independent of thickness ratio, is shown also by the solution with boundary conditions (b), as indicated in Fig. 2 by the straight line "Θ_m' non-uniform (b)," as well as the average temperature rises "Θ_{Av}' non-uniform (a)" and "Θ_{Av}' non-uniform (b)."

The preceding results show quantitatively to what extent overheating may be expected in multiple-wire-size windings, when thin wire is wound near the core as suggested by Emmerich.[6] The conclusion is that the temperature rise is the same as for a uniform winding of the same number of ampere-turns, but wound on a core with zero curvature.

LARGE TEMPERATURE RISE

Insulating materials which were developed recently have made increased operating temperatures possible for magnet coil windings.[9] In order to take full advantage of these new materials, it is imperative to have correct design data at hand. These data are obtainable in part from the solution of Poisson's Eq. (1).

When large temperature rises are considered, it is no longer possible to assume that Q and K are constant. The rate of heating, Q, is a linear function of the temperature, because it contains as a factor the resistivity ρ, which is known to vary linearly with temperature in the range normally expected for operating conditions of electrical equipment. The average thermal conductivity K, being a function of the conductivities of the materials in the coil, may be expected to vary with temperature also; however, it appears difficult to predict the relationship between K and T for any given winding. Experimentally, a coil of Formex wire, immersed in kerosene, was found to have a constant thermal conductivity of 0.020 watt/°C-inch over a temperature range from 12°C to 65°C; while the same coil in air exhibited an increase in K from 0.0057 to 0.0072 watt/°C-inch as the temperature changed from 33°C to 84°C.[7]

Thus, at least for a Formex winding immersed in kerosene, the right side of Eq. (1) should be expressed as a linear function of T. It will be helpful in applying the boundary conditions to let the temperature be represented by the sum of the surface temperature and temperature rise:

$$T=T_s+\Theta.$$

The differential operator ∇^2 will then apply directly to the temperature rise Θ, while the linear function in T is replaced by a linear function in Θ. Poisson's equation then reads as follows

$$\nabla^2\Theta=-u^2\Theta-w^2 \tag{24}$$

where

$$u^2=\frac{\alpha_0\rho_0A^2}{fKL^2h^2} \quad \text{and} \quad w^2=\frac{\rho_0A^2}{fKL^2h^2}(1+\alpha_0T_s).$$

In these expressions, ρ_0 is the resistivity of the metal in the wire at 0°C, and α_0 is the temperature coefficient of resistivity of the wire at 0°C. The boundary conditions are simplified to the extent that at the outside surface of the winding, the temperature rise is zero.

Jakob[5] has published the solutions of Eq. (24) for the solid cylinder ($r\to\infty$) and the flat plate ($r=1$). The maximum temperature rise in the case of the flat winding ($r=1$) is given as follows, in the notation of this paper,

$$\Theta_m=\left(T_s+\frac{1}{\alpha_0}\right)\left[\sec\frac{A(\alpha_0\rho_0)^{\frac{1}{2}}}{L(fK)^{\frac{1}{2}}}-1\right]. \tag{25}$$

From the expansion of the secant function it is readily found that Eq. (25) is approximated by the series

$$\Theta_m=\left(T_s+\frac{1}{\alpha_0}\right)\left[\frac{1}{2!}u^2h^2+\frac{5}{4!}(u^2h^2)^2+\frac{61}{6!}(u^2h^2)^3+\cdots\right]. \tag{26}$$

It is of course possible to use Eq. (25), or its expansion (26), directly in making temperature rise calculations. However, for the purpose of comparison with the design data obtained from Eq. (5), which neglects changes in resistivity, a correction factor Θ_m/Θ_m' has been computed.

If the value of ρ in Eq. (5) is taken as the resistivity of the wire at temperature 0°C, it will be seen that the temperature rise computed from Eq. (5) is

$$\Theta_{m0}'=u^2h^2/2\alpha_0. \tag{27}$$

Substituting this expression in Eqs. (25) and (26) leads to the functional equation

$$\Theta_m=\left(T_s+\frac{1}{\alpha_0}\right)[\sec(2\alpha_0\Theta_{m0}')^{\frac{1}{2}}-1] \tag{28}$$

[7] C. L. Emmerich, thesis, University of Cincinnati (1949), Section V.
[8] C. L. Emmerich, Elec. Eng. 68, 185 (1949).
[9] G. L. Moses and J. J. Torok, Trans. A.I.E.E. 65, 412 (1946).

and to the series expansion

$$\Theta_m=\left(T_s+\frac{1}{\alpha_0}\right)\left[\alpha_0\Theta_{m0}'+\frac{5}{4!}(2\alpha_0\Theta_{m0}')^2+\frac{61}{6!}(2\alpha_0\Theta_{m0}')^3+\cdots\right]. \quad (29)$$

If the value of ρ in Eq. (5) is taken as the resistivity of the wire at temperature T_s, that is, if

$$\rho_s=\rho_0(1+\alpha_0 T_s)$$

as is often done in coil design, then substitution yields the functional equation

$$\Theta_m=\left(T_s+\frac{1}{\alpha_0}\right)\left[\sec\left(\frac{2\Theta_{ms}'}{T_s+1/\alpha_0}\right)^{\frac{1}{2}}-1\right] \quad (30)$$

and the corresponding expansion

$$\Theta_m=\Theta_{ms}'+\frac{5}{6}\cdot\frac{1}{(T_s+1/\alpha_0)}(\Theta_{ms}')^2+\frac{61}{90}\cdot\frac{1}{(T_s+1/\alpha_0)^2}(\Theta_{ms}')^3+\cdots. \quad (31)$$

Dividing Eq. (30) or (31) through by Θ_{ms}' yields the correction factor Θ_m/Θ_{ms}', which is a function of Θ_{ms}' with T_s as a parameter. This family of curves is plotted in Fig. 3, with $1/\alpha_0=234.5$°C.

An example will illustrate the use of these curves: At a surface temperature $T_s=40$°C, the uncorrected temperature rise obtained from Eq. (5) for a particular winding is 84°C, using the value of ρ_s corresponding to $T_s=40$°C. On the curve marked $T_s=40$°C in Fig. 3, the correction factor corresponding to 84°C is 1.35. Hence, the true temperature rise is $1.35\times84=113$°C. The "hot spot" in the coil will therefore reach a temperature of $40+113=153$°C.

It should be kept in mind in using these data that the boundary conditions are idealized. The assumption is made that no heat escapes through the core or through the ends of the coil, and that the temperature at the surface is constant. In actual windings it is probable that heat does escape through the core and ends, thus making the foregoing calculations fall on the safe side; however, the temperature at the surface of the coil may be quite far from the ambient temperature, and it may vary along the surface. This tends to make the calculations uncertain. To take into account the end leakage leads to rather involved computations, as shown by Higgins.[10] Actual surface temperatures are probably obtained easiest by experimental methods.[2-4]

It should be emphasized that Eq. (30) and Fig. 3 apply only to windings of thickness ratio one. Since actual windings are usually in the shape of hollow cylinders, the following computations have been made to evaluate the corrections necessary to allow for the curvature of the winding. It will be found, as in the case of small temperature rise, that the winding of thickness ratio one has a higher maximum temperature rise than a winding in the shape of a hollow cylinder.

For a long, thick, cylindrical winding (heat flow in the radial direction only), with boundary conditions (a), the solution of the equation

$$\frac{d^2\Theta}{dx^2}+\frac{1}{x}\frac{d\Theta}{dx}+u^2\Theta=-w^2 \quad (32)$$

will permit calculation of the temperature rise distribution

$$\Theta(x)=\frac{w^2}{u^2}\left[\frac{J_1(au)Y_0(xu)-J_0(xu)Y_1(au)}{J_1(au)Y_0(bu)-J_0(bu)Y_1(au)}-1\right] \quad (33)$$

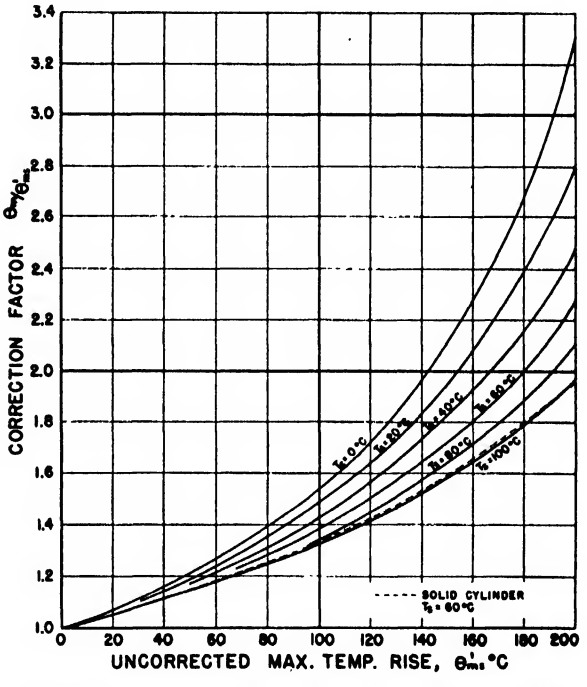

FIG. 3. Correction factor for maximum temperature rise in thin windings.

and of the maximum temperature rise

$$\Theta_m=\left(T_s+\frac{1}{\alpha_0}\right)\times\left\{\frac{2}{\pi au[J_1(au)Y_0(bu)-J_0(bu)Y_1(au)]}-1\right\}. \quad (34)$$

J and Y are Bessel functions of the first and second kind, their order being indicated by subscripts.

[10] T. J. Higgins, Trans. A.I.E.E. 64, 190 (1945) and Trans. A.S.M.E. 66, 665 (1944).

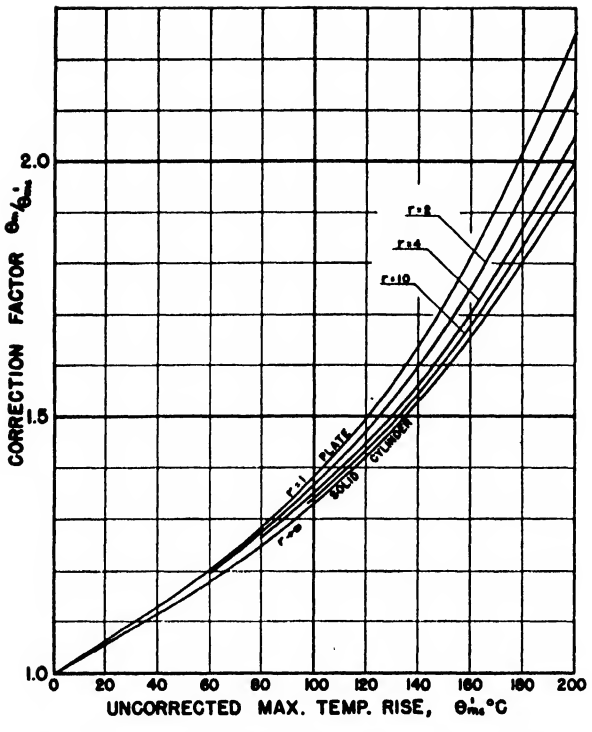

FIG. 4. Correction factor for maximum temperature rise in thick windings, $T_s = 60°C$.

Again, Eq. (34) might be used directly in making temperature rise calculations. However, for the purpose of comparison with design data obtainable from Eq. (14), a correction factor Θ_m/Θ_{ms}' has been computed and plotted in Fig. 4, for the surface temperature $T_s = 60°C$, and using the value of the reciprocal of the thermal coefficient of resistance $1/\alpha_0 = 234.5°C$.

This family of curves is intended to demonstrate that the difference in correction factors for windings of various thickness ratios, other conditions being the same, is rather small. Few actual windings exceed the thickness ratio $r = 2$; thus the approximation made by using the curves in Fig. 3 is not serious. For the purpose of comparison, the curve for a solid cylindrical winding at $T_s = 60°C$ has been shown dotted in Fig. 3.

It may be stated here for the sake of completeness that the non-uniform winding designed for minimum resistance at small temperature rise yields exactly the same temperature rise conditions as the curves in Fig. 3, independent of its thickness ratio.

Up to this point, Poisson's Eq. (1) has been solved for cylindrical windings with Q and K constant; also with K constant and Q a linear function $Q(T)$. If it is assumed that K is also a linear function $K(T)$, then the differential equations become much more complicated, making a solution in closed form difficult. The only exception occurs when $K(T)$ is a multiple of $Q(T)$; that is, when the linear function $K(T)$ would be zero at the same temperature as the temperature for which $Q(T)$ would be zero. Then the right side of Eq. (1) would reduce to a constant again. In practical terms, this requires that the thermal conductivity of the winding must be proportional to the resistivity of the metal in the wire at all temperatures. Ordinary coil windings are not expected to have this special property.

If the function $1/K$ is linear in T, then the right side of Eq. (1), being the product of two linear functions, would become a quadratic function in T. This case has already been considered by Davies,[11] who assumed K to be constant, and $Q(T)$ a quadratic function. The solution in this case contains elliptic functions. It appears that the complete and detailed results of this case are not very useful until it has been established that the thermal conductivities of actual windings are expressed correctly by linear functions $1/K$.

Evaporation and Outgassing in an Inert Atmosphere

R. L. LONGINI
Westinghouse Research Laboratories, East Pittsburgh, Pennsylvania
(Received June 9, 1949)

Experiments on the evaporation outgassing of antimony in vacuum and in an inert atmosphere show that an inert atmosphere is advantageous for outgassing antimony if loss of antimony by evaporation is intollerable. A simple theory based on well-established kenetic theory considerations is given which may explain and did predict the results.

INTRODUCTION

THE introduction of an inert gas into a vacuum system changes the conditions limiting the rates of both evaporation and outgassing. In a vacuum these rates depend on reflection or accommodation coefficients, whereas in the presence of an inert atmosphere diffusion is the rate-determining process.

It has been known for some time that an atmosphere reduces the rate of evaporation of tungsten in lamps or of magnesium[1] in an inert atmosphere.

In the present study, the actual rates were determined experimentally by use of a microbalance on which loss of sorbed gasses and of the parent body of antimony were found by direct weighing of test samples. A helium atmosphere was used. Results indicate that the introduction of an inert atmosphere may prove useful in outgassing volatile materials.

THEORY

The theory is rather crude and may neglect some important effects. It is important to note that the theory came first and predicted the observed results. It is presented as it may prove useful in some other cases.[2]

Let us assume that the test sample is in equilibrium with its various vapors. The vapor of the parent material (antimony in the experiments) is in equilibrium with the solid body, and other vapors are in equilibrium with their sorbed phases.

Suppose we examine any one of the vapors closely. Let n_{i0} be the number of molecules per unit volume of the ith vapor in the space at equilibrium. Now kinetic theory shows us that $n_{i0}\bar{c}_i/4$ of these will cross a unit area per second where $\bar{c}_i$ is the mean velocity of the ith vapor.[3] This will also be the number of molecules striking each unit area of the condensed material, and a fraction a_i will stick. The fraction a_i is known as the accommodation coefficient. At equilibrium, the rate of condensation or sticking must equal the gross rate of evaporation of the ith component R_i, which gives

$$R_i = n_{i0}\bar{c}_i a_i/4. \tag{1}$$

(If a good vacuum is maintained the net rate of evaporation must be given by R_i above, as the vapor will be removed and no condensation from a vapor phase will take place.)

Suppose we admit an inert atmosphere. The evaporating vapors will now have to diffuse away from the condensed phase. Let R_{pi} be this evaporation rate when the inert gas pressure is p. Now $R_{pi}=D_{pi}(\text{grad}n_i)_0$ where D_{pi} is the diffusion coefficient of the ith vapor through the inert atmosphere of pressure p and n_i is the number of molecules of the ith vapor per cubic centimeter. The gradient is taken at the condensing surface as indicated by the subscript zero.

Now, from our previous discussion, we conclude that the vacuum or gross rate R_i is equal to the net rate R_{pi} plus the rate of recondensing $n_{i0}a_i\bar{c}_i/4$, where n_{i0} is the molecular density at the surface.

We can state

$$\frac{R_{pi}}{R_i}=\frac{D_{pi}(\text{grad}n_i)_0}{n_{i0}\bar{c}_i a_i/4+D_{pi}(\text{grad}n_i)_0}. \tag{2}$$

From kinetic theory we have $D_{pi}=g_i T^{\frac{1}{2}}p^{-1}$ and $\bar{c}_i=h_i T^{\frac{1}{2}}$, where g_i and h_i are proportionality constants. Putting these in the above and dividing numerator and denominator each by $g_i(\text{grad}n_i)_0 T^{\frac{1}{2}}$ we have

$$\frac{R_{pi}}{R_i}=\frac{T/p}{T/p+a_i n_{i0}h_i/4g_i(\text{grad}n_i)_0}. \tag{3}$$

In the steady state it can be shown that $n_{i0}/(\text{grad}n_i)_0$ is independent of n_i and is a function of geometry only. (In the one-dimensional case, for example, $n_{i0}/(\text{grad}n_i)_0$ equals the distance between the evaporating surface and the remote absorbing surface.) It is therefore essentially the same for all components. We can rewrite the above as

$$R_{pi}=R_i\frac{T/p}{a_i/G_i+T/p}, \tag{4}$$

where G_i takes into account both the geometry and the proportionality constants for the ith vapor. Now the diffusion coefficients for the various vapors are of the same order of magnitude so that the G_i and thus the ratios R_{pi}/R_i of various components have large differences only because of large differences in the accommodation coefficients.

[1] E. A. Gulbransen, Trans. Electrochem. Soc. 87, 597 (1945).
[2] For comparison see I. Langmuir, Phys. Rev. 2, 329 (1913).
[3] For example, *Cobine, Gaseous Conductors* (McGraw-Hill Book Company, Inc., New York, 1941), p. 19.

The accommodation coefficient for the parent material will probably be close to unity, whereas that for various sorbed vapors may be very small. Thus a pressure of inert gas may do much more to reduce the net evaporation for the parent material than for the sorbed components. The ratio of rates of evaporation of two components is thus pressure dependent

$$\frac{R_{p1}}{R_{p2}} = \frac{R_1}{R_2}\,\frac{T/p+a_2/G_2}{T/p+a_1/G_1}. \tag{5}$$

Anticipating our experimental results with plated antimony and its various sorbed vapors,

$$\frac{R_{p(Sb)}}{R_{p2}} = \frac{R_{(Sb)}}{R_2}\,\frac{T/p+3.3\times10^4}{T/p+4.1\times10^6} \tag{6}$$

where the subscript Sb refers to plated antimony, the subscript 2 refers to an effective "mean" of sorbed vapors. The pressure is in atmospheres, the temperature in degrees Kelvin. In this case the value of $n_{i0}/(\text{grad}n_i)_0$ was about 25 cm. It is apparent that a moderate pressure will make the T/p value small and that the rate of evaporation $R_{p(Sb)}$ will be reduced far more than the rate of outgassing R_{p2}.

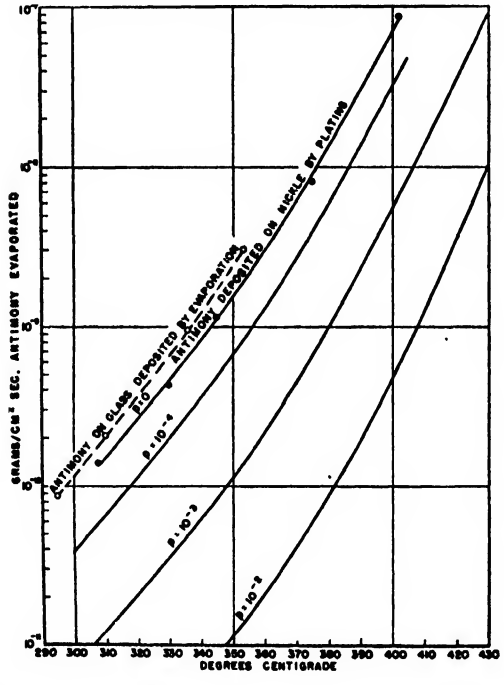

FIG. 1. The rate of evaporation of plated antimony. The rate of evaporation of plated antimony is shown as a function of temperature and helium pressure. The pressures of the isobaric curves are expressed in atmospheres. The vacuum rate of evaporation of antimony from glass is also shown. The experimental points for the vacuum rates are given but those for inert atmospheres were very scattered, varying by a factor of two from the curves shown. Since this is influenced by geometry in any case, the curves are given only to show the order of magnitude of the effect.

EXPERIMENTAL PROCEDURE AND RESULTS

The experiments to determine evaporation rates were carried out on Dr. E. A. Gulbransen's microbalance.[4] This instrument is enclosed in glass and can be evacuated or filled to pressures up to atmospheric with nearly any gas. The sample is suspended from one side of the balance by a tungsten wire so positioned that the sample hangs in a tube which can be heated by a furnace. The counterweight has the same density as the sample to reduce buoyancy effects when gas is admitted.

The balance is calibrated in micrograms and reads the degree of unbalance between the constant counterweight and the sample under investigation. The readings are made with a vernier microscope and are reproducible under most conditions to within one-half a microgram.

Two types of samples were used. The first consisted of 0.005-in. steel shims 1×6 centimeters in extent, plated on both sides with a total of 16 milligrams of antimony from an antimony chloride plating bath. This type was used to determine the rate of evaporation of outgassed plated antimony, the rate of outgassing, and the effect of helium on these rates. The second type consisted of microscope cover glasses each 11×50 millimeters by 0.25 millimeter thick. These were coated with antimony which was deposited by evaporating it from a tungsten wire on which it had been plated. The resultant coating had a surface density of about 16 μg cm^{-2} on each side. These slides were used for determining the rate of evaporation from an evaporated antimony film on glass.

For determining the rate of evaporation of antimony the samples were first outgassed. When the rate of weight loss was constant with time at any one temperature, the sample was believed to be outgassed. This was cross-checked by raising the temperature for a while, then bringing it back to the original temperature. A return of the rate of weight loss to its original steady value was always found.

The various rates were determined by plotting the loss of weight against time at a fixed temperature and observing the slope. During outgassing the resulting plots were curves with steadily, but slowly, decreasing slopes. The slopes of the steady state lines corresponding to outgassed samples were found and, after being put in terms of grams cm^{-2} sec.$^{-1}$, are plotted against temperature in Fig. 1. The rates of evaporation of both forms of antimony have the same slope when plotted against temperature but the evaporated film has a 40 to 50 percent higher rate. This is indicative of the same heat of vaporization but probably of a higher accommodation coefficient for the evaporated film. This indicates an accommodation coefficient of less than 0.7 for plated antimony, a very low value compared to the assumed value of unity used in calculating the calibra-

[4] E. A. Gulbransen, Rev. Sci. Inst. 15, 201 (1944).

tion of the Knudsen gauge. The apparent higher accommodation coefficient for the evaporated film is probably due to a granular structure similar to those seen with an electron microscope for most metal films. The condensing antimony molecule, falling deep into the layer, might have to undergo several reflections before emerging.

It is interesting to note that the evaporation rate of antimony from the glass slide was independent of the amount of antimony on the slide until this was under 2 $\mu g\ cm^{-2}$. Below this the rate dropped slowly to one-half its former value, then dropped suddenly to zero at which point all the antimony had evaporated.

Outgassed samples were observed when a helium atmosphere was introduced. It was found that even slight impurities in the helium had a very decided effect on the results. The helium was passed through hot, partially oxidized copper and then through a drying tube. This should have removed hydrogen, oxygen, and water vapor. Even after great care with this process, the rates determine with helium present were not reproducible with precision. The determined effect of pressure may be off by 50 percent. The figure shows how the rate of evaporation is dependent on temperature and pressure.

Determining the effect of an inert gas pressure on the rate of outgassing was much more difficult. First of all, the outgassing rate in vacuum is not constant so that the pressure effect had to be measured rapidly. Secondly, the effect was so small that 0.1 atmosphere of helium was needed to measure it. These conditions required a much more rapid introduction of gas than the previously described purifier could handle. A long total obstruction activated charcoal trap was built to purify the gas more rapidly.

The tests were carried out as quickly as possible. A rate was determined for the vacuum condition, (1.5×10^{-3} $\mu g\ sec.^{-1}\ cm^{-2}$ at 284°C), then helium at a pressure of 0.1 atmosphere was introduced and a new rate determined; (2.17×10^{-4} $\mu g\ sec.^{-1}\ cm^{-2}$) the helium was then pumped out and the vacuum rate determined again and was found unchanged. A slight buoyancy effect, probably caused by convection currents in the helium, caused jumps in the readings on introduction and exhaust of the gas. The jumps were equal and opposite so that the measured evaporation rate with a gas atmosphere was assumed to be correct. The outgassing rate remained constant during the run with 0.1 atmosphere of helium present. The total loss of weight during the test was about 50 μg. The sample was of antimony plated on steel shim stock. The test was carried out at 284°C.

As Fig. 1 shows the evaporation rate of antimony in vacuum at 284°C was approximately 6×10^{-5} $g/cm^2/sec.$ or one twenty-fifth the rate of outgassing in vacuum at this temperature. During the inert atmosphere part of the test at 0.1 atmos. the outgassing rate was reduced by a factor of 7, but, as Fig. 1 shows, the evaporation rate was reduced by a factor of 100 to 1000. Thus, the introduction of the inert gas had the effect of reducing the evaporation rate to a very small fraction of the outgassing rate.

CONCLUSION

An inert gas requires that evaporated molecules diffuse through it and therefore it limits the rate of evaporation. Many evaporated molecules are reflected by the inert gas back to the evaporating surface where they may recondense.

A difference in the accommodation coefficient of this condensing process may explain completely the alteration of the relative rates of outgassing and evaporation of the parent body when an inert atmosphere is introduced. The introduction of such an atmosphere may prove useful when it is desired to outgas other volatile material, for the evaporation rate is probably reduced far more than the outgassing rate in most cases. In the particular case of plated antimony, for the same rate of outgassing, the rate of loss of antimony by evaporation in an inert atmosphere was less than one one-hundredth the rate of loss in a vacuum.[5]

A Method of Reducing Deflection Defocusing in Cathode-Ray Tubes

R. G. E. Hutter and S. W. Harrison
Physics Laboratories, Sylvania Electric Products, Inc., Bayside, New York
(Received May 26, 1949)

A discussion of deflection defocusing is given to point out the two-dimensional character of the focusing action of deflection fields. A photograph of spot distortion actually observed is shown. A brief theory of combined spherical and cylindrical lenses is given, and a method of spot correction based on the principle of "beam predistortion" is described. An electron gun used for such correction is shown and experimental results obtained with this gun are exhibited.

INTRODUCTION

BOTH practical experience and theoretical analysis[1–3] show than an electron beam passing through a deflection field is subject to a "two-dimensional" focusing action as well as a bending action. In cathode-ray tubes, such a focusing action is undesirable. If the beam is focused to a small spot at the center of the fluorescent screen and is then deflected, the result of the two-dimensional focusing action will be a distortion of the spot.*

The amount of beam distortion produced by a deflection field varies with the form of the deflection field employed. Attempts to reduce the distortion effects by improving the design of the fields have been relatively successful in the case of magnetic deflection. This has not been true in the case of electrostatic fields where one is more limited in the type of change that can be made in the elements producing the field. The fact that there is a change in the velocity of the electrons as well as a variation in the strength of the electrostatic field also makes defocusing effects in this type of field more inherent than in the magnetic field where there is only a variation in field strength.

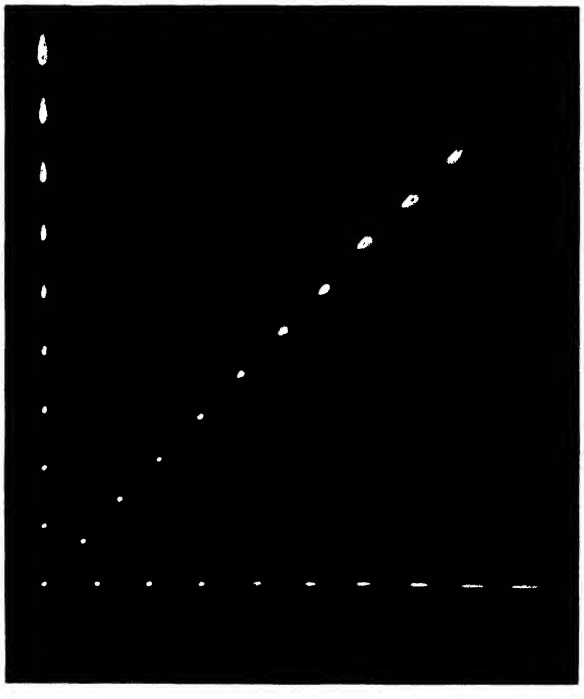

FIG. 1. Spot distortion observed with an electrostatic deflection system of low sensitivity.

The amount of beam distortion associated with any deflection depends also on the parameters of the beam as it enters the field, For a given deflection, a certain set of initial conditions will give a beam which is free of distortion after deflection. Physically, this may be interpreted as saying that the beam is initially distorted in a manner such as to compensate for the distortion produced by the deflection field. To produce such a predistortion, the electron optics of an ordinary axially symmetric focusing system must be modified. The magnitude of this modification will depend on the magnitude and direction of deflection, or, in other words, on the position of the spot on the fluorescent screen.

It is the purpose of this paper to describe a method of spot correction which is based on the principle of beam predistortion. This principle can be employed in both the electrostatic case and the magnetic case, but the particular method described is electrostatic in nature and is used in connection with electrostatic deflection systems.

In describing the method of spot correction it is convenient to begin with a brief discussion of deflection fields. It will be pointed out that the beam distorting action which is associated with deflection is "two-dimensional" in nature. Observed spots will be shown which confirm the character of this type of distortion. This discussion of deflection fields and the effect of such fields on electron beams will be followed by a first-order theory of focusing fields which have spherical and cylindrical lens properties. It will then become apparent that, by combining such focusing fields with deflection fields, the spot distortion effects can be reduced.

Finally, a special electron gun will be described. This

* The properties of a deflection field also cause a non-linear relationship to exist between field strength and deflection. This in turn produces a so-called "pattern distortion." Since this is ordinarily less objectionable, it will be ignored in the present discussion.

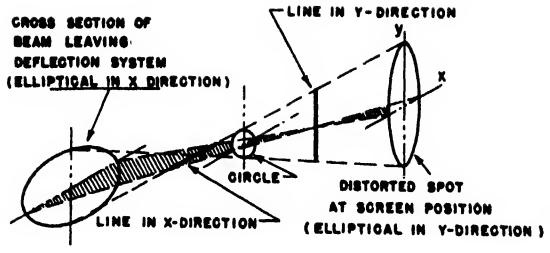

FIG. 2. Distortion which results when an electron beam, point focused before deflection, is deflected in the y-direction.

gun is capable of producing an undistorted spot at any point on the screen to which the beam can be deflected. This means that, at the fluorescent screen, the cross section of a deflected beam is circular and has nearly the same diameter as the cross section of the undeflected beam. Photographs taken of the face of a special tube in which this gun was incorporated will show the degree of spot correction achieved.

I. BEAM DISTORTING EFFECTS OF DEFLECTION FIELDS

Actual cathode-ray tubes employing balanced electrostatic deflection fields are designed to have as little spot distortion as possible by keeping the angle of deflection small. In order to study methods of correcting the spot distortion, an electron gun of low sensitivity and hence large distortion effects was designed. A photograph of spots obtained with this gun is shown in Fig. 1 and it can be seen that the general character of the spot distortion is as described by the theory.[1-3]

Both the calculations and the observed results show that the spot is elongated in the direction of deflection. A closer examination of the calculated results, as well as a closer analysis of experimental results for an initially point-focused beam, shows that this characteristic of the spot distortion is due to a focusing effect of the deflection field which is considerably stronger in the direction of deflection than perpendicular to it. The shape of the deflected electron beam on the gun side of the screen is sketched in Fig. 2.

It can be seen from this that in no portion of the beam is there a convergence of all the electron paths

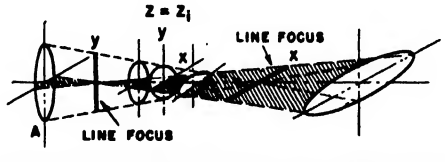

FIG. 3. Shape of an electron beam in the neighborhood of the image plane of a combined spherical and cylindrical electron lens.

to a point. At two places the cross section degenerates into a straight line and at an intermediate point a circular cross section can be found. All other portions of the beam have an elliptical cross section. Reducing the strength of the focusing field of the electron gun will make all paths less convergent, and it is possible to adjust this strength so that the electron beam has a circular cross section at the screen. However, no point focus is now possible in contrast with the point focus assumed at the center of the screen. In the practical case the spot at the center has a finite radius, but no refocusing of the electron lens of rotational symmetry will produce a deflected spot of the same size as the undeflected spot.

A cylindrical lens action must be incorporated in the electron gun to obtain perfect correction for both shape and size. In order to show that this is the case, a brief discussion will be given of the theory of a class of focusing fields which have both spherical and cylindrical lens properties.

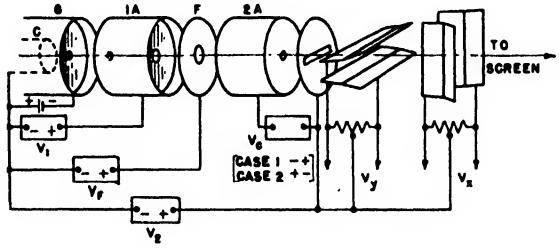

FIG. 4. Electrode arrangement and associated power supplies for an electron gun free of deflection defocusing.

II. THEORY OF COMBINED SPHERICAL AND CYLINDRICAL ELECTRON LENSES

The potential distribution of an electrostatic field which satisfies the symmetry condition,

$$\varphi(x,y,z)=\varphi(-x,y,z)=\varphi(x,-y,z) \tag{1}$$

may be expanded in the series:

$$\varphi(r,z,\theta)=\phi(z)-(1/4)\phi''(z)r^2+\phi_2(z)r^2\cos 2\theta +(1/64)\phi^{IV}(z)r^4-(1/12)\phi_2''(z)r^4\cos 2\theta +\phi_4(z)r^4\cos 4\theta+\cdots. \tag{2}$$

For a field of rotational symmetry $\phi_{2n}(z)=0$. The paraxial ray equations for fields given by Eq. (2) are

$$\left.\begin{aligned} x''+(1/2)(\phi'/\phi)x'+(1/4)(\phi''/\phi)x&=(\phi_2/\phi)x \\ y''+(1/2)(\phi'/\phi)y'+(1/4)(\phi''/\phi)y&=-(\phi_2/\phi)y \end{aligned}\right\}. \tag{3}$$

These equations may be integrated under the following conditions:

(1) The general solution of the paraxial ray equation is known for the case $\phi_{2n}(z)=0$ (spherical lens).

(2) Terms which contain $\phi_{2n}(z)$ (combined spherical and cylindrical lens) may be considered small distortion terms.

With these conditions, the integration of Eq. (3) may be carried out by employing the methods ordinarily used in lens aberration theory.

Let $r(z)$ be the general solution of the paraxial ray equation:

$$r''+(1/2)(\phi'/\phi)r'+(1/4)(\phi''/\phi)r=0. \tag{4}$$

If $r(z)$ has the value r_0 in the object plane $z=z_0$ and

the value r_a in the aperture plane $z=z_a$, the solution may be written

$$r(z)=r_0 r_\gamma(z)+(r_a/r_{aa})r_\alpha(z), \tag{5}$$

where $r_\alpha(z)$ and $r_\gamma(z)$ are two particular solutions which

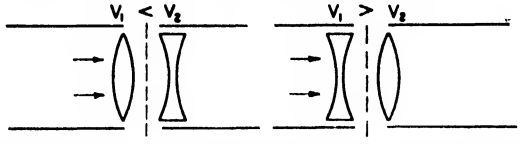

FIG. 5. A simple two-cylinder rotationally symmetric electron lens and the optical analogies for $V_1<V_2$ and $V_1>V_2$.

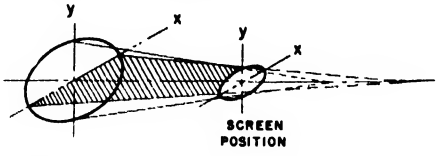

FIG. 6. Distortion of an undeflected electron beam necessary to compensate for the focusing action associated with a deflection in the x-direction.

satisfy the conditions

$$\begin{aligned} r_\alpha(z_0)&=0 \quad r_\alpha'(z_0)=1 \\ r_\gamma(z_0)&=1 \quad r_\gamma(z_a)=0. \end{aligned} \tag{6}$$

The values of $x(z)$ and $y(z)$ of Eq. (3) in the image plane are then given** by:

$$\left.\begin{aligned} x(z_i)=\Delta x_i&=-\frac{M}{(\phi_0)^{\frac{1}{4}}}\int_{z_0}^{z_i}\frac{\phi_2(z)}{(\phi(z))^{\frac{1}{4}}}r(z)r_\alpha(z)dz \\ y(z_i)=\Delta y_i&=+\frac{M}{(\phi_0)^{\frac{1}{4}}}\int_{z_0}^{z_i}\frac{\phi_2(z)}{(\phi(z))^{\frac{1}{4}}}r(z)r_\alpha(z)dz \end{aligned}\right\}. \tag{7}$$

For electron paths for which $r_0=0$, Eqs. (5) and (7) may be combined to give

$$\left.\begin{aligned} \Delta x_i&=-\frac{M}{(\phi_0)^{\frac{1}{4}}}\frac{r_a}{r_{aa}}\int_{z_0}^{z_i}\frac{\phi_2(z)}{(\phi(z))^{\frac{1}{4}}}r_\alpha^2(z)dz \\ \Delta y_i&=+\frac{M}{(\phi_0)^{\frac{1}{4}}}\frac{r_a}{r_{aa}}\int_{z_0}^{z_i}\frac{\phi_2(z)}{(\phi(z))^{\frac{1}{4}}}r_\alpha^2(z)dz \end{aligned}\right\}, \tag{8}$$

where $\phi_0=\phi(z_0)$ and $M=r_\gamma(z_i)$ is the magnification of the rotationally symmetric lens. Equation (8) shows that $\Delta x_i=-\Delta y_i$ and the cross section of the electron beam in the neighborhood of the image plane will vary as is shown in Fig. 3.

The type of lens described above may be used to produce a beam which converges differently in the x- and y-direction. This is the effect which was observed in the defocusing action of a deflection field. Such a lens may thus be used to compensate for the asymmetrical focusing action of a deflection system.

** See Madelung, *Die Mathematischen Hilfsmittel des Physikers* (Dover Publications, New York, 1943), third edition, p. 183.

III. AN ELECTRON GUN FREE OF DEFLECTION DEFOCUSING

On the basis of the analysis given above, it is possible to design an electron gun which is free of deflection defocusing. Such a gun is shown schematically in Fig. 4.

With the exception of a slit electrode, this gun is similar to the electron gun used in Type 7GP4 cathode-ray tubes. The slit is parallel to the first pair of deflection plates. The first and second anode ($1A$ and $2A$) are usually operated at the same high potential with respect to the cathode (i.e., $V_1=V_2$, $V_c=0$). The focusing electrode (F) is operated at a fraction of the value of the anode potential and the voltage of F is adjusted to produce as small a spot as possible on the screen. Because of space charge effects, velocity distribution effects, and lens aberrations, this spot is not a true point focus. The deflection systems are balanced as indicated in Fig. 4. The space between the last aperture in the second anode and the screen is at the uniform potential of the last anode if the deflection potentials V_x and V_y are equal to zero.

The addition of the slit electrode will not change anything when $V_c=0$ and $V_1=V_2$ provided the slit does not intercept electrons and does not distort the field in the neighborhood of the last aperture. If, however, $V_c\neq 0$, the field between an electrode of circular symmetry ($2A$) and one of two-dimensional symmetry (the slit electrode) will constitute a lens similar to that discussed in Section II of this paper.

In order to understand the performance of this modified gun in connection with spot correction, it should first be noted that the sign of the correction voltage V_c may be reversed. It can be reasoned that this reverses the sign of $\phi_2(z)$ in Eqs. (3) and (8). Now when $\phi_2(z)$ is positive, Δx_i is negative and Δy_i positive,

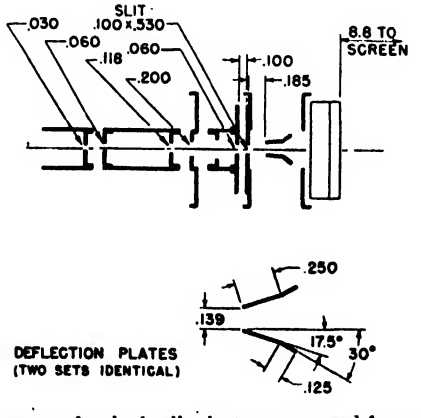

FIG. 7. Diagram of a single-slit electron gun used for correction of spot distortion. The essential dimensions in inches are shown.

and, as can be seen from Fig. 3, the beam is more convergent in the x-direction than in the y-direction. Similarly, with $\phi_2(z)$ negative, the convergence is greater in the y-direction. This reasoning presupposes a knowledge of the field distribution; since the field is

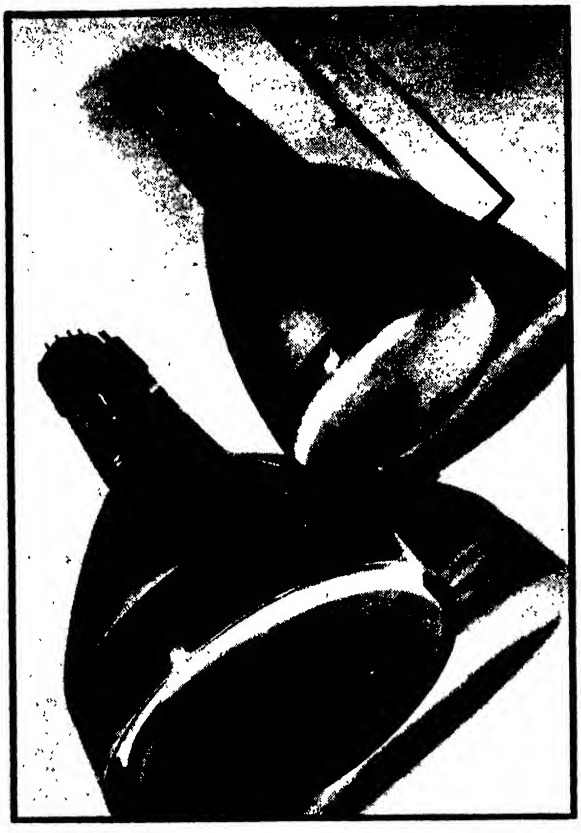

FIG. 8. Special 10-inch tube with single-slit gun and standard 7GP4 electrostatic tube showing over-all length the same for both tubes.

rather complex it is easier to proceed with a light-optical analogy.

Such analogies are often used in electron optics. Take, for instance, a simple rotationally symmetric lens which exists between two cylinders at different potentials. Such a lens is shown in Fig. 5. Although the net effect of this lens is a converging action, it should be pointed out that part of the lens has a diverging action and part a converging action. The regions in which these actions exist will depend on the potentials on the two cylinders and the two possible cases are shown, with the light optical analogies, in Fig. 5. The same thing may be said of apertured disks which separate two regions of uniform potential; this analogy holds if one of the rotationally symmetric electrodes is replaced by a slit electrode. In the latter case, of course, the lens action in the region of the slit electrode will be two-dimensional.

The performance of the modified gun may now be explained. Consider first a deflection in the y-direction and the correction for the spot distortion associated with such a deflection. With $V_c=0$, V_1, V_2 and V_f are adjusted so that the beam is "point-focused" at the center of the screen. (V_1 may or may not be equal to V_2). If the polarity of V_c is then as shown for case I in Fig. 4, an increase of V_c will mean:

(1) A reduction in the strength of the rotationally symmetric lens associated with $1A$, F, and $2A$;

(2) The creation of a "two-dimensional" diverging lens near the slit electrode and a converging, rotationally symmetric lens near the last aperture of $2A$.

With the possibility of varying V_f which changes the strength of the spherical lens, and V_c, which changes the relative convergence in the x- and y-directions, it is possible to distort the beam in such a way that its cross section at the screen position is similar to that shown at A in Fig. 3. It follows that the beam converges less in the y-direction than in the x-direction and that the rays in both the yz- and xz-planes intersect the screen before they cross the z axis. Since a given predistortion of this nature is necessary to compensate for the focusing action associated with a deflection in the y-direction, it is possible to adjust the spot at the center of the screen in such a way that the beam will be point-focused at the screen when deflected. In practice, the procedure is to deflect the beam, observe the spot distortion, and then adjust V_f and V_c so that the spot distortion is eliminated.

Since the electron gun also provides a deflection in the x-direction, it is necessary to provide for spot correction in this direction too. For this, another slit electrode following the first slit electrode with the slit rotated through 90° can be used with nearly the same potential arrangement. However, it is possible to use the single slit electrode shown in Fig. 4 for correction in both the x- and y-directions as will be shown. The polarity of V_c is chosen as illustrated for case II in Fig. 4. Now an increase of V_c will mean:

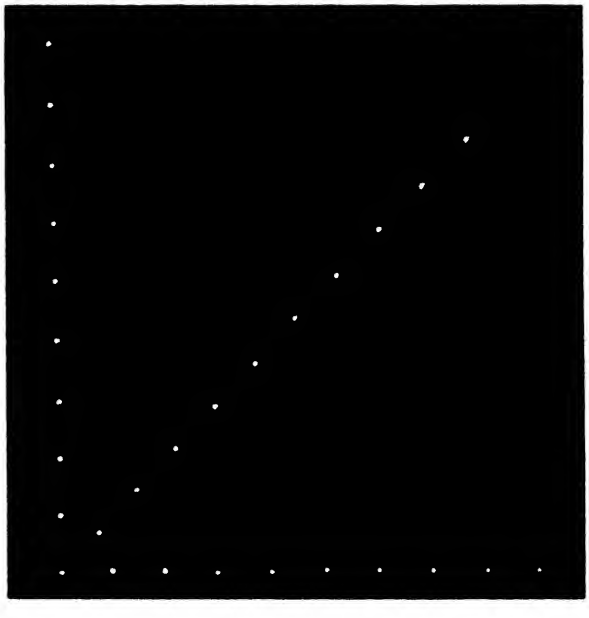

FIG. 9. Corrected spots on special 10-inch electrostatic tube with proper predistortion of the beam. The spots before correction were shown in Fig. 1.

(1) An increase in the strength of the rotationally symmetric lens associated with $1A$, F, and $2A$;

(2) The creation of a "two-dimensional" converging lens near the slit electrode and a diverging rotationally symmetric lens near the last aperture of $2A$.

Again, the possibility of varying V_f and V_c means that the beam can be predistorted, but in this case the two-dimensional lens is converging in the y-direction and the resulting beam will be less convergent in the x-direction than in the y-direction as illustrated in Fig. 6. This is the type of predistortion necessary to compensate for the focusing action associated with a deflection in the x-direction, and again the spot distortion of a deflected beam can be eliminated by adjusting V_f and V_c.

Since the spot in a cathode-ray tube is brought to an arbitrary position on the screen by deflection in both the x- and y-directions, there is some focusing in each direction due to the deflection fields. Equal amounts of focusing in each direction may be compensated for by weakening the axially symmetric focus, V_f. If the focusing action is stronger in one direction than in the other, the excess is treated just as a focusing action in one direction. Physically, this means that, for any position of the spot on the screen, it is always possible to find a combination of V_c and ΔV_f which produces a corrected spot.

IV. EXPERIMENTAL RESULTS

In an effort to check the analysis experimentally, a gun was constructed with the dimensions shown in Fig. 7. The deflection system of this gun was purposely made poor from the point of view of spot distortion by shortening the deflection plates. The gun was sealed in a ten-inch bulb with an over-all length equal to that of a standard Type 7GP4 tube. The special ten-inch tube and the 7GP4 are shown in Fig. 8. The spot distortion which results when the special tube is operated with $V_c=0$ was shown in Fig. 1. The results obtained after proper predistortion of the beam are shown in Fig. 9. The functional relationship between V_c, ΔV_f, and the deflection voltages are plotted in Figs. 10 and 11. Voltages must be applied to both pairs of deflection plates to produce a deflection along the 45° radius and, in this case, the "deflection voltage" read from the abscissa in Fig. 11 is the square root of the sum of the squares of the x- and y-deflection voltages.

It is apparent from Fig. 9 that nearly perfect spots are obtained when the predistortion is applied, even for deflections which normally produce a considerable amount of distortion. Commercial tubes have, of course, much less deflection defocusing than is obtained with the special tube without correction. However, if the angle of deflection in a regular tube were

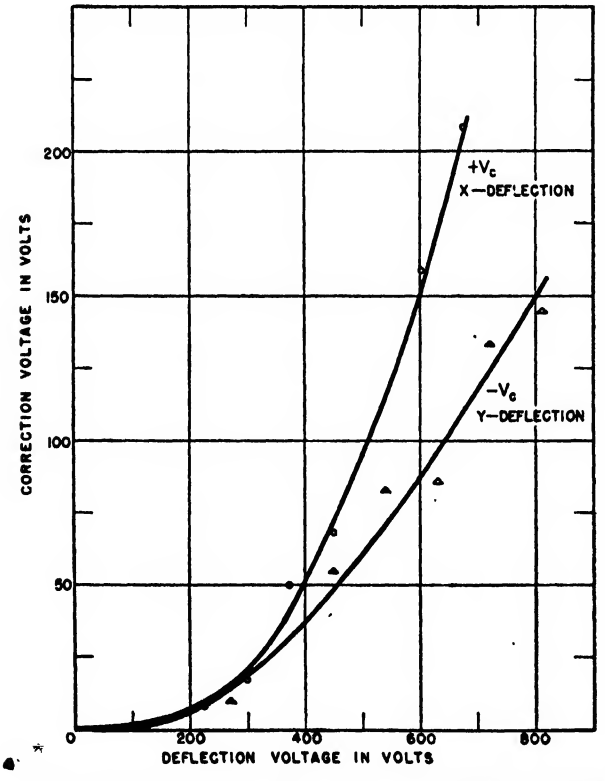

FIG. 10. Variation of correction voltages with deflection voltage for correction of spot distortion as shown in Fig. 9. The last anode voltage was 2000 volts and the grid bias (−162) volts with a pulse of 20 μsec., 110 cycles.

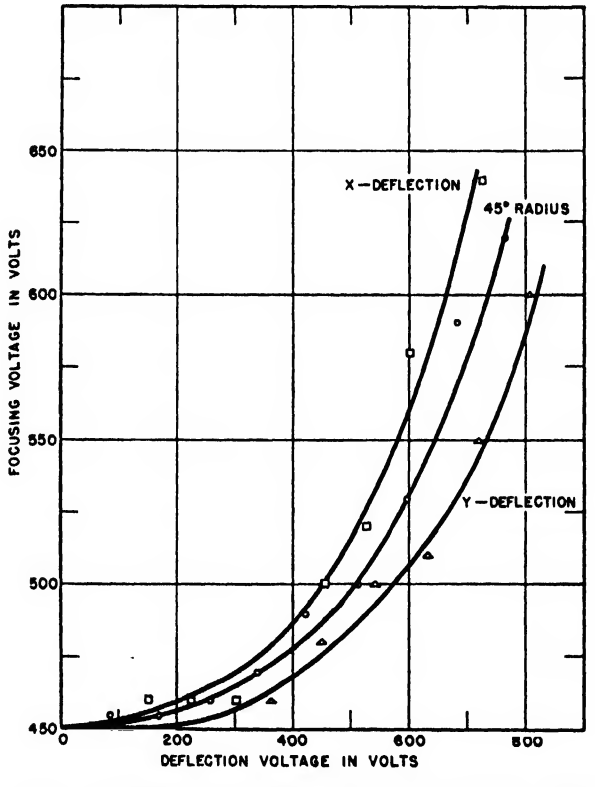

FIG. 11. Variation of focusing voltage with deflection voltage for correction of spot distortion as shown in Fig. 9. The last anode voltage was 2000 volts and the grid bias (−162) volts with a pulse of 20 μsec., 110 cycles.

increased in order to reduce the length of the tube, the spot distortion would be quite objectionable. In such a situation correction by predistortion would be very effective.

C. CONCLUDING REMARKS

The discussion above has been limited to the case of a tube employing a static deflection. In the operation of a cathode-ray tube under normal circumstances, circuits which permit automatic correction during the scanning cycle are required but will not be discussed here. The magnitudes of the correction potentials and their functional relationships to the deflection potentials depend on the particular design of the focusing and deflection systems and upon the degree of spot correction desired.

Although the correction method discussed here is for an electrostatic focusing and deflection system, it is possible to apply the principle of beam predistortion to magnetic focusing and deflection systems as well. In this connection, however, it should be pointed out that magnetic lenses, either spherical or cylindrical, are everywhere converging, i.e., there is no diverging region. If spot correction is attempted by the use of "two-dimensional" magnetic lenses, two such lenses rotated 90° with respect to each other are required.

The authors wish to take this opportunity of acknowledging the valuable contributions made by L. H. McKee of these laboratories in carrying out most of the experimental part of the work described.

Transmission of Elastic Waves through a Stratified Solid Medium

WILLIAM T. THOMSON*
University of Wisconsin, Madison, Wisconsin
(Received June 14, 1949)

The transmission of a plane elastic wave at oblique incidence through a stratified solid medium consisting of any number of parallel plates of different material and thickness is studied theoretically. The matrix method is used to systematize the analysis and to present the equations in a form suitable for computation.

INTRODUCTION

THE transmission of elastic waves in a homogeneous solid has been extensively treated by G. G. Stokes.[1] Barring surface waves of the type discussed by Rayleigh,[2] such waves are propagated as dilatation and rotation waves (frequently referred to as shear waves), each traveling with a different speed. It is thus necessary in dealing with such problems first to express the particle displacements in terms of the dilatation and rotation.[3]

The transmission of plane elastic waves through a stratified medium consisting of alternate parallel planes of solid and liquid layers has been treated by R. B. Lindsay[4] and others.[5,6] Since ideal fluids are incapable of sustaining tangential forces, the shearing stresses in the solid-liquid strata must vanish at the surfaces of the solid plates, thus reducing the problem to that of a single plate.

When the stratified medium consists of parallel solid plates without liquid layers between them, the problem cannot be reduced to that of a single section. The equations for one section must now be related to those of the adjoining section by the continuity of particle velocity, normal and shearing stresses at the interface. This is most conveniently accomplished by matrices which avoids unwieldly mathematical expressions and facilitates the computational task. The direction of propagation through each strata is established by Snell's law.

Nomenclature

ξ, η, ζ = particle displacement in x, y, z directions
$\dot{\xi}, \dot{\eta}, \dot{\zeta}$ = particle velocity in x, y, z directions
Δ = dilatation
ω = rotation (subscript indicates direction of normal to rotation plane)
$c_\Delta = [(\lambda+2G)/\rho]^{\frac{1}{2}}$ = velocity of dilatational wave in solid
$c_\omega = (G/\rho)^{\frac{1}{2}}$ = velocity of rotation or shear wave in solid
c_0 = velocity of propagation in the fluid
$\lambda = \nu E/[(1+\nu)(1-2\nu)]$
E = Young's modulus of elasticity
ν = Poisson's ratio
G = modulus of elasticity in shear

ρ = mass density
p = frequency in radians/sec.
$h = p/c_\Delta$
$k = p/c_\omega$
σ = normal stress
τ = shearing stress (subscript indicates direction of normal to plane of shear)
l, m, n = direction cosines of normal to advancing wave with respect to x, y, z axes
d = thickness of plates
$P = hn_\Delta d$
$Q = kn_\omega d$
R = reflection coefficient
T = transmission coefficient
$\varphi', \varphi'', \varphi'''$ = incident, reflected and transmitted waves in fluid surrounding the stratified medium
θ_0 = incident angle.

GENERAL EQUATIONS FOR DISPLACEMENTS IN TERMS OF DILATATION AND ROTATION

The dilatation and rotation are defined by the following equations.

$$\Delta = \frac{\partial \xi}{\partial x} + \frac{\partial \eta}{\partial y} + \frac{\partial \zeta}{\partial z} \tag{1}$$

$$\left.\begin{aligned} \omega_x &= \tfrac{1}{2}\left(\frac{\partial \zeta}{\partial y} - \frac{\partial \eta}{\partial z}\right) \\ \omega_y &= \tfrac{1}{2}\left(\frac{\partial \xi}{\partial z} - \frac{\partial \zeta}{\partial x}\right) \\ \omega_z &= \tfrac{1}{2}\left(\frac{\partial \eta}{\partial x} - \frac{\partial \xi}{\partial y}\right) \end{aligned}\right\}. \tag{2}$$

Differentiating Δ with respect to x, y, and z, we obtain the three equations

$$\left.\begin{aligned} \nabla^2\xi &= \frac{\partial \Delta}{\partial x} - 2\frac{\partial \omega_z}{\partial y} + 2\frac{\partial \omega_y}{\partial z}, \\ \nabla^2\eta &= \frac{\partial \Delta}{\partial y} - 2\frac{\partial \omega_x}{\partial z} + 2\frac{\partial \omega_z}{\partial x}, \\ \nabla^2\zeta &= \frac{\partial \Delta}{\partial z} - 2\frac{\partial \omega_y}{\partial x} + 2\frac{\partial \omega_x}{\partial y}. \end{aligned}\right\} \tag{3}$$

The general solution for the displacements in terms of Δ and ω which also satisfies the wave equation for dilation and rotation of harmonic time variation is

$$\left.\begin{aligned} \xi &= -\frac{1}{h^2}\frac{\partial \Delta}{\partial x} + \frac{2}{k^2}\frac{\partial \omega_z}{\partial y} - \frac{2}{k^2}\frac{\partial \omega_y}{\partial z}, \\ \eta &= -\frac{1}{h^2}\frac{\partial \Delta}{\partial y} + \frac{2}{k^2}\frac{\partial \omega_x}{\partial z} - \frac{2}{k^2}\frac{\partial \omega_z}{\partial x}, \\ \zeta &= -\frac{1}{h^2}\frac{\partial \Delta}{\partial z} + \frac{2}{k^2}\frac{\partial \omega_y}{\partial x} - \frac{2}{k^2}\frac{\partial \omega_x}{\partial y}. \end{aligned}\right\} \tag{4}$$

For instance, from the first of Eq. (4)

$$\nabla^2\xi = -\frac{1}{h^2}\frac{\partial}{\partial x}(\nabla^2\Delta) + \frac{2}{k^2}\frac{\partial}{\partial y}(\nabla^2\omega_z) - \frac{2}{k^2}\frac{\partial}{\partial z}(\nabla^2\omega_y)$$

which compared with the first of Eq. (3) results in the wave equations

$$\begin{aligned} (\nabla^2 + h^2)\Delta &= 0, \\ (\nabla^2 + k^2)\omega_z &= 0, \\ (\nabla^2 + k^2)\omega_y &= 0. \end{aligned}$$

GENERAL EQUATIONS FOR STRESSES IN TERMS OF DILATATION AND ROTATION

From the theory of elasticity we have the equations for stress in terms of displacements as follows:

$$\sigma_x = \lambda\Delta + 2G(\partial\xi/\partial x)$$

and two others,

$$\tau_x = G\left(\frac{\partial \eta}{\partial z} + \frac{\partial \zeta}{\partial y}\right)$$

and two others. Hence by substituting from Eq. (4) we obtain the equations for stress in terms of ∇ and ω

$$\sigma_x = \lambda\Delta + 2G\left(-\frac{1}{h^2}\frac{\partial^2\Delta}{\partial x^2} + \frac{2}{k^2}\frac{\partial^2\omega_z}{\partial x\partial y} - \frac{2}{k^2}\frac{\partial^2\omega_y}{\partial x\partial z}\right)$$

$$\sigma_y = \lambda\Delta + 2G\left(-\frac{1}{h^2}\frac{\partial^2\Delta}{\partial y^2} + \frac{2}{k^2}\frac{\partial^2\omega_x}{\partial y\partial z} - \frac{2}{k^2}\frac{\partial^2\omega_z}{\partial x\partial y}\right)$$

$$\sigma_z = \lambda\Delta + 2G\left(-\frac{1}{h^2}\frac{\partial^2\Delta}{\partial z^2} + \frac{2}{k^2}\frac{\partial^2\omega_y}{\partial x\partial z} - \frac{2}{k^2}\frac{\partial^2\omega_x}{\partial y\partial z}\right)$$

$$\begin{aligned} \tau_x = 2G\Bigg(&-\frac{1}{h^2}\frac{\partial^2\Delta}{\partial y\partial z} - \frac{1}{k^2}\frac{\partial^2\omega_z}{\partial x\partial z} - \frac{1}{k^2}\frac{\partial^2\omega_x}{\partial y^2} \\ &+ \frac{1}{k^2}\frac{\partial^2\omega_x}{\partial z^2} + \frac{1}{k^2}\frac{\partial^2\omega_y}{\partial x\partial y}\Bigg) \end{aligned} \tag{5}$$

$$\begin{aligned} \tau_y = 2G\Bigg(&-\frac{1}{h^2}\frac{\partial^2\Delta}{\partial x\partial z} - \frac{1}{k^2}\frac{\partial^2\omega_x}{\partial x\partial y} - \frac{1}{k^2}\frac{\partial^2\omega_y}{\partial z^2} \\ &+ \frac{1}{k^2}\frac{\partial^2\omega_y}{\partial x^2} + \frac{1}{k^2}\frac{\partial^2\omega_z}{\partial y\partial z}\Bigg) \end{aligned}$$

$$\begin{aligned} \tau_z = 2G\Bigg(&-\frac{1}{h^2}\frac{\partial^2\Delta}{\partial x\partial y} - \frac{1}{k^2}\frac{\partial^2\omega_y}{\partial y\partial z} - \frac{1}{k^2}\frac{\partial^2\omega_z}{\partial x^2} \\ &+ \frac{1}{k^2}\frac{\partial^2\omega_z}{\partial y^2} + \frac{1}{k^2}\frac{\partial^2\omega_x}{\partial x\partial z}\Bigg). \end{aligned}$$

TRANSMISSION OF PLANE WAVES THROUGH STRATIFIED SOLID PLATES

Choosing the coordinate axes as shown in Fig. 1, ω_x, ω_y and m will be zero. Considering the nth plate, the dilitation and rotation satisfying the wave equation are

$$\Delta=[\Delta' \exp(ih(l_\Delta x+n_\Delta z))+\Delta'' \exp(ih(l_\Delta x-n_\Delta z))]e^{ipt}$$
$$\omega=[\omega' \exp(ik(l_\omega x+n_\omega z))+\omega'' \exp(ik(l_\omega x-n_\omega z))]e^{ipt} \quad (6)$$

where the primed and double primed quantities represent the advancing and reflected waves. Substituting into Eq. (4) and (5) and omitting the trivial time factor, we obtain the following equations at $x=0$, $z=d$, and $x=0$, $z=0$, expressed in matrix form.

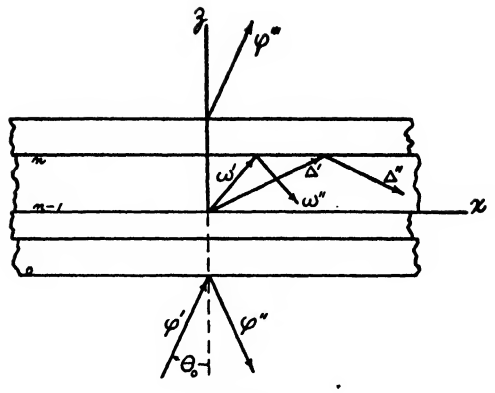

FIG. 1.

$$\begin{vmatrix} \xi_n \\ \zeta_n \\ \sigma_n \\ \frac{\tau_n}{2G} \end{vmatrix} = \begin{vmatrix} \frac{pl_\Delta}{h}\cos P & \frac{ipl_\Delta}{h}\sin P & \frac{2pn_\omega}{k}\cos Q & \frac{i2pn_\omega}{k}\sin Q \\ \frac{ipn_\Delta}{h}\sin P & \frac{pn_\Delta}{h}\cos P & -\frac{i2pl_\omega}{k}\sin Q & -\frac{2pl_\omega}{k}\cos Q \\ (\lambda+2Gn_\Delta^2)\cos P & i(\lambda+2Gn_\Delta^2)\sin P & -4Gl_\omega n_\omega \cos Q & -i4Gl_\omega n_\omega \sin Q \\ il_\Delta n_\Delta \sin P & l_\Delta n_\Delta \cos P & -i(l_\omega^2-n_\omega^2)\sin Q & -(l_\omega^2-n_\omega^2)\cos Q \end{vmatrix} \begin{vmatrix} \Delta'+\Delta'' \\ \Delta'-\Delta'' \\ \omega'-\omega'' \\ \omega'+\omega'' \end{vmatrix}, \quad (7)$$

$$\begin{vmatrix} \xi_{n-1} \\ \zeta_{n-1} \\ \sigma_{n-1} \\ \frac{\tau_{n-1}}{2G} \end{vmatrix} = \begin{vmatrix} \frac{pl_\Delta}{h} & 0 & \frac{2pn_\omega}{k} & 0 \\ 0 & \frac{pn_\Delta}{h} & 0 & -\frac{2pl_\omega}{k} \\ (\lambda+2Gn_\Delta^2) & 0 & -4Gl_\omega n_\omega & 0 \\ 0 & l_\Delta n_\Delta & 0 & -(l_\omega^2-n_\omega^2) \end{vmatrix} \begin{vmatrix} \Delta'+\Delta'' \\ \Delta'-\Delta'' \\ \omega'-\omega'' \\ \omega'+\omega'' \end{vmatrix}. \quad (8)$$

The inversion of Eq. (8) is

$$\begin{vmatrix} \Delta'+\Delta'' \\ \Delta'-\Delta'' \\ \omega'-\omega'' \\ \omega'+\omega'' \end{vmatrix} = \begin{vmatrix} -\frac{4Gl_\omega n_\omega}{D_1} & 0 & -\frac{2pn_\omega}{kD_1} & 0 \\ 0 & -\frac{(l_\omega^2-n_\omega^2)}{D_2} & 0 & \frac{2pl_\omega}{kD_2} \\ -\frac{(\lambda+2Gn_\Delta^2)}{D_1} & 0 & \frac{pl_\Delta}{hD_1} & 0 \\ 0 & -\frac{l_\Delta n_\Delta}{D_2} & 0 & \frac{pn_\Delta}{hD_2} \end{vmatrix} \begin{vmatrix} \xi_{n-1} \\ \zeta_{n-1} \\ \sigma_{n-1} \\ \frac{\tau_{n-1}}{2G} \end{vmatrix} \quad (9)$$

where

$$D_1=-\left[\frac{2pn_\omega}{k}(\lambda+2Gn_\Delta^2)+\frac{pl_\Delta}{h}4Gl_\omega n_\omega\right],$$
$$D_2=-\left[\frac{pn_\Delta}{h}(l_\omega^2-n_\omega^2)-\frac{2pl_\omega}{k}l_\Delta n_\Delta\right]. \tag{10}$$

Thus by substituting Eq. (9) in (7) we obtain the recurrence formula

$$\begin{bmatrix}\xi_n\\ \dot{\zeta}_n\\ \sigma_n\\ \dfrac{\tau_n}{2G}\end{bmatrix}=\begin{bmatrix}a_{11}&a_{12}&a_{13}&a_{14}\\ a_{21}&a_{22}&a_{23}&a_{24}\\ a_{31}&a_{32}&a_{33}&a_{34}\\ a_{41}&a_{42}&a_{43}&a_{44}\end{bmatrix}\begin{bmatrix}\xi_{n-1}\\ \dot{\zeta}_{n-1}\\ \sigma_{n-1}\\ \dfrac{\tau_{n-1}}{2G}\end{bmatrix} \tag{11}$$

where the expressions for the matrix elements are given in the Appendix.

The continuity of particle velocities and stresses at the interface enables one to express the quantities at the nth plate in terms of corresponding quantities at the first plate. Starting with Eq. (11) we can write

$$\begin{bmatrix}\xi_n\\ \dot{\zeta}_n\\ \sigma_n\\ \dfrac{\tau_n}{2G}\end{bmatrix}=[a_n]\,[a_{n-1}]\cdots[a_1]\begin{bmatrix}\xi_0\\ \dot{\zeta}_0\\ \sigma_0\\ \dfrac{\tau_0}{2G}\end{bmatrix}$$
$$=\begin{bmatrix}A_{11}&A_{12}&A_{13}&A_{14}\\ A_{21}&A_{22}&A_{23}&A_{24}\\ A_{31}&A_{32}&A_{33}&A_{34}\\ A_{41}&A_{42}&A_{43}&A_{44}\end{bmatrix}\begin{bmatrix}\xi_0\\ \dot{\zeta}_0\\ \sigma_0\\ \dfrac{\tau_0}{2G}\end{bmatrix} \tag{12}$$

where $[a_k]$ represents the square matrix of Eq. (11) for the kth plate.

The direction cosines l_Δ, n_Δ, l_ω and n_ω for each plate can be obtained from Snell's law.

$$\frac{\sin\theta_0}{c_0}=\frac{\sin\theta_\Delta}{c_\Delta}=\frac{\sin\theta_\omega}{c_\omega}. \tag{13}$$

Letting θ_1 and θ_2 be the critical angles for the dilation and shear waves respectively, it is apparent that for any plate there will be three regions for θ_0.

(1) When $0\leq\theta_0\leq\theta_1$, both θ_Δ and θ_ω will be real.
(2) When $\theta_1<\theta_0\leq\theta_2$, θ_Δ will be complex and θ_ω real.
(3) When $\theta_2<\theta_0\leq\pi/2$, both θ_Δ and θ_ω will be complex.

As an example, in region (2) we let $\theta_\Delta=\alpha+i\beta$ and obtain $\alpha=\pi/2$ and $\cosh\beta=(c_\Delta/c_0)\sin\theta_0$. Thus we replace $\sin\theta_\Delta$ and $\cos\theta_\Delta$ by $\cosh\beta$ and $i\sinh\beta$ respectively.

If the planes 0 and n terminate in a liquid medium, the shearing stresses τ_0 and τ_n must vanish, resulting in the boundary equation,

$$A_{41}\xi_0+A_{42}\dot{\zeta}_0+A_{43}\sigma_0=0. \tag{14}$$

Substituting Eq. (14) into Eq. (12) with $\tau_0=\tau_n=0$

$$\begin{bmatrix}\dot{\zeta}_n\\ \sigma_n\end{bmatrix}=\begin{bmatrix}\left(A_{22}-\dfrac{A_{21}A_{42}}{A_{41}}\right)&\left(A_{23}-\dfrac{A_{21}A_{43}}{A_{41}}\right)\\ \left(A_{32}-\dfrac{A_{31}A_{42}}{A_{41}}\right)&\left(A_{33}-\dfrac{A_{31}A_{43}}{A_{41}}\right)\end{bmatrix}\begin{bmatrix}\dot{\zeta}_0\\ \sigma_0\end{bmatrix}. \tag{15}$$

To determine the transmission and reflection, we have from Eq. (6) with $\omega=0$ for the liquid medium, the following.

$$\begin{aligned}\dot{\zeta}_n&=c_0n_0\varphi''' & \dot{\zeta}_0&=c_0n_0(\varphi'-\varphi'')\\ \sigma_n&=-c_0^2\rho_0\varphi''' & \sigma_0&=-c_0^2\rho_0(\varphi'+\varphi'')\end{aligned} \tag{16}$$

where φ', φ'' and φ''' represent the incident, reflected, and transmitted waves respectively. Substituting into Eq. (15) the reflection and transmission coefficients become,

$$R=\left|\frac{\varphi''}{\varphi'}\right|^2=\left|\frac{\begin{array}{l}[A_{22}-(A_{21}A_{42}/A_{41})]-[A_{33}-(A_{31}A_{43}/A_{41})]\\ \quad-[A_{23}-(A_{21}A_{43}/A_{41})](c_0\rho_0/n_0)+[A_{32}-(A_{31}A_{42}/A_{41})](n_0/c_0\rho_0)\end{array}}{\begin{array}{l}[A_{22}-(A_{21}A_{42}/A_{41})]+[A_{33}-(A_{31}A_{43}/A_{41})]\\ \quad+[A_{23}-(A_{21}A_{43}/A_{41})](c_0\rho_0/n_0)+[A_{32}-(A_{31}A_{42}/A_{41})](n_0/c_0\rho_0)\end{array}}\right|^2, \tag{17}$$

$$T=1-R. \tag{18}$$

SPECIAL CASES

The following special cases are of interest.

(1) Stratified medium is fluid, thus all shearing stresses are zero. Letting $G=Q=c_\omega=0$, we find that the 1st and 4th columns of $[a_k]$ are zero. This requires that all terms in $[A]$ vanish except the four central terms and we obtain the equations

$$\begin{bmatrix}\dot{\zeta}_n\\ \sigma_n\end{bmatrix}=\begin{bmatrix}A_{22}&A_{23}\\ A_{32}&A_{33}\end{bmatrix}\begin{bmatrix}\dot{\zeta}_0\\ \sigma_0\end{bmatrix} \tag{19}$$

$$R=\left|\frac{A_{22}-A_{33}-A_{23}(c_0\rho_0/n_0)+A_{32}(n_0/c_0\rho_0)}{A_{22}+A_{33}+A_{23}(c_0\rho_0/n_0)+A_{32}(n_0/c_0\rho_0)}\right|^2, \quad (20)$$

$$\begin{vmatrix} a_{22} & a_{23} \\ a_{32} & a_{33} \end{vmatrix} = \begin{vmatrix} \cosh nd & \frac{in}{c\rho}\sinh nd \\ \frac{ic\rho}{n}\sinh nd & \cosh nd \end{vmatrix}. \quad (21)$$

Thus for a single liquid layer we obtain the well-known relation (see Rayleigh, Part II, Eq. (10), p. 88)

$$R=\frac{[(n_1/n_0)(c_0\rho_0/c_1\rho_1)-(n_0/n_1)(c_1\rho_1/c_0\rho_0)]^2}{4\cot^2 h_1n_1d_1+[(n_1/n_0)(c_0\rho_0/c_1\rho_1)+(n_0/n_1)(c_1\rho_1/c_0\rho_0)]^2}. \quad (22)$$

(2) Stratified medium is solid, and the incident ray is normal to the plates. In this case the shears vanish and Eqs. (20), (21), and (22) become applicable with $n_0=n_1=1$.

(3) Transmission through a single solid plate at the critical angles.

(*a*) At the critical angle θ_1 for the dilation wave $l_\Delta=1$ and $n_\Delta=0$. Re-examination of Eqs. (7) and (8) shows that every term in the second row is zero which requires that the terms in the second row of Eq. (11) be also zero. Furthermore, Eq. (15) becomes

$$\begin{vmatrix} \dot{\zeta}_1 \\ \sigma_1 \end{vmatrix} = \begin{vmatrix} 0 & \left(a_{23}-a_{21}\frac{a_{43}}{a_{41}}\right) \\ 0 & \left(a_{33}-a_{31}\frac{a_{43}}{a_{41}}\right) \end{vmatrix} \begin{vmatrix} \dot{\zeta}_0 \\ \sigma_0 \end{vmatrix} \quad (23)$$

and the ratio φ''/φ' reduces to

$$\frac{\varphi''}{\varphi'}=\frac{[a_{23}-a_{21}(a_{43}/a_{41})]-[a_{33}-a_{31}(a_{43}/a_{41})]}{[a_{23}-a_{21}(a_{43}/a_{41})]+[a_{33}-a_{31}(a_{43}/a_{41})]}. \quad (24)$$

Re-evaluating a_{ij}, it can be shown that $[a_{23}-a_{21}(a_{43}/a_{41})]=0$ and $[a_{33}-a_{31}(a_{43}/a_{41})]\neq 0$, thus $\varphi''/\varphi'=-1$ and the transmission is zero.[7]

(*b*) At the critical angle θ_2 for the shear wave $l_\omega=1$ and $n_\omega=0$. We find for this case that the first and third rows in Eq. (11) are zeros. Consequently

$$\frac{\varphi''}{\varphi'}=\frac{(a_{22}/a_{32})-1}{(a_{22}/a_{32})+1} \quad (25)$$

which is equal to -1 only if $a_{22}=0$ and $a_{23}\neq 0$. Thus we find no transmission at θ_2 if the relationship

$$\cosh n_\Delta d=2l_\Delta(c_\omega/c_\Delta) \quad (26)$$

is satisfied, where n_Δ and l_Δ are the direction cosines corresponding to θ_2.

[7] W. C. Schneider and C. J. Burton, J. App. Phys. **20**, 48–58 (1949).

APPENDIX

Matrix elements for Eq. (11) are given with the following substitution.

$$\frac{p}{h}=c_\Delta \qquad n_\Delta=\cos\theta_\Delta$$

$$\frac{p}{k}=c_\omega \qquad n_\omega=\cos\theta_\omega$$

$$G=\rho c_\omega^2 \qquad l_\Delta=\sin\theta_\Delta$$

$$(\lambda+2Gn_\Delta^2)=\rho c_\Delta^2\cos 2\theta_\omega \qquad l_\omega=\sin\theta_\omega$$

$$D_1=-2\rho c_\Delta c_\omega[c_\omega\sin\theta_\Delta\sin 2\theta_\omega+c_\Delta\cos\theta_\omega\cos 2\theta_\omega]$$

$$D_2=[c_\Delta\cos\theta_\Delta\cos 2\theta_\omega+c_\omega\sin\theta_\omega\sin 2\theta_\Delta]$$

$$a_{11}=-\frac{2\rho c_\Delta c_\omega}{D_1}[c_\omega\sin\theta_\Delta\sin 2\theta_\omega\cos P+c_\Delta\cos\theta_\omega\cos 2\theta_\omega\cos Q]$$

$$a_{13}=-\frac{2c_\Delta c_\omega\sin\theta_\Delta\cos\theta_\omega}{D_1}[\cos P-\cos Q]$$

$$a_{21}=-\frac{2ic_\Delta c_\omega\rho}{D_1}[c_\omega\cos\theta_\Delta\sin 2\theta_\omega\sin P-c_\Delta\sin\theta_\omega\cos 2\theta_\omega\sin Q]$$

$$a_{23}=-\frac{2ic_\Delta c_\omega}{D_1}[\cos\theta_\Delta\cos\theta_\omega\sin P+\sin\theta_\Delta\sin\theta_\omega\sin Q]$$

$$a_{31}=-\frac{2c_\Delta^2c_\omega^2\rho^2}{D_1}\sin 2\theta_\omega\cos 2\theta_\omega[\cos P-\cos Q]$$

$$a_{33}=-\frac{2c_\Delta c_\omega\rho}{D_1}[c_\Delta\cos\theta_\omega\cos 2\theta_\omega\cos P+c_\omega\sin\theta_\Delta\sin 2\theta_\omega\cos Q]$$

$$a_{41}=\frac{-i\rho}{D_1}[c_\omega^2\sin 2\theta_\Delta\sin 2\theta_\omega\sin P+c_\Delta^2\cos^2 2\theta_\omega\sin Q]$$

$$a_{43}=-\frac{i}{D_1}[c_\omega\cos\theta_\omega\sin 2\theta_\Delta\sin P-c_\Delta\sin\theta_\Delta\cos 2\theta_\omega\sin Q]$$

$$a_{12}=\frac{-i}{D_2}[c_\Delta\sin\theta_\Delta\cos 2\theta_\omega\sin P+c_\omega\cos\theta_\omega\sin 2\theta_\Delta\sin Q]$$

$$a_{14}=-\frac{2ic_\Delta c_\omega}{D_2}[\sin\theta_\Delta\sin\theta_\omega\sin P+\cos\theta_\Delta\cos\theta_\omega\sin Q]$$

$$a_{22}=\frac{1}{D_2}[c_\Delta\cos\theta_\Delta\cos 2\theta_\omega\cos P+c_\omega\sin\theta_\omega\sin 2\theta_\Delta\cos Q]$$

$$a_{24}=\frac{2c_\Delta c_\omega\sin\theta_\omega\cos\theta_\Delta}{D_2}[\cos P-\cos Q]$$

$$a_{32}=\frac{i\rho}{D_2}[c_\Delta^2\cos^2 2\theta_\omega\sin P+c_\omega^2\sin 2\theta_\Delta\sin 2\theta_\omega\sin Q]$$

$$a_{34}=\frac{2i\rho c_\Delta c_\omega}{D_2}[c_\Delta\sin\theta_\omega\cos 2\theta_\omega\sin P-c_\omega\cos\theta_\Delta\sin 2\theta_\omega\sin Q]$$

$$a_{42}=\frac{\sin 2\theta_\Delta\sin 2\theta_\omega}{2D_2}[\cos P-\cos Q]$$

$$a_{44}=\frac{1}{D_2}[c_\omega\sin\theta_\omega\sin 2\theta_\Delta\cos P+c_\Delta\cos\theta_\Delta\cos 2\theta_\omega\cos Q].$$

The Theory of N Coupled Parallel Antennas*

RONOLD KING
Cruft Laboratory, Harvard University, Cambridge, Massachusetts
(Received July 21, 1949)

The integral-equation theory of coupled antennas developed by King and Harrison, Tai and Bouwkamp for two- and three-coupled antennas is generalized to any number of units symmetrically arranged around a circle. The case of four antennas at the corners of a square is discussed in detail. Application to cage and corner-reflector antennas is indicated.

The analysis of N parallel antennas arranged in line is carried out to determine the driving voltages required to maintain specified currents. It is shown that the inverse problem cannot be carried out in general except as a problem in simultaneous integral equations, but that the special conditions obtaining for half-wave dipoles permit an approximate analysis for the currents with given voltages. This is carried through.

1. GENERAL THEORY

THE conventional method of calculating the mutual impedance of two antennas[1-4] is based on assumed sinusoidally distributed currents on the antennas. A more rigorous method due to King and Harrison[5] and, independently, Bouwkamp,[6] solves the simultaneous integral equations for the currents in two coupled antennas and defines the self- and mutual impedances of the antennas as the coefficients of the currents in the simultaneous voltage equations. This method was improved by C. T. Tai[7] and generalized from two antennas to three arranged at the vertices of an equilateral triangle. Tai extended the analysis to N antennas symmetrically arranged in a circle only in certain special cases. This paper removes the limitations unnecessarily imposed by Tai.

The arrays of antennas to be discussed consist of N geometrically identical units each of half-length h and radius a that satisfy the inequalities, $\beta_0 a = 2\pi a/\lambda_0 \ll 1$, $a \ll h$. The several units may be center-driven by arbitary voltages or center-loaded by different impedances provided the assumed geometrical identity of the units is not significantly disturbed by the driving or load connections or the structure of generators or impedors. In practice, this means either that the driving and load connections are all alike—as when similar open-wire lines are used between all antennas and the generators or loads—or that generators and loads or the cross-sectional dimensions of transmission lines are so small in physical size that generators and loads are equivalent to dimensionless, lumped elements.

The discussion is limited to arrays of *parallel* antennas so that all currents that contribute significantly to the far-zone field are co-directional and, hence, maintain a vector potential that has no component perpendicular to the antennas that are assumed to be parallel to the z-axis of a coordinate system. That is, $\mathbf{A} = \mathfrak{z}\mathbf{A}_z$.

Each antenna is required to have geometrical symmetry with respect to its center, and it must be center-driven or center-loaded. Furthermore, all elements have their centers in the xy-plane, i.e., they are not staggered. These conditions are imposed in order that the currents and vector potentials be even functions of z, the charges and scalar potentials odd functions of z. Thus, with complex quantities set in bold face,

$$\mathbf{I}_z(-z) = \mathbf{I}_z(z); \quad \mathbf{q}(-z) = -\mathbf{q}(z), \tag{1}$$

$$\mathbf{A}_z(-z) = \mathbf{A}_z(z); \quad \boldsymbol{\phi}(-z) = -\boldsymbol{\phi}(z). \tag{2}$$

Let it be assumed at the outset that all generators are "slice" generators, i.e., discontinuities in scalar potential, and all load impedances or tuning reactances lumped or geometrically dimensionless. These assumptions eliminate complications arising from transmission-line end-effects and coupling effects that are necessarily characteristic of particular driving and coupling circuits. Since such junction-effects are localized, they do not alter the formulation of the general problems of coupled antennas, and account may be taken of them later using appropriately designed corrective networks of lumped elements.[8,9] Accordingly, let the driving

voltage at the center of a typical antenna k be defined as follows:

$$\mathbf{V}_{k0}=\lim_{\delta\to 0}[\phi_k(\delta)-\phi_k(-\delta)]. \quad (3)$$

If the several conditions which have been imposed thus far are satisfied, the vector potential, $\mathbf{A}_z(z)$, on the surface of each of the N antennas satisfies the same one-dimensional wave equation as when the antenna is isolated. For example, on the surface of the kth antenna the equation is:

$$\partial^2\mathbf{A}_{kz}(z)/\partial z^2+\beta_0^2\mathbf{A}_{kz}(z)=j(\beta_0^2/\omega)\mathbf{z}^i\mathbf{I}_{kz}(z)\doteq 0. \quad (4)$$

For simplicity, the term which has the internal impedance per unit length, $\mathbf{z}^i$, as a factor is set equal to zero. For good conductors its effect is negligibly small. If desired, the appropriate terms are easily added to the final solution. The general solution of the homogeneous equation for the range $0\leqq z\leqq h$ is[10]

$$\mathbf{A}_{kz}(z)=-(j/v_0)[\mathbf{C}_k\cos\beta_0 z+\tfrac{1}{2}\mathbf{V}_{k0}\sin\beta_0 z]. \quad (5)$$

The arbitrary constant $\mathbf{C}_k$ must be determined from the boundary condition at $z=h$.

The integral for the vector potential at a point z on the surface of antenna k is as follows

$$\mathbf{A}_{kz}(z)=\frac{1}{4\pi v_0}\int_{-h}^{h}\sum_{i=1}^{N}\mathbf{I}_i(z_i')\frac{\exp(-j\beta_0 R_{ki})}{R_{ki}}dz_i', \quad (6a)$$

where

$$R_{ki}=((z_k-z_i')^2+b_{ki}^2)^{\frac{1}{2}};\quad R_{kk}=((z_k-z_k')^2+a^2)^{\frac{1}{2}}. \quad (6b)$$

Subscripts are used on the coordinate z where necessary to indicate on which antenna the distance from the xy-plane is measured. Note that the primed coordinates locate an element of integration on the axis of an antenna, the unprimed coordinates an element on the surface; b_{ki} is the distance between the axes of antenna i and antenna k.

The substitution of (6a) in (5) gives one of N simultaneous integral equations for the N currents in the N coupled elements of the array. As usual $\zeta_0=v_0/\nu_0\doteq 376.7$ ohms.

$$\int_{-h}^{h}\sum_{i=1}^{N}\mathbf{I}_{iz}(z_i')\frac{\exp(-j\beta_0 R_{ki})}{R_{ki}}dz_i'=\frac{-j4\pi}{\zeta_0}[\mathbf{C}_k\cos\beta_0 z+\tfrac{1}{2}\mathbf{V}_{k0}\sin\beta_0 z];\quad k=1,2,\cdots N. \quad (7)$$

Since the solution of N simultaneous integral equations of this type has not been accomplished even for $N=2$, the only cases for which a solution is available are those in which all the N equations are alike, so that they reduce to only a single equation. Evidently, such a reduction involves restrictions in addition to those already imposed. Mathematically it implies that the current $\mathbf{I}_{kz}(z')$, which is included in the sum in (7), can be factored out in front of the sign of summation and the remaining sum is a constant that does not vary with the numerical value of k. That is, the desired equation must have the following form:

$$\int_{-h}^{h}\mathbf{I}_{kz}(z_k')\mathbf{K}_\Sigma(z,z')dz_k'=\frac{-j4\pi}{\zeta_0}[\mathbf{C}_k\cos\beta_0 z+\tfrac{1}{2}\mathbf{V}_{k0}\sin\beta_0 z], \quad (8a)$$

where

$$\mathbf{K}_\Sigma(z,z')=\sum_{i=1}^{N}\left[\frac{\mathbf{I}_{iz}(z_i')}{\mathbf{I}_{ik}(z_k')}\exp(-j\beta_0 R_{ik})\right]\frac{1}{R_{ik}}$$

is independent of k, (8b)

and

$$R_{ik}=((z_i-z_k')+b_{ik}^2)^{\frac{1}{2}};\quad R_{kk}=((z_k-z_k')^2+a^2)^{\frac{1}{2}}. \quad (8c)$$

Evidently, this is not true in general. It is necessary that both the ratio of currents and the function of R_{ik} be independent of k.

Physically, the reduction of the N simultaneous integral equations to a single equation necessarily means that the N units are electrically and geometrically indistinguishable. These conditions certainly require the antennas to be located at the corners of an N-sided equilateral polygon. If this is true

$$\sum_{i=1}^{N}\exp(-j\beta_0 R_{ik})/R_{ik}$$

is obviously independent of k. The simplest way to make the current ratio in (8b) independent of k is to require all currents to be equal in magnitude and in phase, a condition achieved by identical driving voltages on all units. However, this condition is severer than required. Another, somewhat more general possibility is to have the current in each unit equal in magnitude but differing in phase from the next unit around the polygon by a fixed angle $m\theta$. That is,

$$\mathbf{I}_{iz}(z')=\mathbf{I}_{i-1,z}(z')p^m;\quad m=0,1,2,\cdots N-1, \quad (9a)$$

where

$$p=e^{j\theta};\quad \theta=2\pi/N. \quad (9b)$$

Or, more generally,

$$\mathbf{I}_{iz}(z')=\mathbf{I}_{kz}(z')\mathbf{p}^{(i-k)m}. \quad (10)$$

With (9a) substituted in (7), this reduces to the desired form (8a) with

$$\mathbf{K}_\Sigma(z,z')=\sum_{i=1}^{N}\mathbf{p}^{(i-k)m}\frac{\exp(-j\beta_0 R_{ik})}{R_{ik}}. \quad (11)$$

[10] R. King and D. Middleton, "The cylindrical antenna; current and impedance," Quart. App. Math. 3, 302-335 (1946).

Note that the variable of integration is changed from z_i' to z_k'. Obviously (8c) and (6b) are expressions for the *same* distances. It is readily shown that (11) is independent of k by adding an arbitrary integer q to k. Since the *order* of summation makes no difference, the same integer q may be added to i to give $i'=i+q$. The limits of summation of i' are the same as for i. Thus,

$$\mathbf{K}_\Sigma(z, z') = \sum_{i'=1}^{N} \mathbf{p}^{(i'-k-q)} \frac{\exp(-j\beta_i R_{i'k+q})}{R_{i'k+q}}. \tag{12}$$

Since $i'-k-q=i-q$, and geometrical symmetry makes

$$R_{ik} = R_{i+q,\,k+q}, \tag{13}$$

it follows that (12) is identically the same as (11). Since $\mathbf{K}_\Sigma(z, z')$ is independent of k, it is convenient to choose $k=1$ and define the kernel $\mathbf{K}_\Sigma(z, z')$ as follows:

$$\mathbf{K}_{\Sigma m}(z, z') = \sum_{i=1}^{N} \mathbf{p}^{(i-l)m} \frac{\exp(-j\beta_0 R_{il})}{R_{il}}. \tag{14}$$

Currents of equal magnitude and with a progressive, constant phase difference around the symmetrically located units are possible only when the driving voltages are equal in magnitude and have the same phase relations as the currents. That is

$$\mathbf{V}_{i0} = \mathbf{V}_{k0}\mathbf{p}^{(i-k)m}. \tag{15}$$

Since the constant $\mathbf{C}_k$ in (8a) has $\mathbf{V}_{k0}$ as a factor when it is evaluated, it follows that multiplication of (8a) by $\mathbf{p}^{(i-k)m}$ on both sides changes it to an equation for antenna i instead of for antenna k.

The integral equation for the current in the upper half of each antenna in the symmetrical array is:

$$\int_{-h}^{h} \mathbf{I}(z')\mathbf{K}_{\Sigma m}(z, z')dz' = \frac{-j4\pi}{\zeta_0}[\mathbf{C}\cos\beta_0 z + \tfrac{1}{2}\mathbf{V}_0 \sin\beta_0 z], \tag{16}$$

with $\mathbf{K}_{\Sigma m}(z, z')$ given in (14). This equation is formally exactly like that for two coupled antennas.[7] However, the kernel is more complicated since it involves N terms instead of two. The solution of (16) evidently is the same as for two antennas with $\mathbf{K}_{\Sigma m}(z, z')$ substituted for $\mathbf{K}_s(z, z')$. By mere changes in notation an expression for the current is obtained with an expansion parameter defined in terms of $\mathbf{K}_{\Sigma m}(z, z')$ instead of $\mathbf{K}_s(z, z')$. The current so obtained applies to any one of the N units, say antenna 1. Currents in the other units are obtained by multiplying this current by $\mathbf{p}^{m(i-1)}$ with $i=2, 3, \cdots N$.

It has been shown that the general problem of N-coupled, parallel, identical, non-staggered antennas reduces to a single integral equation that is like the equation for an isolated antenna provided the antennas are all located at the corners of a regular polygon and provided they are individually excited by generators or transmission lines that maintain voltages across their terminals that are equal in magnitude and vary progressively in phase by a constant angle from unit to unit around the polygon. For an array of N antennas the constant phase angle may have any one of the values $m\theta$ where $\theta=2\pi/N$ and m is an integer less than N. Since $m=0$ is a possible value, it is seen that there are N available and different angles for each of which a single integral equation governs all currents. These N possible values of m are called *phase sequences*, as is customary in the well-known method of symmetrical components. They may be defined as follows:

Zero phase sequence:

$$m=0: \quad \mathbf{V}_{10}=\mathbf{V}_{20}=\mathbf{V}_{30}=\cdots=\mathbf{V}_{N0}=\mathbf{V}^{(0)}; \quad \mathbf{I}_{10}=\mathbf{I}_{20}=\mathbf{I}_{30}=\cdots=\mathbf{I}_{N0}=\mathbf{I}^{(0)}. \tag{17a}$$

$2\pi/N$ phase sequence:

$$m=1: \quad \mathbf{V}_{10}=\mathbf{V}^{(1)};\ \mathbf{V}_{20}=\mathbf{p}\mathbf{V}^{(1)};\ \mathbf{V}_{30}=\mathbf{p}^2\mathbf{V}^{(1)};\ \cdots;\ \mathbf{V}_{N0}=\mathbf{p}^{N-1}\mathbf{V}^{(1)}; \quad \mathbf{I}_{10}=\mathbf{I}^{(1)};\ \mathbf{I}_{20}=\mathbf{p}\mathbf{I}^{(1)};\ \mathbf{I}_{30}=\mathbf{p}^2\mathbf{I}^{(1)};\ \cdots;\ \mathbf{I}_{N0}=\mathbf{p}^{N-1}\mathbf{I}^{(1)}. \tag{17b}$$

$4\pi/N$ phase sequence:

$$m=2: \quad \mathbf{V}_{10}=\mathbf{V}^{(2)};\ \mathbf{V}_{20}=\mathbf{p}^2\mathbf{V}^{(2)};\ \mathbf{V}_{30}=\mathbf{p}^4\mathbf{V}^{(2)};\ \cdots;\ \mathbf{V}_{N0}=\mathbf{p}^{2N-2}\mathbf{V}^{(2)}; \quad \mathbf{I}_{10}=\mathbf{I}^{(2)};\ I_{20}=\mathbf{p}^2\mathbf{I}^{(2)};\ I_{30}=\mathbf{p}^4\mathbf{I}^{(2)};\ \cdots;\ \mathbf{I}_{N0}=\mathbf{p}^{2N-2}\mathbf{I}^{(2)}. \tag{17c}$$

$2m\pi/N$ phase sequence:

$$m=m: \quad \mathbf{V}_{10}=\mathbf{V}^{(m)};\ \mathbf{V}_{20}=\mathbf{p}^m\mathbf{V}^{(m)};\ \mathbf{V}_{30}=\mathbf{p}^{2m}\mathbf{V}^{(m)};\ \cdots;\ \mathbf{V}_{N0}=\mathbf{p}^{mN-m}\mathbf{V}^{(m)}; \quad \mathbf{I}_{10}=\mathbf{I}^{(m)};\ \mathbf{I}_{20}=\mathbf{p}^m\mathbf{I}^{(m)};\ \mathbf{I}_{30}=\mathbf{p}^{2m}I^{(m)};\ \cdots;\ \mathbf{I}_{N0}=\mathbf{p}^{mN-m}\mathbf{I}^{(m)}. \tag{17d}$$

$2(N-1)\pi/N$ phase sequence:

$$m=N-1: \quad \mathbf{V}_{10}=\mathbf{V}^{(N-1)};\ \mathbf{V}_{20}=\mathbf{p}^{N-1}\mathbf{V}^{(N-1)};\ \mathbf{V}_{30}=\mathbf{p}^{2N-2}\mathbf{V}^{(N-1)};\ \cdots;\ \mathbf{V}_{N0}=\mathbf{p}^{N^2-2N+1}\mathbf{V}^{(N-1)}; \quad \mathbf{I}_{10}=\mathbf{I}^{(N-1)};\ \mathbf{I}_{20}=\mathbf{p}^{N-1}\mathbf{I}^{(N-1)};\ \mathbf{I}_{30}=\mathbf{p}^{2N}\mathbf{I}^{(N-1)};\ \cdots;\ \mathbf{I}_{N0}=\mathbf{p}^{N^2-2N+1}\mathbf{I}^{(N-1)}. \tag{17e}$$

Note that superscripts on $\mathbf{p}$ are powers, superscripts on $\mathbf{V}$ and $\mathbf{I}$ are written in parentheses and denote phase-sequence numbers. Note also that

$$\mathbf{p}^N = e^{j2\pi} = 1;\ \mathbf{p}^{N/2} = e^{j\pi} = -1; \quad \mathbf{p}^{N/4} = e^{j\pi/2} = j;\ \mathbf{p}^{3N/4} = e^{j3\pi/2} = -j. \tag{18}$$

The current $\mathbf{I}^{(m)}$ in each antenna can be determined independently for each phase sequence with an arbitrary value of driving voltage $\mathbf{V}^{(m)}$ using (16). If each antenna is imagined to be driven by all voltages in all N

phase sequences simultaneously, with the N voltages in each unit in series, the following driving voltages apply:

$$\mathbf{V}_{10}=\mathbf{V}^{(0)}+\mathbf{V}^{(1)}+\mathbf{V}^{(2)}+\cdots+\mathbf{V}^{(N-1)}=\sum_{i=0}^{N-1}\mathbf{V}^{(i)} \tag{19a}$$

$$\mathbf{V}_{20}=\mathbf{V}^{(0)}+\mathbf{p}\mathbf{V}^{(1)}+\mathbf{p}^2\mathbf{V}^{(2)}+\cdots+\mathbf{p}^{N-1}\mathbf{V}^{(N-1)}=\sum_{i=0}^{N-1}\mathbf{p}^i\mathbf{V}^{(i)} \tag{19b}$$

$$\mathbf{V}_{30}=\mathbf{V}^{(0)}+\mathbf{p}^2\mathbf{V}^{(1)}+\mathbf{p}^4\mathbf{V}^{(2)}+\cdots+\mathbf{p}^{2N-2}\mathbf{V}^{(N-1)}=\sum_{i=0}^{N-1}\mathbf{p}^{2i}\mathbf{V}^{(i)} \tag{19c}$$

$$\vdots$$

$$\mathbf{V}_{N0}=\mathbf{V}^{(0)}+\mathbf{p}^{N-1}\mathbf{V}^{(1)}+\mathbf{p}^{2N-2}\mathbf{V}^{(2)}+\cdots+\mathbf{p}^{N-2N+1}\mathbf{V}^{(N-1)}=\sum_{i=0}^{N-1}\mathbf{p}^{Ni-i}\mathbf{V}^{(i)}. \tag{19d}$$

Similarly the resultant currents in the antennas are:

$$\mathbf{I}_{10}=\sum_{i=0}^{N-1}\mathbf{I}^{(i)} \tag{20a}$$

$$\mathbf{I}_{20}=\sum_{i=0}^{N-1}\mathbf{p}^i\mathbf{I}^{(i)} \tag{20b}$$

$$\vdots$$

$$\mathbf{I}_{N0}=\sum_{i=0}^{N-1}\mathbf{p}^{Ni-i}\mathbf{I}^{(i)}. \tag{20c}$$

Since the N voltages $\mathbf{V}^{(i)}$, $i=0, 1, 2, \cdots N-1$, are arbitrary, it is possible to determine a set of N such voltages which satisfy (19a-d) for all possible values of $\mathbf{V}_{10}, \mathbf{V}_{20}, \cdots \mathbf{V}_{N0}$. That is, the general problem of solving for the N currents in N coupled antennas located at the corners of a regular polygon may be carried out by first solving for the N independent currents due to voltages chosen to satisfy the conditions of the N phase sequences. An appropriate superposition of these N solutions yields the currents and impedances in all units due to an arbitrary set of driving voltages.

As a simple illustration, let the general theory be applied to two coupled antennas. In this case $N=2$ and m is restricted to the values 0 and 1. That is, there are two phase sequences, the zero phase sequence previously called the symmetrical case, and the π phase-sequence previously called the antisymmetrical case.

Equations corresponding to (19) and (20) are

$$\mathbf{V}_{10}=\mathbf{V}^{(0)}+\mathbf{V}^{(1)}=\mathbf{V}^{s}+\mathbf{V}^{a}, \tag{21a}$$

$$\mathbf{V}_{20}=\mathbf{V}^{(0)}+\mathbf{p}\mathbf{V}^{(1)}=\mathbf{V}^{(0)}-\mathbf{V}^{(1)}=\mathbf{V}^{s}-\mathbf{V}^{a}. \tag{21b}$$

The corresponding kernels for the integral equation are obtained from (14) with $m=0$ and 1 to be

$$\mathbf{K}_{\Sigma 0}(z, z')\equiv\mathbf{K}_{s}(z, z')=\frac{\exp(-j\beta_0 R_{11})}{R_{11}}+\frac{\exp(-j\beta_0 R_{12})}{R_{12}} \tag{22a}$$

$$\mathbf{K}_{\Sigma 1}(z, z')\equiv\mathbf{K}_{a}(z, z')=\frac{\exp(-j\beta_0 R_{11})}{R_{11}}+\frac{\exp(-j\beta_0 R_{12})}{R_{12}}. \tag{22b}$$

These results are the same as previously obtained.[7] The theory for N antennas in terms of N phase sequences is a simple generalization of the theory developed by Tai for two and three antennas with two and three phase sequences. Its application to four antennas follows.

2. FOUR ANTENNAS AT CORNERS OF A SQUARE

The integral equation for the current in the upper half of each of four identical, parallel, non-staggered antennas placed at the corners of a square of side $b_{12}=b$ and diagonal $b_{13}=b\sqrt{2}$ is the same as (1.16). The kernel in this case is obtained from (1.15) with $n=4$. It is

$$\mathbf{K}_{\Sigma m}(z, z')=\frac{\exp(-j\beta_0 R_{11})}{R_{11}}+\mathbf{p}^m\frac{\exp(-j\beta_0 R_{12})}{R_{12}}+\mathbf{p}^{2m}\frac{\exp(-j\beta_0 R_{13})}{R_{13}}+\mathbf{p}^{3m}\frac{\exp(-j\beta_0 R_{14})}{R_{14}} \tag{1}$$

where

$$\mathbf{p}=e^{j\theta};\ \theta=\pi/2 \tag{2a}$$

so that

$$\mathbf{p}=j;\ \mathbf{p}^2=-1;\ \mathbf{p}^3=-j;\ \mathbf{p}^4=1. \tag{2b}$$

With $n=4$, it follows that

$$m=0, 1, 2, 3. \tag{4}$$

The four phase sequences are illustrated schematically in Fig. 1. They include the zero-phase sequence ($m=0$) with all antennas in phase; the $\pi/4$ or positive phase sequence ($m=1$) with antenna $k+1$ leading antenna k by $\pi/4$, $k=1, 2, 3, 4$; the π-phase sequence ($m=2$) with currents alternating in direction around the square; and the $3\pi/4$, $-\pi/4$, or negative phase sequence with antenna $k+1$ leading antenna k by $3\pi/4$, $k=1, 2, 3, 4$.

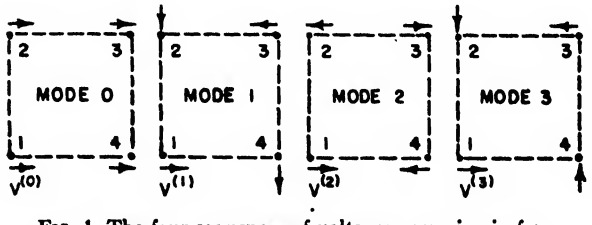

FIG. 1. The four sequences of voltages occurring in four coupled antennas.

The four kernels are

$$m=0:\quad \mathbf{K}_{\Sigma 0}(z,z')=\frac{\exp(-j\beta_0 R_{11})}{R_{11}}+\frac{\exp(-j\beta_0 R_{12})}{R_{12}}+\frac{\exp(-j\beta_0 R_{13})}{R_{13}}+\frac{\exp(-j\beta_0 R_{14})}{R_{14}} \tag{5a}$$

$$m=1:\quad \mathbf{K}_{\Sigma 1}(z,z')=\frac{\exp-(j\beta_0 R_{11})}{R_{11}}+j\frac{\exp(-j\beta_0 R_{12})}{R_{12}}-\frac{\exp(-j\beta_0 R_{13})}{R_{13}}-j\frac{\exp(-j\beta_0 R_{14})}{R_{14}} \tag{5b}$$

$$m=2:\quad \mathbf{K}_{\Sigma 2}(z,z')=\frac{\exp(-j\beta_0 R_{11})}{R_{11}}-\frac{\exp(-j\beta_0 R_{12})}{R_{12}}+\frac{\exp(-j\beta_0 R_{13})}{R_{13}}-\frac{\exp(-j\beta_0 R_{14})}{R_{14}} \tag{5c}$$

$$m=3:\quad \mathbf{K}_{\Sigma 3}(z,z')=\frac{\exp(-j\beta_0 R_{11})}{R_{11}}-\frac{\exp(-j\beta_0 R_{12})}{R_{12}}-\frac{\exp(-j\beta_0 R_{13})}{R_{13}}+j\frac{\exp(-j\beta_0 R_{14})}{R_{14}}. \tag{5d}$$

These expressions can be simplified if use is made of the geometrical condition $R_{12}=R_{14}$ with which (5) becomes

$$m=0:\quad \mathbf{K}_{\Sigma 0}(z,z')=\frac{\exp(-j\beta_0 R_{11})}{R_{11}}+2\frac{\exp(-j\beta_0 R_{12})}{R_{12}}+\frac{\exp(-j\beta_0 R_{13})}{R_{13}} \tag{6a}$$

$$m=1,3:\quad \mathbf{K}_{\Sigma 1}(z,z')=\mathbf{K}_{\Sigma 3}(z,z')=\frac{\exp(-j\beta_0 R_{11})}{R_{11}}-\frac{\exp(-j\beta_0 R_{13})}{R_{13}} \tag{6b}$$

$$m=2:\quad \mathbf{K}_{\Sigma 2}(z,z')=\frac{\exp(-j\beta_0 R_{11})}{R_{11}}-2\frac{\exp(-j\beta_0 R_{12})}{R_{12}}+\frac{\exp(-j\beta_0 R_{13})}{R_{13}}. \tag{6c}$$

If these three kernels are substituted in

$$\Psi_{\Sigma m}(z)\sin\beta_0(h-|z|)=\int_{-h}^{h}\mathbf{K}_{\Sigma m}(z,z')\sin\beta_0(h-z')dz', \tag{7a}$$

the corresponding expansion parameters may be evaluated from

$$\Psi_{\Sigma m}=\left\{\begin{array}{ll}|\Psi_{\Sigma m}(0)|; & \beta_0 h\leqq\pi/2\\ |\Psi_{\Sigma m}(h-\lambda_0/4)|; & \beta_0 h\geqq\pi/2\end{array}\right\} \tag{7b}$$

with

$$\Psi_{\Sigma 0}(z)\sin\beta_0(h-z)=[C_a(h,z)+2C_b(h,z)+C_c(h,z)]\sin\beta_0 h+[S_a(h,z)+2S_b(h,z)+S_c(h,z)]\cos\beta_0 h. \tag{8a}$$

$$\mathbf{I}_{\Sigma 1}(z)\sin\beta_0(h-z)=[C_a(h,z)-C_c(h,z)]\sin\beta_0 h+[S_a(h,z)-S_c(h,z)]\cos\beta_0 h \tag{8b}$$

$$\mathbf{I}_{\Sigma 2}(z)\sin\beta_0(h-z)=[C_a(h,z)-2C_b(h,z)+C_c(h,z)]\sin\beta_0 h+[S_a(h,z)-2S_b(h,z)+S_c(h,z)]\cos\beta_0 h. \tag{8c}$$

The function $C_c(h,z)$ and $S_c(h,z)$ are like the corresponding functions with subscript a defined by Tai[7] with c substituted for a, where $c=b_{13}=b\sqrt{2}$.

With the expansion parameters for the four phase sequences evaluated, the corresponding currents and impedances may be determined just as for two and three antennas.

The general case in which each of the four antennas is driven by an arbitrary voltage may be solved by superposition using the following relations:

$$\mathbf{V}_{10}=\mathbf{V}^{(0)}+\mathbf{V}^{(1)}+\mathbf{V}^{(2)}+\mathbf{V}^{(3)} \tag{9a}$$

$$\mathbf{V}_{20}=\mathbf{V}^{(0)}+j\mathbf{V}^{(1)}-\mathbf{V}^{(2)}-j\mathbf{V}^{(3)} \tag{9b}$$

$$\mathbf{V}_{30}=\mathbf{V}^{(0)}-\mathbf{V}^{(1)}+\mathbf{V}^{(2)}-\mathbf{V}^{(3)} \tag{9c}$$

$$\mathbf{V}_{40}=\mathbf{V}^{(0)}-j\mathbf{V}^{(1)}-\mathbf{V}^{(2)}+j\mathbf{V}^{(3)}. \tag{9d}$$

Alternatively, solving for the phase-sequence voltages,

$$\mathbf{V}^{(0)}=\tfrac{1}{4}(\mathbf{V}_{10}+\mathbf{V}_{20}+\mathbf{V}_{30}+\mathbf{V}_{40}) \tag{10a}$$

$$\mathbf{V}^{(1)}=\tfrac{1}{4}(\mathbf{V}_{10}-j\mathbf{V}_{20}-\mathbf{V}_{30}+j\mathbf{V}_{40}) \tag{10b}$$

$$\mathbf{V}^{(2)}=\tfrac{1}{4}(\mathbf{V}_{10}-\mathbf{V}_{20}+\mathbf{V}_{30}-\mathbf{V}_{40}) \tag{10c}$$

$$\mathbf{V}^{(3)}=\tfrac{1}{4}(\mathbf{V}_{10}+j\mathbf{V}_{20}-\mathbf{V}_{30}-j\mathbf{V}_{40}). \tag{10d}$$

The same equations apply to the currents if I is substituted for V in (9) and (10). By setting

$$\mathbf{V}^{(0)}=\mathbf{I}^{(0)}\mathbf{Z}^{(0)};\ \mathbf{V}^{(1)}=\mathbf{I}^{(1)}\mathbf{Z}^{(1)};\ \mathbf{V}^{(2)}=\mathbf{I}^{(2)}\mathbf{Z}^{(2)};\ \mathbf{V}^{(3)}=\mathbf{I}^{(3)}\mathbf{Z}^{(3)} \tag{11}$$

in (9) and substituting (10) with I written for V in the resulting equations, the following results are obtained:

$$\mathbf{V}_{i0}=\sum_{j=1}^{4}\mathbf{I}_{j0}\mathbf{Z}_{ij};\quad i=1,2,3,4. \tag{12}$$

The evaluation of the self-impedance $\mathbf{Z}_{ii}$ and mutual impedances $\mathbf{Z}_{ij}$ is facilitated if note is taken of the following relations which are a consequence of geometrical and electrical symmetry and the reciprocal theorem:

$$\mathbf{Z}^{(1)}=\mathbf{Z}^{(3)} \tag{13a}$$

$$\mathbf{Z}_{11}=\mathbf{Z}_{22}=\mathbf{Z}_{33}=\mathbf{Z}_{44} \tag{13b}$$

$$\mathbf{Z}_{12}=\mathbf{Z}_{23}=\mathbf{Z}_{34}=\mathbf{Z}_{41}=\mathbf{Z}_{21}=\mathbf{Z}_{32}=\mathbf{Z}_{43}=\mathbf{Z}_{14} \tag{13c}$$

$$\mathbf{Z}_{13}=\mathbf{Z}_{24}=\mathbf{Z}_{31}=\mathbf{Z}_{42}. \tag{13d}$$

With (13a–d) the following impedances are obtained directly:

$$\mathbf{Z}_{11}=\tfrac{1}{4}[\mathbf{Z}^{(0)}+2\mathbf{Z}^{(1)}+\mathbf{Z}^{(2)}] \tag{14a}$$

$$\mathbf{Z}_{12}=\tfrac{1}{4}[\mathbf{Z}^{(0)}-\mathbf{Z}^{(2)}] \tag{14b}$$

$$\mathbf{Z}_{13}=\tfrac{1}{4}[\mathbf{Z}^{(0)}-2\mathbf{Z}^{(1)}+\mathbf{Z}^{(2)}]. \tag{14c}$$

Alternatively, solving for the sequence impedances,

$$\mathbf{Z}^{(0)}=\mathbf{Z}_{11}+2\mathbf{Z}_{12}+\mathbf{Z}_{13} \tag{15a}$$

$$\mathbf{Z}^{(1)}=\mathbf{Z}_{11}-\mathbf{Z}_{13} \tag{15b}$$

$$\mathbf{Z}^{(2)}=\mathbf{Z}_{11}-2\mathbf{Z}_{12}+\mathbf{Z}_{13}. \tag{15c}$$

The symmetry between the phase-sequence impedances and the self- and mutual impedances in (15a–c) and the phase-sequence kernels and the exponential terms in (6a–c) is apparent.

With (14a–c) used in (12) with (13), the currents in the four antennas due to arbitrary driving voltages may be determined.

3. CAGE ANTENNAS

Cage antennas are arrays of N closely spaced parallel antennas excited in the *zero phase sequence* so that *all currents are in phase*. The kernel for an N unit array is

$$\mathbf{K}_{\Sigma 0}(z,z')=\sum_{i=1}^{N}\frac{\exp(-j\beta_0 R_{1i})}{R_{1i}} \tag{1}$$

and the expansion function is

$$\Psi_{\Sigma 0}(z)=\int_{-h}^{h} g(z,z')\mathbf{K}_{\Sigma 0}(z,z')dz', \tag{2}$$

where $g(z,z')=\sin\beta_0(h-z')/\sin\beta_0(h-z)$. This may be expressed as follows:

$$\Psi_{\Sigma 0}(z)=\Psi_{K1}(z)+\Psi_{b12}(z)=\Psi_{b13}(z)+\cdots \tag{3}$$

where

$$\Psi_{K1}(z)=\int_{-h}^{h} g(z,z')\frac{\exp(-j\beta_0 R_{11})}{R_{11}}dz';$$

$$R_{11}=((z-z')^2+a^2)^{\frac{1}{2}} \tag{4a}$$

$$\Psi_{b12}(z)=\int_{-h}^{h} g(z,z')\frac{\exp(-j\beta_0 R_{12})}{R_{12}}dz';$$

$$R_{12}=((z-z')^2+b_{12}^2)^{\frac{1}{2}} \tag{4b}$$

$$\Psi_{b13}(z)=\int_{-h}^{h} g(z,z')\frac{\exp(-j\beta_0 R_{13})}{R_{13}}dz';$$

$$R_{13}=((z-z')^2+b_{13}^2)^{\frac{1}{2}} \tag{4c}$$

$$\Psi_{b1N}(z)=\int_{-h}^{h} g(z,z')\frac{\exp(-j\beta_0 R_{1N})}{R_{1N}}dz';$$

$$R_{1N}=((z-z')^2+b_{1N}^2)^{\frac{1}{2}}. \tag{4d}$$

The distance between centers of antennas 1 and 2 is b_{12}, between antennas 1 and N it is b_{1N}.

For antennas sufficiently closely spaced so that

$$\beta_0 b_{1N}\ll 1, \tag{5}$$

$$\Psi_{b1N}(z_r)=\Psi_{K1}(z_r)-2\ln(b_{1N}/a), \tag{6}$$

where $z_r=0$ for $\beta_0 h\leqq\pi/2$, $z_r=h-\lambda_0/4$ for $\beta_0 h\geqq\pi$. Hence,

$$\Psi_{\Sigma 0}=|\Psi_{\Sigma 0}(z_r)|=|N\Psi_{K1}(z_r)-2\sum_{i=2}^{N}\ln b_{1i}/a| \tag{7a}$$

$$=|N\Psi_{K1}(z_r)-2\ln(b_a b_{13}b_{14}\cdots b_{1N}/a^{N-1})|\cdot \tag{7b}$$

Using this formula for the expansion parameter, the current in and impedance for each of the N antennas forming the cage may be determined just as for a single antenna.

For antennas that are not too long, a satisfactory approximate value of the expansion parameter for a single antenna is

$$\Psi_{K1}=2[\ln 2h/a-1]. \tag{8}$$

Since the contribution to Ψ_{K1} by the imaginary part of $\Psi_{K1}(z_r)$ is not great, an approximate formula for (7b) is obtained by replacing $\Psi_{K1}(z_r)$ by Ψ_{K1} as given by (8). The result is

$$\Psi_{\Sigma 0}\doteq N\Psi_{K1}-2\ln(b_{12}b_{13}b_{14}\cdots b_{1N}/a^{N-1}) \tag{9a}$$

$$\doteq 2[\ln(2h)^N/ab_{12}b_{13}\cdots b_{1N}]. \tag{9b}$$

It is a simple matter to determine the radius a_e of a single antenna carrying N times the current of each unit in the cage and having $1/N$ times the impedance. It is necessary merely to set $a=a_e$ in (8), multiply (8) by N, and equate the result to (9b). Thus solving for a_e

$$a_e=(ab_{12}b_{13}b_{14}\cdots b_{1N})^{1/N}. \tag{10}$$

Therefore, a cage antenna consisting of N *closely spaced*, parallel, identical units arranged at regular intervals around a circle is *approximately* equivalent to a single antenna of much larger radius, in the sense that the total current and its axial distribution are approximately the same, and its impedance is $1/N$ that of the individual units if these are all driven separately.

4. CORNER REFLECTOR ANTENNAS

The obvious application of the general theory of N antennas to the corner reflector antenna using the theorem of images has been carried out by Tai[7] in general, since his analysis did not exclude the case of N antennas when the phases alternate.

5. PARALLEL ARRAYS WITH ALL ELEMENTS DRIVEN; BROADSIDE AND END-FIRE ARRAYS; CIRCUIT PROPERTIES[11]

The most important arrays of identical, parallel, non-staggered, center-driven antennas consist of N units

[11] The three-element broadside array was analyzed by C. W. Harrison, Jr., Proc. I.R.E. 34, 204 (1946) using a method which did not take account of the coupled antennas in the kernel but only in a correction term. By limiting himself to the three-element broadside array, Harrison had to deal with only two simultaneous integral equations which he solved approximately.

spaced at equal intervals b along a straight line as shown in Fig. 2. In one class of arrays, the N currents are made equal in magnitude by appropriate driving voltages, and it is the phase relations which determine the different field characteristics of different arrays. For example, in the broadside array all currents are in phase; in the end-fire array the phase of the currents increases from one antenna to the next by an angle $\beta_0 b$. In another class of arrays, the magnitudes of the currents decrease in a prescribed manner from the center of the array outward in both directions.

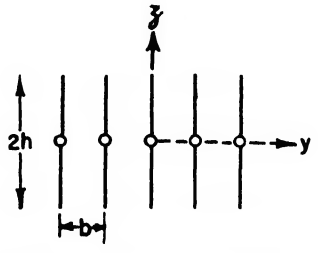

FIG. 2. Five-element parallel array.

Since there are no conditions of symmetry in an array of antennas uniformly spaced along a straight line which make it possible to reduce the N simultaneous integral equations given in (1.7) to a single equation, the conclusion is inevitable that the determination of the N currents and N impedances in terms of arbitrary driving voltages cannot be carried out with available mathematical techniques. Fortunately, an approximate solution of the important inverse problem of determining the N voltages required to maintain N currents with specified relative magnitudes and phases is possible.

The integral equations for the currents in the upper halves ($0 \leqq z \leqq h$) of the N coupled antennas are given by (1.7). They may be expressed as follows:

$$\int_{-h}^{h} \mathbf{I}_{ms}(z_m')\mathbf{K}_p(z_m, z_m')dz_m = \frac{-j4\pi}{\zeta_0}[\mathbf{C}_m \cos\beta_0 z_m + \tfrac{1}{2}\mathbf{V}_{0m} \sin\beta_0 z_m]; \quad m=1, 2, \cdots N, \quad (1a)$$

where the kernel is

$$\mathbf{K}(z_m, z_m') = \sum_{i=1}^{N} \frac{\mathbf{I}_{is}(z')}{\mathbf{I}_{ms}(z_m')} \frac{\exp(-j\beta_0 R_{mi})}{R_{mi}}; \quad m=1, 2, \cdots N, \quad (1b)$$

and where

$$R_{mi} = ((z_m - z_i')^2 + b_{mi}^2)^{\frac{1}{2}}; \; R_{mm} = ((z_m - z_m')^2 + a^2)^{\frac{1}{2}}. \quad (1c)$$

The distance between the centers of antenna m and antenna i is $b_{mi} = |m-i|b$, where b is the equal distance between adjacent units.

The N kernels $\mathbf{K}_p(z_m, z_m')$ are functions of the distributions of current in all antennas and of the distances R_{mi}. They are not independent. However, an approximate solution of (1a) may be obtained by assuming that the *distributions* of current as functions of z' are the same in all N units, but without thereby restricting the magnitudes or the phases of the input currents at $z=0$. It is readily agreed that this is a reasonable assumption if the antennas are identical. Indeed, it has already been shown in the analysis of two coupled antennas[7] driven either in phase or 180 degrees out of phase that the distributions of current do not differ significantly from each other or from the distribution along an isolated antenna provided $\beta_0 h$ does not greatly exceed $\pi/2$. When $\beta_0 h$ is near π the distributions differ considerably for very closely spaced antennas, but as the separation is increased, the currents become more and more nearly alike. Let it be assumed, therefore, that it is a good approximation to set

$$\frac{\mathbf{I}_{is}(z_i')}{\mathbf{I}_{ms}(z_m')} \doteq k_{mi} \exp(j\theta_{mi}), \quad (2)$$

where k_{mi} is the specified real ratio of magnitudes and δ_{mi} the specified phase difference between the currents in antennas k and m except when the antennas are close together *and* have half-lengths h near $\lambda_0/2$.

Substitution of (2) in (1a) gives:

$$\mathbf{K}_p(z_m, z_m') = \sum_{i=1}^{N} k_{mi} \exp(j\theta_{mi}) \frac{\exp(-j\beta_0 R_{mi})}{R_{mi}}; \quad m=1, 2, \cdots N. \quad (3)$$

The N kernels defined in (3) are not alike. They are not and cannot be made independent of m since for geometrical reasons,

$$R_{mi} \neq R_{m+q,\, i+q}, \quad (4)$$

where q is an integer for all values of m and q from 1 to N.

However, since all quantities in (3) are assumed to be known for all values of m, the N kernels can be evaluated independently. In particular, (1a) can be solved separately for $\mathbf{I}_{ms}(z)$ for each value of m. Thus, it is seen that the restrictions on the current contained in (2) have reduced the N *simultaneous* integral equations for determining N independent currents, to N *independent* integral equations for determining the N voltages $\mathbf{V}_{m0}$ that are required to maintain the N specified currents.

Since (1a) differs from the corresponding equation for two antennas only in the number of terms in the kernel, the formal solution for the current and the impedance as a function of the driving voltage may be carried out directly.[7] The expression for the input impedance of antenna m in the presence of $N-1$ parallel antennas all so driven that they have pre-assigned currents is like that for two antennas[7] with additional P

and **Q** terms each multiplied by the appropriate ratio factor and phase factor for the current. Thus,

$$(\mathbf{Z}_m)_{in}=\frac{-j\zeta_0\Psi_{pm}}{2\pi}\left\{\frac{\Psi_{pm}\cos\beta_0 h+\mathbf{F}_1(h)+\mathbf{P}_{1z}(h)}{[\Psi_{pm}+\mathbf{F}_1(0)+\mathbf{P}_{1z}(0)]\sin\beta_0 h-[\mathbf{G}_1(0)+\mathbf{Q}_{1z}(0)]\cos\beta_0 h+[\mathbf{G}_1(h)+\mathbf{Q}_{1z}(h)]}\right\}, \tag{5}$$

where

$$\Psi_{pm}=|\Psi_{pm}(0)|\,;\quad \beta_0 h\leqq\pi/2 \tag{6a}$$

$$\Psi_{pm}=|\Psi_{pm}(h-\lambda_0/4)|\,;\ \beta_0 h\geqq\pi/2 \tag{6b}$$

$$\Psi_{pm}(z)\sin\beta_0(h-z)=[C_a(h,z)+\sum_{\substack{i=1\\ i\neq m}}^{N} k_{mi}\times\exp(j\theta_{mi})C_{bmi}(h,z)]\sin\beta_0 h-[S_a(h,z)+\sum_{\substack{i=1\\ i\neq m}}^{N} k_{mi}\exp(j\theta_{mi})S_{bmi}(h,z)]\cos\beta_0 h. \tag{6c}$$

Also,

$$\mathbf{P}_1(z)=\sum_{\substack{i=1\\ i\neq m}}^{N} k_{mi}\exp(j\theta_{mi})\mathbf{P}_{1mi}(z) \tag{7a}$$

$$\mathbf{Q}_1(z)=\sum_{\substack{i=1\\ i\neq m}}^{N} k_{mi}\exp(j\theta_{mi})\mathbf{Q}_{1mi}(z) \tag{7b}$$

$$\mathbf{P}_{1mi}(z)=-\int_{-h}^{h}\mathbf{F}_{1z'}\frac{\exp(-j\beta_0 R_{mi})}{R_{mi}}dz'=-C_{bmi}(h,z)+E_{bmi}(h,z)\cos\beta_0 h \tag{8a}$$

$$\mathbf{Q}_{1mi}(z)=-\int_{-h}^{h}\mathbf{G}_{1z'}\frac{\exp(-j\beta_0 R_{mi})}{R_{mi}}dz'=-S_{bmi}(h,z)+E_{bmi}(h,z)\sin\beta_0 h \tag{8b}$$

$$R_{mi}=((z_m-z_i')^2+b_{mi}^2)^{\frac{1}{2}}. \tag{8c}$$

$\mathbf{F}_1(0)$, $\mathbf{F}_1(h)$, $\mathbf{G}_1(0)$ and $\mathbf{G}_1(h)$ as well as $C(h,z)$, $S(h,z)$ and $E(h,z)$ are as in reference 7 with Ψ_{pm} substituted for Ψ. Note that b_{mi} is the distance between centers of antennas m and i. Note that when $N=2$, $\theta_{mi}=0$, $k_{mi}=1$, (5) reduces to the previous formula[7] for two symmetrically driven antennas. Alternatively, when $N=2$, $\theta_{mi}=\pi$, $k_{mi}=1$, (5) reduces to the formula for two antisymmetrically driven antennas.

By evaluation of the functions $\mathbf{P}_{1z}$ and $\mathbf{Q}_{1z}$ together with the expansion parameter Ψ_{pm} for *each* value of m, the input impedance of each antenna in the presence of the others may be evaluated. Note that, in general, the antennas are in identical pairs except for the central unit for N odd, so that the number of different values of these functions is $N/2$ for N even, $(N+1)/2$ for N odd. Multiplication of the impedances so determined by the appropriate, assigned, input current gives the driving voltages required to maintain these currents.

In practice, antennas in parallel arrays usually have electrical half-lengths $\beta_0 h$ that are $\pi/2$ or near $\pi/2$. Significantly, this is precisely the value of $\beta_0 h$ for which the initial assumption of identical *distributions* (but not magnitudes or phases) of current is best satisfied and for which a maximum simplification of the intricate formula (5) is possible. With $\beta_0 h=\pi/2$, (5) becomes:

$$(\mathbf{Z}_m)_{in}=\frac{j\zeta_0}{4\pi}\left\{\frac{C_a(h,h)+\sum_{\substack{i=1\\ i\neq m}}^{N} k_{mi}\exp(j\theta_{mi})C_{bmi}(h,h)}{1-\frac{1}{2\Psi_{pm}}[C_a(h,0)+S_a(h,h)-E_a(h,h)+\sum_{\substack{i=1\\ i\neq m}}^{N} k_{mi}\exp(j\theta_m)\{C_{bmi}(h,0)+S_{bmi}(h,h-E_{bmi}(h,h)\}]}\right\}. \tag{9}$$

Except for antennas that are extremely closely spaced, the expansion parameter Ψ_{pm} cannot differ greatly from the value Ψ_{K1} for each of the antennas when isolated. In most driven arrays of the types considered in this section, b is not less than $\lambda_0/4$ and frequently is $\lambda_0/2$. Since the term with $1/2\Psi_{pm}$ as a factor in the denominator of (9) necessarily is small compared with unity for antennas of small radius it may be neglected. That this is indeed a good approximation already has been demonstrated for two coupled antennas[7] with $\beta_0 h=\pi/2$. If this term is neglected, (9) reduces to

$$(\mathbf{Z}_m)_{in}=\frac{j\zeta_0}{4\pi}[C_a(h,h)+\sum_{\substack{i=1\\ i\neq m}}^{N} k_{mi}\exp(j\theta_{mi})C_{bmi}(h,h)];\quad m=1,2,\cdots N. \tag{10}$$

Multiplication of (10) by $\mathbf{I}_{m0}$, noting that

$$\mathbf{I}_{i0}=\mathbf{I}_{m0}k_{mi}\exp(j\theta_{mi}), \tag{11}$$

reveals that (10) is equivalent to

$$\begin{aligned}
V_{10}&=I_{10}Z_{11}+I_{20}Z_{12}+I_{30}Z_{13}+\cdots+I_{N0}Z_{1N},\\
V_{20}&=I_{10}Z_{21}+I_{20}Z_{22}+I_{30}Z_{23}+\cdots+I_{N0}Z_{2N},\\
&\cdots\\
V_{N0}&=I_{10}Z_{N1}+I_{20}Z_{N2}+I_{30}Z_{N3}+\cdots+I_{N0}Z_{NN}, \qquad (12)
\end{aligned}$$

where

$$Z_{11}=Z_{22}=Z_{33}=\cdots Z_{NN}=\frac{j\zeta_0}{2\pi}C_a(h,h)=Z_0 \qquad (13)$$

$$Z_{12}=Z_{21}=\frac{j\zeta_0}{2\pi}C_{b12}(h,h) \qquad (14a)$$

$$Z_{13}=Z_{31}=\frac{j\zeta_0}{2\pi}C_{b13}(h,h) \qquad (14b)$$

$$\cdots$$

$$Z_{1N}=Z_{N1}=\frac{j\zeta_0}{2\pi}C_{b1N}(h,h). \qquad (14c)$$

Note that the self-impedances Z_{ii} of the coupled antennas are all the same as the self-impedance Z_0 of an isolated antenna. Moreover, the mutual impedances Z_{ij} are the same as if only antennas i and j were present. Therefore, it may be concluded that for parallel arrays in which antennas of half-length near $h=\lambda_0/4$ are coupled, the self-impedance of an isolated antenna may be used for each antenna and the mutual impedance between any pair taken to be the same as for that pair when isolated. Accordingly, the self-impedance and the mutual impedance may be obtained from first-order curves of Z_{e1},[7] for the appropriate value of $\Omega=2\ln 2h/a$.

It is significant to note that in spite of the initial *general* statement to the contrary, the Eqs. (13) may be solved for either the driving voltages given the current or the currents given the driving voltages. However, this is true only approximately and only in the special case of antennas for which $\beta_0 h=\pi/2$ and Ψ_{12} is not too small.

The simple method of analyzing N coupled antennas in terms of self-impedances of isolated antennas and mutual impedances of two coupled antennas obviously is *not valid* for antennas with half-lengths that exceed $\lambda_0/4$ considerably. Specifically, when $\beta_0 h=\pi$, (5) becomes

$$(Z_m)_{in}=\frac{j\zeta_0\Psi_{pm}^2}{2\pi}\times\left\{\frac{1-(1/\Psi_{pm})[F_1(h)+P_1(h)]}{[G_1(0)+Q_{12}(0)+G_1(h)+Q_{12}(h)]}\right\}. \qquad (15)$$

Since the term involving the most significant contributions from the coupled antennas now appear in the factor Ψ_{pm}^2 and in the terms in Q in the denominator, it is not possible to express $V_{m0}=I_{m0}(Z_m)_{in}$ as a simple sum of self- and mutual terms. $(Z_m)_{in}$ can be evaluated from (16) and V_{m0} evaluated for each antenna if the currents are known. The reverse is not possible.

For the broadside array, $k_{mi}=1$, $\theta_{mi}=0$ with $\beta_0 b=\pi$. For the end-fire array, $\theta_{mi}=\pm(m-i)\beta_0 b$ with $\beta_0 b=\pi/2$ for the unilateral end-fire, π for bilateral end-fire. The analysis in this section has demonstrated that common assumptions, such as that equal driving voltages will produce equal currents in all units of a broadside array, are erroneous except for the two-element array. The different impedances of the differently situated units require different voltages if the currents are to be the same.

Conventional methods of driving parallel arrays in which currents in the units are assumed to be respectively in phase (broadside array) or alternately 180 degrees out-of-phase (bilateral end-fire array) are shown in Fig. 3 and Fig. 4 for three-element arrays. The transmission line connecting the units in the broadside array is assumed to be *spiraled* and *not crossed-over* as shown in the figure so that it is the equivalent of a smooth line one-half wave-length long. Actually, the currents in the three antennas in Figs. 3 and 4 are neither all equal in magnitude nor all in phase (broadside) or alternately 180 degrees out-of-phase (bilateral end-fire) for two reasons. These are, (1) the input impedance of the central unit differs from that of the two outer units since this unit is not in the same position relative to the other antennas in the array; (2) the transmission-line end-effects and coupling effects are different for the central unit from what they are for the two outer units.

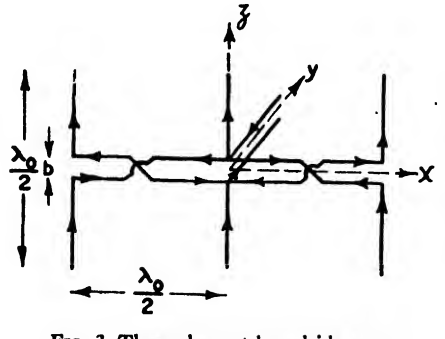

FIG. 3. Three-element broadside array.

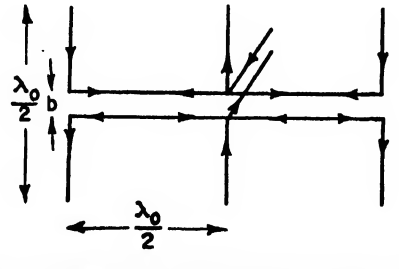

FIG. 4. Three-element bidirectional end-fire array.

Let the problem of transmission-line end-effects and coupling effects between each antenna and the feeding line be sidestepped in this paper by assuming that the distance b between the conductors of the line is sufficiently small to make these effects negligible. If this is done, formulas for the ratio of the current in antenna 1 or 3 (which have equal currents) to the current in the central unit 2 are obtained readily for $\beta_0 h = \pi/2$ since the simple formula (13) with $N=3$ is a good approximation. With negligible terminal-zone effects, the two sections of line of length $\lambda_0/2$ are one-to-one transformers so that the same voltage is applied to each of the three units. That is

$$\mathbf{V}_{30}=\mathbf{V}_{20}=\mathbf{V}_{10}. \tag{16}$$

Moreover, since antennas 1 and 3 are geometrically and electrically identical, it follows that

$$\mathbf{I}_{30}=\mathbf{I}_{10};\ \mathbf{Z}_{12}=\mathbf{Z}_{23}. \tag{17}$$

With (13) and (12) the following relations are obtained directly when $N=3$:

$$\mathbf{V}_{10}=\mathbf{V}_{20}=\mathbf{I}_{10}(\mathbf{Z}_{11}+\mathbf{Z}_{13})+\mathbf{I}_{20}\mathbf{Z}_{12}=2\mathbf{I}_{10}\mathbf{Z}_{12}+\mathbf{I}_{20}\mathbf{Z}_{22}. \tag{18}$$

The solution of (18) for the ratio of currents is

$$\mathbf{I}_{20}/\mathbf{I}_{10}=(\mathbf{Z}_{11}+\mathbf{Z}_{13}-2\mathbf{Z}_{12})/(\mathbf{Z}_{22}-\mathbf{Z}_{12}). \tag{19}$$

The expressions for the impedances are

$$\mathbf{Z}_{3in}=\mathbf{Z}_{1in}\equiv\frac{\mathbf{V}_{10}}{\mathbf{I}_{10}}=\mathbf{Z}_{11}+\mathbf{Z}_{13}+\mathbf{Z}_{12}\left[\frac{\mathbf{Z}_{11}+\mathbf{Z}_{13}-2\mathbf{Z}_{12}}{\mathbf{Z}_{22}-\mathbf{Z}_{12}}\right] \tag{20}$$

$$\mathbf{Z}_{2in}\equiv\frac{\mathbf{V}_{20}}{\mathbf{I}_{20}}=\mathbf{Z}_{22}+2\mathbf{Z}_{12}\left[\frac{\mathbf{Z}_{22}-\mathbf{Z}_{12}}{\mathbf{Z}_{11}+\mathbf{Z}_{12}-2\mathbf{Z}_{12}}\right]. \tag{21}$$

If all antennas are identical and have no series impedances,

$$\mathbf{Z}_{33}=\mathbf{Z}_{22}=\mathbf{Z}_{11}=\mathbf{Z}_{s1}. \tag{22}$$

In this case it is evident that $\mathbf{I}_{30}=\mathbf{I}_{10}$ must differ considerably from $\mathbf{I}_{20}$, and $\mathbf{Z}_{3in}=\mathbf{Z}_{1in}$ from $\mathbf{Z}_{2in}$ since $\mathbf{Z}_{13}$ and $\mathbf{Z}_{12}$ are far from the same. For example,

$$\Omega=10,\ b=\lambda_0/2,\ \mathbf{Z}_{s1}\doteq 73+j31;\quad \mathbf{Z}_{12}=-13-j26;\ \mathbf{Z}_{13}=3+j16. \tag{23}$$

It is possible to make the currents all equal when the driving voltages are the same by connecting an impedance in series with the central unit, antenna 2. Specifically, let

$$\mathbf{Z}_{33}=\mathbf{Z}_{11}=\mathbf{Z}_{s1};\ \mathbf{Z}_{22}=\mathbf{Z}_{s1}+\mathbf{Z}_2. \tag{24}$$

Upon setting the currents equal in (19) and using (24), the result is,

$$\mathbf{Z}_2=\mathbf{Z}_{13}-\mathbf{Z}_{12}. \tag{25}$$

It is seen that $\mathbf{Z}_2$ is quite a large impedance with a significant real part so that appreciable ohmic losses are involved which lower the efficiency of transmission. Since the electromagnetic field of a three-element array in which the current in the central unit is greater than that in the outer units may be more desirable than when the currents are all equal, it is seldom advantageous to use $\mathbf{Z}_2$ as specified in (25) in series with the central unit. An alternative procedure is to connect reactances in series with the *outer* units in order to make the phases of all three units the same. That is, in place of (24), let

$$\mathbf{Z}_{33}=\mathbf{Z}_{11}=\mathbf{Z}_{s1}+jX_1;\ \mathbf{Z}_{22}=\mathbf{Z}_{s1}. \tag{26}$$

The values in (16) now must be substituted in (20) and X_1 adjusted to make the expression real. That is,

$$\frac{\mathbf{I}_{20}}{\mathbf{I}_{10}}=\frac{(R_{s1}+R_{13}-2R_{12})+j(X_1+X_{s1}+X_{13}-2X_{12})}{(R_{s1}-R_{12})+j(X_{s1}-X_{12})} \tag{27}$$

must be real. This is true when

$$\frac{X_1+X_{s1}+X_{13}-2X_{12}}{R_{s1}+R_{13}-2R_{12}}=\frac{X_{s1}-X_{12}}{R_{s1}-R_{12}}, \tag{28a}$$

or when

$$X_1=\left(\frac{X_{s1}-X_{12}}{R_{s1}-R_{12}}\right)\times(R_{s1}+R_{13}-2R_{12})-X_{s1}-X_{13}+2X_{12}. \tag{28b}$$

Evidently

$$\frac{\mathbf{I}_{20}}{\mathbf{I}_{10}}=\frac{R_{s1}+R_{13}-2R_{12}}{R_{s1}-R_{12}}. \tag{29}$$

This ratio may be considerably greater than one.

Similar analyses may be carried out for arrays of any number of parallel units.

A Dimensional Analysis of Metal Cutting*

D. C. Drucker† and H. Ekstein‡
Armour Research Foundation, Chicago, Illinois
(Received June 30, 1949)

Dimensional analysis is used in a study of the behavior of metal when it is cut. Present theories are described and some additional significant variables are found. The analysis provides a basis for the interpretation of known experimental results, and should serve as a guide for future experimental and theoretical investigations.

INTRODUCTION

IF a problem is so complicated that a sufficiently comprehensive theory cannot be developed at the time, a very useful approach to a solution is to write down the independent variables of the problem and form their dimensionless combinations.[1] The significance of each independent dimensionless variable can then be determined from prior knowledge, reasoning, or experiment, and usually many of the dimensionless combinations can be ruled out as insignificant, that is, having no noticeable influence upon the result. Then, if the important independent combinations are the same, all dependent dimensionless variables will also be the same for both experimental and production runs. This means that practical predictions, such as of power requirement and chip continuity or surface finish, can be made from a limited set of experiments or field information without actually testing or ever having tested the proposed set-up. As the dimensionless combinations are not unique, a rearrangement is often worthwhile, for in this way the number of physically important variables may be materially reduced. This procedure has had widespread application in fluid mechanics and associated problems and is well standardized. Its use in mechanical problems is increasing as its value becomes more evident.[2]

Another, and more subtle, use of dimensional analysis is to check the physical completeness of a theory before embarking on the arduous task of grinding out mathematical formulas and numerical calculations. This, too, is illustrated in the following discussion and extension of present theories of metal cutting.

IDEALIZED METAL CUTTING

All theory must involve approximation to, or idealization of, actual behavior. Metal cutting offers a very difficult problem even for the two-dimensional case, Fig. 1, and the description proposed by Piispanen[3] and independently by Ernst and Merchant[4] was a tremendous forward step. The chip is assumed to come off continuously and there is no built-up edge. The fundamental action is a plastic shearing of each plane as it passes OA, the final appearance being similar to that which would be obtained with an inclined deck of very thin cards.

The resultant force R exerted by the tool on the chip per unit width of cut, Fig. 2, its horizontal or power component H, the shear angle φ, the chip thickness, and so forth, are dependent variables determined by the properties of the material being cut and by other independent variables. No one has yet devised a general theory which takes all into account. The major question is which variables are most important and how do they enter. In the simplest theory it is assumed that the independent variables are only the rake angle α, the depth of cut t, the cutting speed V, a constant friction angle between tool and chip β, and a fixed yield stress in shear τ_y. Once this initial step has been taken, R, φ, H, and so forth can be found; Ernst and Merchant have written down the results. However, a dimensional analysis will show that despite its great value there are practical physical limitations for any theory, elaborate or simple, of the form

$$\varphi \text{ or } H \text{ a function of } \alpha, t, V, \beta, \tau_y.$$

φ is dimensionless as are α, and β, but H is a force per

[1] The reviewer of this paper brought to the authors' attention the excellent article by F. F. P. Bisacre and G. H. Bisacre, "Life of carbide-tipped turning tools," Proc. Inst. Mech. Eng. War Emergency Issue No. 35, 157, 452–469 (1947). A dimensional analysis is included which in certain respects is more complete than ours. However the approach and the objective are quite different and a few variables important here are not included. The reviewer also pointed out that Dr. B. T. Chao has submitted a paper to the Institution of Mechanical Engineers in which, following Bisacre and Bisacre, considerable use is made of $K/Vc\rho t$.

[2] For a particular example in which there are very many independent variables but only one is found to be of real importance in the practical range, see D. C. Drucker and H. Tachau, "A new design criterion for wire rope," J. App. Mech. XII, No. 1, A-33–A-38 (1945).

[3] V. Piispanen, "Lastunmodostumisen teoriaa (Theory of chip formation)," Teknillinen Aikakauslehti XXVII, No. 9, 315–322 (1937).

[4] H. Ernst and M. E. Merchant, "Chip formation, friction, and finish," The Cincinnati Milling Machine Company (1940); (also "Surface treatment of metals," Symposium, Trans. A.S.M.E., 299–378 (1941); M. E. Merchant, "Mechanics of the metal cutting process"; I. "Orthogonal cutting and a type 2 chip," J. App. Phys., XVI, No. 5, 267–275 (1945); II. "Plasticity conditions in orthogonal cutting," J. App. Phys., XVI, No. 6, 318–324 (1945).

unit length, t is a length, V is a length over time, and τ_y is a force divided by length squared. The first step is the formation of the independent dimensionless combinations of the independent variables. It is easily seen that only α and β remain. V alone contains time and τ_y alone contains units of force so that a dimensionless combination cannot be formed with either, and both must be eliminated. Then t remains as the only independent variable involving length, and it must also be dropped. Therefore, any dimensionless quantity containing a dependent variable must turn out to be a function of α and β only, for example,

$$\varphi = \varphi(\alpha, \beta)$$

and

$$H/t\tau_y = H/t\tau_y(\alpha, \beta).$$

This is illustrated by the formulas given by Ernst and Merchant for these conditions, for example,

$$\varphi = 45° - (\beta - \alpha)/2.$$

More elaborate theories are possible and other results can be obtained, but if they are based upon the same five independent quantities only, no formula developed can contain either the speed or the depth of cut as independent variables. As both are known to be important in several ways, such theories, although very useful, are definitely incomplete. Also, the predictions for different materials appear too similar. The calculated shear angle φ will be the same if the friction and rake angles are the same, no matter what the properties of the material.

The most general theory now in use includes the material to the extent of considering the variation of the yield stress in shear with the normal stress σ on the shear plane. The change is generally negligible at ordinary stress magnitudes, but the stresses encountered in metal cutting are extremely high, exceeding 200,000 p.s.i. for mild steel. If the relation is linear, of the form $\tau_y = \tau_0 + k\sigma$, the previous dimensional analysis must be modified by replacing τ_y by the new independent variables τ_0 and k. As k is dimensionless, the result can be written immediately as

$$\phi = \phi(\alpha, \beta k)$$
$$H/t\tau_0 = H/t\tau_0(\alpha, \beta, k)$$

which is shown by Merchant's modified expressions,[4] for example

$$\phi = C/2 - (\beta - \alpha)/2,$$

where C is arc *ctnk*. There is still no influence of depth or speed of cut.

NEW CONCEPTS AND VARIABLES

The necessity for new concepts and the accompanying variables is thus made clear by the dimensional reasoning. It is known that as the speed is decreased or as the depth is increased, the chip will gradually change from the continuous type to the segmental. Present theories therefore cannot indicate under what conditions they break down, that is, when the picture they postulate is no longer valid. Furthermore, the shear angle and the specific cutting force generally do vary with V and t, which was shown to be incompatible with any theory using only the variables mentioned above. Therefore, there is a strong suggestion that a variable T_0 with the dimension of time be introduced. Such an independent variable with physical meaning would include the cutting speed by adding the dimensionless group VT_0/t. T_0 could be a time required for the material to fracture. It would not be valid to introduce such a variable unless T_0 would be of the order of magnitude of the essential time interval in the cutting operation. However, a simple calculation shows that the time in which the shearing action takes place in actual cutting is extremely short and furthermore the time in the ideal case, Fig. 1, is zero. Thus, dimensional analysis can lead to new and useful concepts; in metal cutting the transition from the continuous to the discontinuous chip apparently is governed by the time available for fracture. The transition value of VT_0/t will, of course, depend on the shear strain, which in turn depends upon α and β only. If the additional variables which will be considered later are of minor significance, then the dimensional analysis shows that a given percentage increase in t requires the same percentage increase in V to obtain the same degree of chip continuity and, therefore, approximately the same surface finish.

Another important omission in the idealized picture of cutting is the lack of prediction of any effect of depth of cut on the specific cutting force. It is always observed in practice that when t is small, the value of $H/t\tau_0$ rises very sharply as t decreases. This fact leads to the consideration of lengths which might be significant in cutting. The nose radius of the tool r_N, which was assumed as zero, could account for this phenomenon qualitatively and would appear in the variable r_N/t.

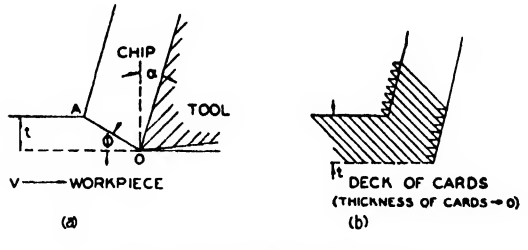

FIG. 1. Two-dimensional cutting.

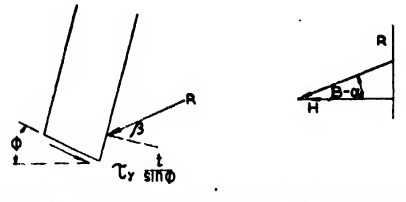

FIG. 2. Forces on chip of unit width (perpendicular to paper).

TABLE I

Variable	Units	Description
c	$FLM^{-1}\theta^{-1}/J$	specific heat, for example, B.t.u./lb.mass/deg.F
d	L	spacing of disturbances in crystal structure
G	FL^{-2}	shear modulus of elasticity
K	$FT^{-1}\theta^{-1}/J$	thermal conductivity, for example, B.t.u./sq.ft./deg.F/hr. for a unit thickness.
k	none	slope of curve of yield point in shear *vs.* normal stress on the shear plane
r_N	L	nose radius of tool
T_0	T	time required for fracture
t	L	depth of cut
V	LT^{-1}	cutting speed – relative speed of tool and workpiece
α	none	rake angle
γ_L	none	ductility—a limiting value of shearing strain
μ	none	a coefficient of rubbing friction—not necessarily simply tan β described previously
ψ_t	θ	a transition temperature of the metal, for example, melting point
ψ_w	θ	workpiece temperature
ρ	ML^{-3}	mass density
τ_0	FL^{-2}	yield stress in shear

However, it is found that the major part of the depth effect is independent of this ratio; a sharp tool taking a shallow cut is not equivalent to a more rounded tool at larger depths but instead will give a much higher specific cutting force. The effect is, therefore, apparently not one that would be observed in a perfectly homogeneous material. A grain size or, possibly better, a mean distance between imperfections of the metal, seems to provide a reasonable choice.

The preceding additional variables might be termed borderline because they apply or become important when the ideal picture starts to break down visibly. While they are very important, it is also true that the experimental results often do not agree well in detail with the present limited theory even when the chip is definitely continuous and the depth of cut is large enough to avoid the equivalent of a size effect. This is not surprising because no mention has been made so far of temperature changes, which are always large locally and usually have an appreciable influence throughout. The tangential force between tool and chip is certainly markedly dependent upon temperature; the yield point in shear will also be affected although the enormously high strain rate may nullify much of the temperature change; ductility will be radically altered; and so on. Again dimensional analysis can point the way.

THE GENERAL CASE

For the analysis of the general case, it is desirable to list all of the independent variables that are to be considered, with their units of force F or mass M, length L, time T, and temperature θ. Both F and M will be used for convenience, $F \equiv MLT^{-2}$. The mechanical equivalent of heat, J, is included to emphasize that a conversion of heat to mechanical units will be necessary at times (see Table I).

If this were a complete list of the independent variables, a functional form of the solution could be obtained easily. There are sixteen quantities and four fundamental units so that twelve independent dimensionless groups exist. If, for example, the shear angle φ, the horizontal force per unit width of cut H, or the temperature rise at the shear plane ψ, is being investigated, then φ, $H/t\tau_0$, or $\psi/(\psi_t-\psi_w)$ can be expressed as a function of $[\alpha, \mu, \gamma_L, k, VT_0/t, r_N/t, d/t, \tau_0/G, \rho V^2/\tau_0, K/Vc\rho t, \tau_0/Jc\rho(\psi_t-\psi_w), \psi_t/\psi_w]$.

The groupings are arbitrary within a very wide choice. Some of the dimensionless variables have been discussed already, the others were chosen because physical meaning could be attached to them easily. The variables α and μ which appear in the idealized theory are definitely important, and k will always have influence. Borderline variables VT_0/t, d/t, and γ_L become important as the continuity of the chip decreases. The ratio r_N/t can usually be ignored for a properly sharpened tool.

More analysis is required for the temperature variables. The shear strain (a function of the independent variables) multiplied by $\tau_0/Jc\rho$ would be the temperature rise at the shear plane if k were zero and if the heat generated were convected but not otherwise conducted away by the metal. $K/Vc\rho t$ is essentially the ratio of the heat conducted from the shear plane to the heat convected by the moving metal. If the temperature rise at the shear plane should be small compared with all significant temperature rises, $\psi_t-\psi_w$, for the metal being cut, then the three-temperature variables can be neglected.

The two remaining groups would seem to be borderline variables, but controlled experimentation is necessary before a definite statement can be made. τ_0/G is the maximum elastic shear strain (the resilience could be used in a somewhat more complicated group). $\rho V^2/\tau_0$ is essentially the ratio of inertia stress to the yield stress in shear and is always extremely small.

So far, the positive aspects of dimensional analysis have been emphasized. Unfortunately, it, too, has its drawbacks. The list of variables may not be sufficiently complete, nor, what is far worse, truly independent. The matter of completeness is rarely obvious, significant omissions may show up when an experimental program cannot be correlated with the use of variables already written down. However, this same trouble must be cleared up before an analytical approach can be successful.

Some of the difficulties can be seen by a re-examination of the list. Quantities like specific heat, thermal conductivity, ductility, coefficient of friction, and yield stress vary not only from one material to the other, but, unpleasantly, also in a given material as the cutting conditions vary. The symbols must therefore be interpreted as the (fixed) values for a given material under a specified set of conditions. If these initial values

and the remaining variables completely determine the values for all other sets of conditions, then the list of variables is complete. This will require at the very least a number of coefficients similar to k, for example, a set of constants for the non-linear variation of specific heat and of thermal conductivity with temperature. If independent quantities of this type exist, no matter how many there may be, there is no essential additional complication as far as an experimental program is concerned although theoretical solutions may be practically ruled out. The metal being cut enters in so many ways that only in the simplest fundamental work will it be possible to substitute other materials, as can very often be done in fluid mechanics problems. Therefore, in most cases, the large number of required constants which should be added to the list of variables will automatically be the same in model and prototype, experiment and production, or two production runs. In fact, some of the dimensionless combinations already considered are similarly fixed. Therefore, at appreciable depths of cut, probably only

$$(\alpha, VT_0/t, K/Vc\rho t)$$

are of major significance *for a given material and temperature of workpiece.*

It is interesting that almost as in the Reynolds and Froude numbers for fluids, V and t appear in ratio in one-dimensionless variable and as a product in the other. Therefore, complete similarity between two experiments cannot be obtained using one material and is rarely practicable. This discouraging result is almost always found when the list of variables is reasonably extensive. However, it may be true, as for fluids, that the range of importance of each dimensionless group containing V, t is markedly separate, or that the phenomena they control are quite distinct. There is a strong probability that this is true for metal cutting. VT_0/t seems to control the degree of continuity of the chip while $K/Vc\rho t$ should be of major importance in the definitely continuous range. Only careful experimental investigations of many different metals will provide the answer.

In the previous discussion, the tool itself has hardly been considered. Here, again, it is likely that in only a few cases can information be obtained with one tool material and applied to another in a quantitative manner. Also, the use of a cutting fluid or coolant would add many variables. All of these difficulties merely emphasize the impossibility at present of developing a mathematical theory which could quantitatively cover even a small section of the complete problem, and demonstrate the necessity of carefully conceived experimental investigations based on dimensional analysis.

CONCLUSION

The best procedure to obtain a clear picture of metal cutting would seem to be an experimental analysis of dry two-dimensional cutting on the basis of the dimensionless variables already discussed. Despite the very large volume of data on the cutting of metals there is only a little information that is directly useful for this particular fundamental purpose.

The two main variables, V and t, appearing in VT_0/t and $K/Vc\rho t$, are of prime significance because they can be varied in a known and simple manner, but most of the others are of equal physical importance and may merit careful study. Those involving workpiece temperature directly can also be varied without too much difficulty and offer interesting possibilities.

It is quite likely that additional variables will be found necessary to explain all results and that a rearrangement of some of the suggested dimensionless groups will be advantageous.

The Current Build-Up in a Planar Diode

EDWARD H. GAMBLE*
Polytechnic Institute of Brooklyn, Brooklyn, New York
(Received June 29, 1949)

A theoretical study has been made of the initial electron flow when a signal voltage $V(t)$ is applied across an idealized planar diode. The analysis is based upon three fundamental postulates: Poisson's equation, Newton's equation, and the continuity equation. This quasi-stationary study includes both the growth and motion of the space-charge cloud of electrons across the interelectrode space and the transient build-up of the current in the external circuit. The analytical forms and numerical plots of the current build-up under space-charge-limited and temperature-limited operation are compared for various "large" and "small" signal voltages.

STATEMENT OF THE PROBLEM

A STUDY of the initial electron flow when a signal voltage $V(t)$ is applied across a planar diode has been undertaken. This problem may be attacked from two possible directions. One can make a study of the way in which the space-charge cloud of electrons forms and determine the motion of this charge under the action of the electric field due to the applied signal and the counter effect of the charge upon this field. The other approach is that of studying the transient build-up of the current in the external circuit.

This latter approach is the one which will be adopted to secure the immediate results of interest to the electronics engineer. By analogy to hydrodynamics, one may specify the quantities describing the moving electron either in the Lagrange variables (t,τ) or the Euler variables $[t,x]$. t is the clock time measured from the instant when the voltage is applied to the diode, and τ denotes the instant when a particular group of electrons is emitted from the cathode surface. τ is referred to as the "emission" time.

The diode configuration is shown in Fig. 1.

DETERMINATION OF THE DENSITY OF THE SPACE-CHARGE CLOUD

The symbol Φ denotes the scalar potential, E the electric field density, and ρ the space-charge density.

If one makes the assumption that any signal voltages which one may apply across the electrodes of the vacuum diode do not change significantly in the time required for an electromagnetic wave to propagate the interelectrode space, one may treat the entire problem as quasi-stationary. The three basic electronic equations reduce to Poisson's equation, Euler or Newton's equation of motion, and the continuity equation. The formulation of the important physical quantities then becomes

$$E[t,x]=-\frac{V(t)}{h}+\frac{1}{h\epsilon_0}\int_0^h(h-\xi)\rho[t,\xi]d\xi-\frac{1}{\epsilon_0}\int_0^x\rho[t,\xi]d\xi \quad (1)$$

$$\Phi[t,x]=\frac{x}{h}V(t)-\frac{x}{h\epsilon_0}\int_0^h(h-\xi)\rho[t,\xi]d\xi+\frac{1}{\epsilon_0}\int_0^x(x-\xi)\rho[t,\xi]d\xi \quad (2)$$

$$I(t)=\frac{\epsilon_0}{h}\frac{d}{dt}V(t)+\frac{1}{h}\int_0^h\left\{-\rho[t,x]\frac{\partial x}{\partial t}\right\}dx \quad \text{and}$$

$$=\frac{\epsilon_0}{h}\dot{V}(t)+I_{\text{ind}}(t), \quad (3)$$

where the subscript *ind* signifies that the quantity is related to the current induced in the external circuit due to the motion of the electrons.

$$x(t,\tau)=u(\tau,\tau)[t-\tau]+\frac{e}{mh}\int_\tau^t(t-\eta)V(\eta)d\eta-\frac{e}{mh\epsilon_0}\int_\tau^t(t-\eta)\left\{\int_0^h(h-\xi)\rho[\eta,\xi]d\xi\right\}d\eta+\frac{e}{m\epsilon_0}\int_\tau^t(t-\eta)\left\{\int_0^x\rho[\eta,\xi]d\xi\right\}d\eta, \quad (4)$$

where $u(\tau,\tau)$ denotes the initial velocity of the τ-group of electrons.

If one restricts the problem to the initial electron flow and hence the period of time to that of the transit time of the first electron,

$$0<t<t_1, \quad \tau=0, \quad (5)$$

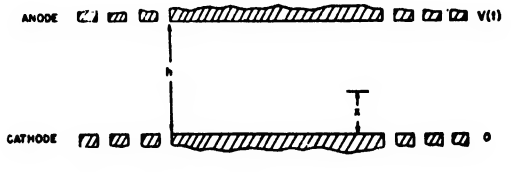

FIG. 1. Planar diode configuration.

* Now with Curtiss-Wright Corporation, Columbus, Ohio.

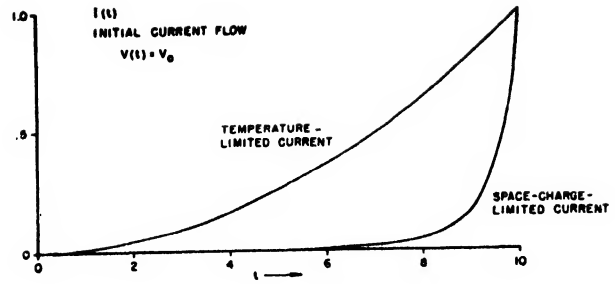

FIG. 2.

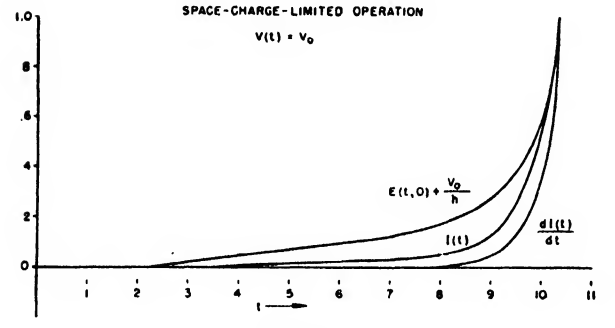

FIG. 3.

Eq. (4) becomes

$$x(t,0)=u(0,0)t+\frac{e}{mh}\int_0^t(t-\eta)V(\eta)d\eta$$
$$-\frac{e}{mh\epsilon_0}\int_0^t(t-\eta)\left\{\int_0^h(h-\xi)\rho[\eta,\xi]d\xi\right\}d\eta$$
$$+\frac{e}{m\epsilon_0}\int_0^t(t-\eta)\left\{\int_0^x\rho[\eta,\xi]d\xi\right\}d\eta. \quad (6)$$

Equation (6) may be considered as an integral equation for $\rho[t,x]$ when one specifies the position x and the time t. Knowing the form of $\rho[t,x]$, this quantity may be substituted into Eqs. (1)–(3) to determine the other desired quantities.

DETERMINATION OF THE EXTERNAL CURRENT

If one chooses the total current $I(t)$ as the unknown quantity to be found, the important equations are

$$E(t,\tau)=E_c(\tau,\tau)-\frac{V(t)}{h}-\frac{1}{\epsilon_0}\{q_{\text{ind}}(t)-q_{\text{ind}}(\tau)\}$$
$$=E_c(\tau,\tau)-\frac{V(t)}{h}-\frac{1}{\epsilon_0}\int_\tau^t I_{\text{ind}}(\eta)d\eta, \quad (7)$$

where $E_c(\tau,\tau)$ is the field at the cathode at the instant τ, and

$$q_{\text{ind}}(t)=\int_0^t I_{\text{ind}}(\eta)d\eta, \quad (8)$$

$$\Phi(t,\tau)=-\int_\tau^t E(t,\eta)\frac{\partial x(t,\eta)}{\partial\eta}d\eta$$
$$=-E_c(\tau,\tau)x(t,\tau)+\frac{x(t,\tau)}{\epsilon_0}\int_\tau^t I(\eta)d\eta$$
$$+\int_\tau^t x(t,\eta)\frac{\partial E(\eta)}{\partial\eta}d\eta, \quad (9)$$

$$x(t,\tau)=u(\tau,\tau)[t-\tau]-\frac{e}{2m}E_c(\tau,\tau)[t-\tau]^2$$
$$+\frac{e}{m\epsilon_0}\int_\tau^t\frac{(t-\eta)^2}{2}I(\eta)d\eta$$
$$=u(\tau,\tau)[t-\tau]-\frac{e}{2m}E_c(\tau,\tau)[t-\tau]^2$$
$$+\frac{e}{mh}\int_\tau^t(t-\eta)V(\eta)d\eta$$
$$+\frac{e}{m\epsilon_0}\int_\tau^t\frac{(t-\eta)^2}{2}I_{\text{ind}}(\eta)d\eta. \quad (10)$$

SPACE-CHARGE-LIMITED CURRENT BUILD-UP

If one applies the boundary conditions

$$E_c(\tau,\tau)=E[t,0]=0, \quad u(\tau,\tau)=0, \quad (11)$$

the relations given above reduce to those found previously by Wang[1] for the space-charge-limited planar diode. For conditions (5), the basic integral equation becomes

$$V(t)=\frac{h}{\epsilon_0}q(t)-\frac{e}{m\epsilon_0^2}\int_0^t\frac{(t-\eta)^2}{2}q(\eta)I(\eta)d\eta. \quad (12)$$

Differentiating Eq. (12) twice with respect to t, one finds that

$$\frac{\partial^2V}{\partial t^2}=\frac{h}{\epsilon_0}\ddot{q}(t)+\frac{e}{2mh}q^2(t). \quad (13)$$

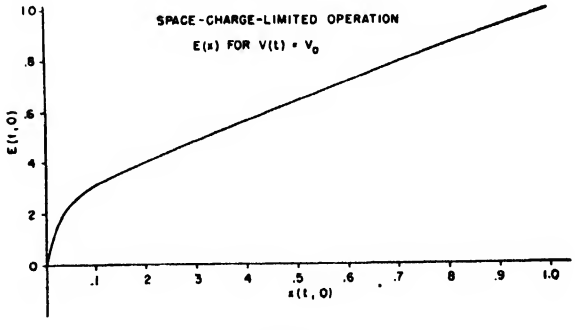

FIG. 4.

[1] C. C. Wang, "Large signal high frequency electronics of thermionic vacuum tubes," Proc. I. R. E. (April, 1941).

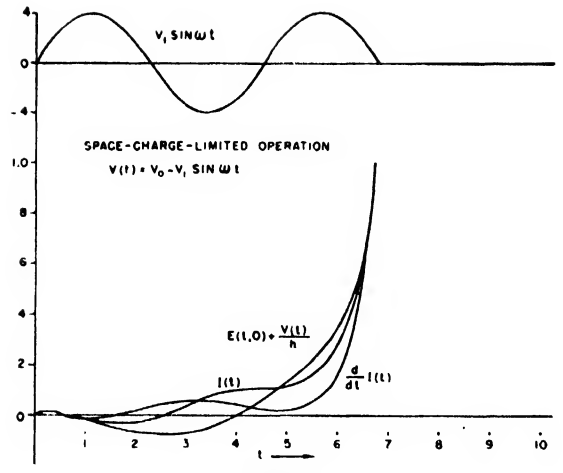

FIG. 5.

The solution of Eq. (13) for $(d/dt)q(t)=I(t)$ will give the current build-up for the space-charge-limited diode during this initial period before the electrons strike the anode.

TEMPERATURE-LIMITED CURRENT BUILD-UP

The conditions for temperature-limited operation may be defined as

$$I_0=\text{saturation current}=\left\{-\rho[t,x]\frac{\partial x}{\partial t}\right\} \tag{14}$$

$$E[t,x]=-V(t)/h=E(t) \tag{15}$$

$$\Phi[t,x]=[x(t,\tau)/h]V(t). \tag{16}$$

For the period before any electrons strike the anode,

$$x(t,\tau)=u(\tau,\tau)[t-\tau]+\frac{e}{mh}\int_\tau^t(t-\eta)V(\eta)d\eta \tag{17}$$

$$\Phi(t,\tau)=\frac{u(\tau,\tau)}{h}[t-\tau]V(t)+\frac{V(t)}{mh^2}\int_\tau^t(t-\eta)V(\eta)d\eta \tag{18}$$

$$I(t)=\frac{\epsilon_0}{h}\dot{V}(t)+\frac{I_0}{h}u(\tau,\tau)[t-\tau]+\frac{I_0e}{mh^2}\int_\tau^t(t-\eta)V(\eta)d\eta. \tag{19}$$

SOME SPECIFIC CASES

We now have all of the basic formulas necessary to determine the initial current build-up. It will be advantageous to compare the space-charge-limited and the temperature-limited cases. These are the solutions of Eqs. (13) and (19), respectively, for conditions (5).

Let $V(t)=V_0$, so that the build-up for a constant applied signal with its application to pulses may be determined. Figure 2 shows an enlarged plot of the solutions for this case. This plot shows the final current rising to the same value for both classes of operation. This will, in general, not be true. The functional form of the current as a function of time is of importance.

The temperature-limited current according to Eq. (19) is

$$I_{\text{ind}}(t)=(I_0e/mh^2)V_0(t^2/2) \tag{20}$$

for negligible initial velocity $u(\tau,\tau)$.

The position of the leading edge of the electron cloud is given by Eq. (17).

$$x(t,0)=u(\tau,\tau)\cdot t+(V_0/2mh)t^2. \tag{21}$$

The current and space charge always build up as the same power of time t for the temperature-limited operation.[2]

The numerical solution of Eq. (13) indicates that the space-charge-limited current rises much more rapidly than a square of the clock time. An accurate empirical formula for this current is given by Eq. (22)

$$I_{\text{ind}}(t)=I_{\text{const}}\left\{30.121\left(\frac{t}{t_1}\right)^{10}-51.009\left(\frac{t}{t_1}\right)^{9}+21.889\left(\frac{t}{t_1}\right)^{8}\right\}. \tag{22}$$

The complete analytical solution of Eq. (13) for this case is an elliptic integral

$$I_{\text{ind}}(t)=\dot{q}_{\text{ind}}(t)=\int_0^t\left[\int_0^\eta I_{\text{ind}}(\xi)d\xi\right]^2 d\eta. \tag{23}$$

For this case, Eq. (7) reduces to

$$E(t,0)+\frac{V_0}{h}=-\frac{q_{\text{ind}}(t)}{\epsilon_0}=-\frac{1}{\epsilon_0}\int_0^t I(\eta)d\eta$$

$$=-\frac{1}{\epsilon_0}I_{\text{const}}\left\{39.405\left(\frac{t}{t_1}\right)^{11}-73.406\left(\frac{t}{t_1}\right)^{10}+35.001\left(\frac{t}{t_1}\right)^{9}\right\}. \tag{24}$$

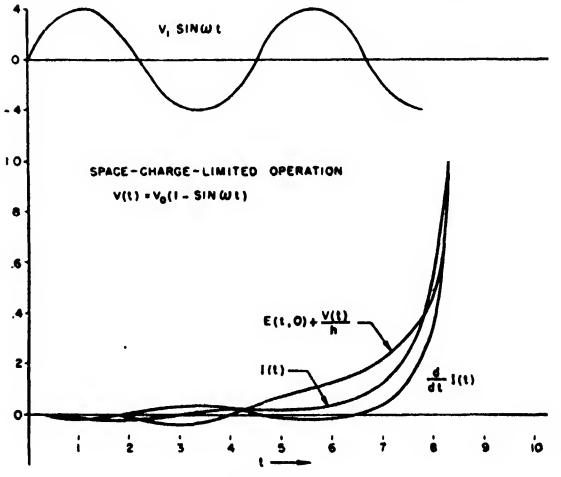

FIG. 6.

[2] B. Salzberg, "Large signal high frequency theory of the vacuum tube," dissertation for D.E.E. at the Polytechnic Institute of Brooklyn, Brooklyn, New York (1941).

Hence, a plot of $q(t)$, as shown in Fig. 3, is also a plot of the electric field as a function of time. For the determination of the leading edge of the electron cloud, one must employ Eq. (10)

$$x(t,0)=\frac{e}{2m\epsilon_0}30.121I_{\text{const}}\int_{\tau=0}^{t}(t-\eta)^2F(\eta)d\eta, \quad (25)$$

where

$$F(\eta)=\left[\frac{(t-\eta)^{10}}{t_1^{10}}-1.6935\frac{(t-\eta)^9}{t_1^9}+0.7267\frac{(t-\eta)^8}{t_1^8}\right]$$

$$x(t,0)=\frac{e}{m\epsilon_0}15.06I_{\text{const}}\left[\left(\frac{t}{t_1}\right)^{10}-1.6935\left(\frac{t}{t_1}\right)^9-0.7267\left(\frac{t}{t_1}\right)^8\right]t^2. \quad (26)$$

A plot can be made of $E(x)$ by a comparison of $E(t,0)$ given by the uppermost plot of Fig. 3 and the data computed from Eq. (26). This is shown in Fig. 4.

For the applied signal

$$V(t)=V_0-V_1\sin\omega t \quad (27)$$

for

$$V_1>V_0, \quad \omega>1/t_1, \quad (28)$$

the functional forms of $I(t)$ and $(d/dt)I(t)$ are shown in Fig. 5. The function

$$[E(t,0)+(V(t)/h)]$$

is also plotted in Fig. 5. The electric field $E(t,0)$ for the applied voltage given by Eq. (27) is

$$E(t,0)=-\frac{V_0}{h}+\frac{V_1\sin\omega t}{h}-\frac{1}{\epsilon_0}\int_{\tau=0}^{t}I_{\text{ind}}(\eta)d\eta. \quad (29)$$

The actual value of the ratio V_0/V_1 is not determinable from the numerical solution of Eq. (13) since only the second time derivative of the applied signal

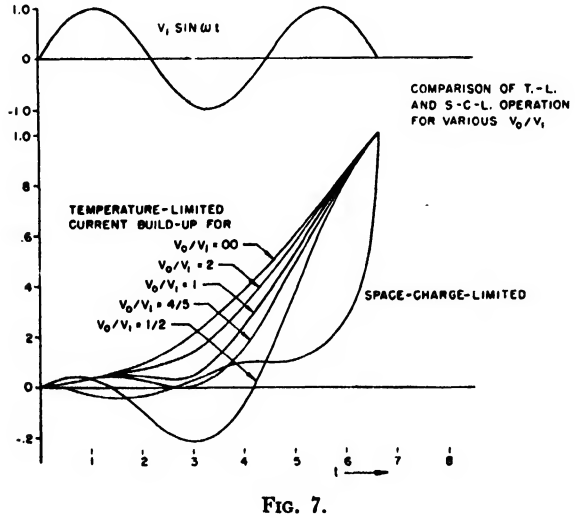

FIG. 7.

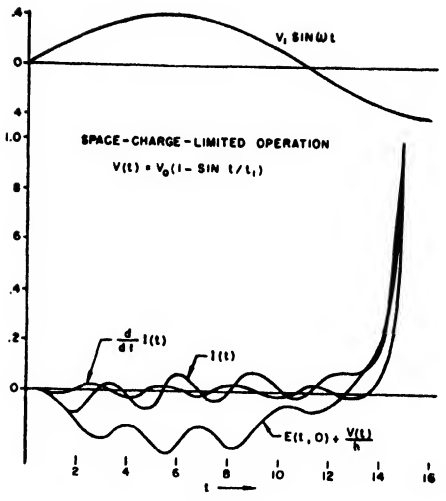

FIG. 8.

enters into the equation. However, experience has shown that if this ratio becomes too much smaller than *one*, the field will be negative and the electrons will never reach the anode. The period of the applied signal is clearly shown on the graph in order that one may visualize the time sequence. For the particular case where $V_0/V_1=1$, Fig. 6 shows the form of the current and the electric field as functions of time. A comparison of Figs. 5 and 6 for $I(t)$ indicates that the period of time during which the current is constant has been lengthened and the build-up time extended when the full modulation effect takes place for the amplitude ratio *one*.

It was considered advisable to make a direct comparison of the current build-up for space-charge-limited operation and temperature-limited operation for the applied signal given by Eq. (27) and conditions (28). Figure 7 shows this comparison. Several values of the ratio V_0/V_1 were chosen and plots made. The formula for the temperature-limited current is found by the substitution of Eq. (27) into Eq. (19).

$$I(t)=V_1\left\{-\frac{\epsilon_0}{h}\omega\cos\omega t+\frac{I_0e}{mh^2}\left[\frac{V_0}{V_1}\frac{t^2}{2}-\frac{t}{\omega^2}+\frac{\sin\omega t}{\omega^2}\right]\right\}. \quad (30)$$

The uppermost plot of Fig. 7 shows directly the comparison of the space-charge-limited current and the temperature-limited current for the case $V_0/V_1=\frac{1}{2}$. Another interesting plot is given in Fig. 7 which shows the variation of the build-up current with changes of the ratio V_0/V_1. This covers most of the range of large signals.

When the frequency of the time-varying component of the signal voltage is nearly equal to the reciprocal of the transit time, one finds that the build-up time is lengthened since the electric field is negative for a longer period of time. One point of interest is the large difference in the period of oscillation of the electric field and the current and the period of the signal com-

ponent. This is clearly shown in Fig. 8. The basic form of the signal voltage is

$$V(t)=V_0(1-\sin t/t_1). \quad (31)$$

CONCLUSIONS

The initial current build-up of thermionic vacuum tubes under space-charge-limited operation is a function of higher powers of time than under temperature-limited operation. The build-up may be considerably delayed or shortened when sinusoidally varying signals whose amplitude is comparable to the constant signal voltage are applied. The results shown in this paper should be of particular interest to engineers studying microsecond pulsing of thermionic vacuum tubes.

ACKNOWLEDGMENT

The author wishes to express his gratitude to the ONR who sponsored a special fellowship which enabled the author to carry on the research work given in this paper. A vote of thanks is due to the Reeves Instrument Company which made their analog computer available for numerical solutions. Thermocouples of the Refractory Metals

F. Haydn Morgan and W. E. Danforth

Bartol Research Foundation of The Franklin Institute, Swarthmore, Pennsylvania

(Received July 13, 1949)

The thermoelectric power of several refractory thermocouples was investigated, W-Ta for temperature measurements up to 3000°C, W-Mo up to 2600°C, Ta-Mo up to 2600°C and W-W/Mo (alloy 50 percent Mo/50 percent W) up to 2900°C.

Basic calibration was carried out using several melting points and the results were verified and interpolated by means of an optical pyrometer.

The couples W-Ta and W-Mo have been applied in this laboratory to the temperature measurement requirements in high temperature vacuum furnaces and determinations of spectral emissivity.

IN order to satisfy the need for accurate measurements of high temperature in electronic research, the thermocouples of the refractory metals have been investigated. Existing literature did not exceed 2000°C, with the exception of Morugina,[1] who studied W-Ta; and Pirani and Wagenheim,[2] who reported on W-W/Mo (75 percent W/25 percent Mo).

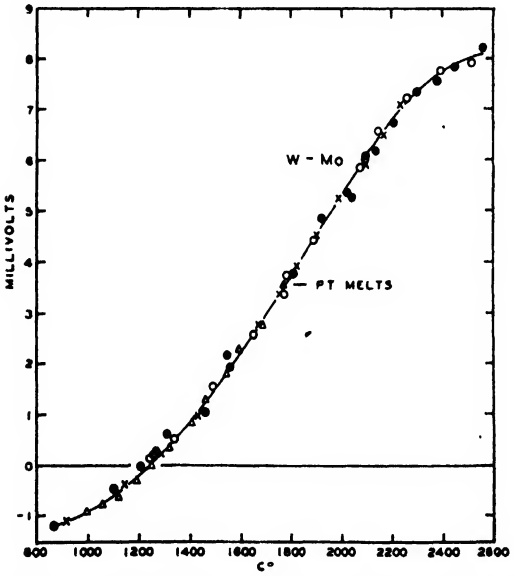

FIG. 1. Composite calibration data for W-Mo thermocouple. The different types of points represent different runs with optical pyrometer. The solid triangle represents melting point data taken with platinum in a vacuum furnace.

For the optical pyrometer comparisons the thermocouple wires 0.005 in. or 0.002 in. diameter were spot-welded to a 0.030-in. tungsten wire, which was heated by passage of current. This was placed in a bell jar and evacuated to 10^{-5} mm Hg. A Leeds and Northrup Type K potentiometer was used to measure the e.m.f. and a Leeds and Northrup Optical Pyrometer to measure the brightness temperature. Using 0.43 as the spectral emissivity[3] the brightness temperature was converted to true temperature. The cold junction was held at room temperature.

The melting point calibrations were obtained by spot-welding the thermocouple to the midpoint of a 2-cm length of 0.030-in. wire of the standard metal. The following metals were used:[4] Gold 1063.0°C ±0.0°, Nickel 1455°C±1°, Platinum 1773.5°C±1°, Molybdenum 2625°C±50°, and Tantalum 3000°C ±100°. An optical pyrometer would detect no temperature differences in the vicinity of the couple. The po-

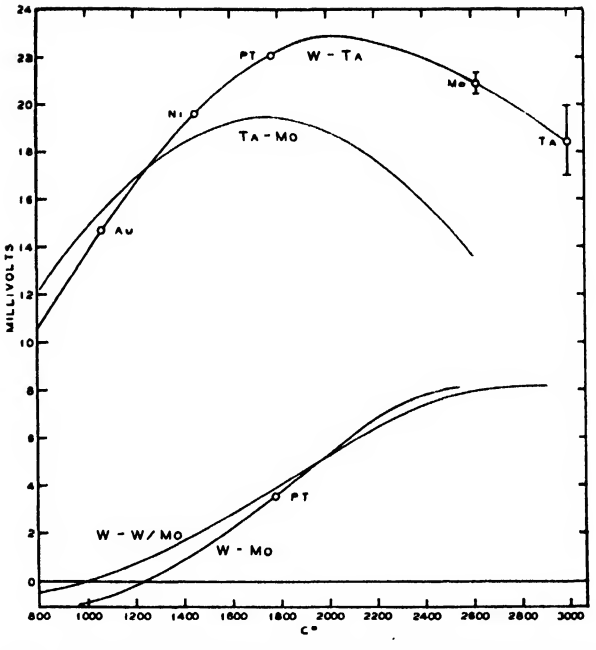

FIG. 2. Calibration curves of four refractory thermocouples. Melting point data are indicated on the W-Ta and W-Mo curves.

tentiometer was kept in balance as the temperature was slowly raised. When the wire melted, permitting the thermocouple to cool, the potentiometer would suddenly go out of balance. The last point of balance was taken as the melting point.

Considerable time was spent verifying the reproducibility of the present results. Wire stock from different spools and of different sizes was tested. Figure 1 shows composite calibration results in the case of the W-Mo couple. Similar sets of data were taken with the other couples and the resulting average curves are plotted in Fig. 2 and presented in Table I.

W-Ta (contrary to Morugina's findings of a straight line) gives a curve which rises from 14 millivolts at 1000°C to a maximum of 22.9 millivolts at 2000°C and then decreases as the temperature is increased. The slope of the curve between 1300°C and 1800°C is 8 microvolts per degree. The couple was found to be reproducible up to 2000°C, for which the graph shows pyrometer data. Above this temperature the pyrometer data showed excessive spread and, for some reason that was not determined, did not agree with the melting points of Mo and Ta which have been plotted.

The W-Mo curve has negative values below 1250°C, where it passes through zero and then rises to 8 millivolts at 2500°C. The average slope of the curve between these temperatures is 6.5 microvolts per degree. The scatter of the data in this case was relatively small, and agrees with literature published by B. Osann and Schroeder,[5] which gave the W-Mo curve up to 1850°C.

The W-W/Mo (50 percent W–50 percent M) curve is of very similar form to the W-Mo curve. It passes through zero at 1000°C and rises to 8 millivolts at 2600°C where it tends to saturate. The slope of the curve is 5 microvolts per degree.

The Ta-Mo curve crosses the W-Ta curve at 1250°C or 17.3 millivolts. This temperature value agrees, as it should, with the temperature for zero output of the W-Mo couple. It reaches a maximum of 20.2 millivolts at 1700°C. Due to this maximum at such a low temperature, it has not been used for practical applications.

The W-Ta couple is being used for spectral emissivity determination of different materials. The couple is spot-welded to a 0.030-in. tungsten wire which is coated with the material being investigated. The W-Mo couple is being used for temperature measurements in a vacuum furnace, where optical pyrometry is difficult.

Interaction of a Spiral Electron Beam and a Resonant Microwave Cavity*

F. K. Willenbrock and S. P. Cooke
Cruft Laboratory, Harvard University, Cambridge, Massachusetts
(Received July 18, 1949)

The interaction between the electromagnetic field in a cavity and an electron beam projected along the axis of the cavity is examined. The particular cavity considered here is of the cylindrical TE11n_s type in a steady axial magnetic field. If the cavity is excited in a linearly polarized mode, the electromagnetic field will drive the electrons in a helical trajectory with an expanding radius, and the electrons will excite and transfer energy to a degenerate mode oriented spatially at right angles to the driving field. In the driving plane of polarization (both planes of polarization if the cavity is excited in a circularly polarized mode), the electron beam will excite a field in phase opposition to the driving field in a manner analogous to the counter e.m.f. in an electromechanical generator. The converse case of a TE11n_s cavity excited by a spiral beam of electrons is also considered.

I. QUALITATIVE DISCUSSION OF SPIRALING ELECTRON BEAMS

THE behavior of a beam of electrons in a crossed electric and magnetic field has been widely discussed. In the recent literature,[1–3] several different uses of spiraling beams have been suggested. Malter[1] examines the impedance change in a parallel plate condenser through which an electron beam is projected in the presence of a steady magnetic field. Smith and Schulman[2] discuss the effect of spiraling electron beams on the frequency and Q of resonant systems. Spiral beam control has been used for frequency and amplitude modulation in several experimental magnetrons.[4–6]

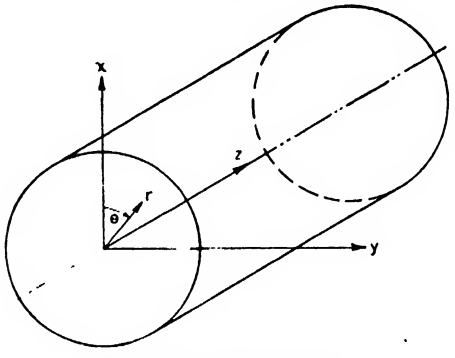

Fig. 1. Coordinate system.

Truell[3] considers the possibility of measuring the amplitude of an electromagnetic field by the deflection of an electron beam in the presence of a steady magnetic field.

The present investigation is a study of the interaction of an axial beam of electrons with a cylindrical cavity oscillating in a TE11n_s mode with a steady magnetic field superimposed along the axis of the cavity. The theory of the interaction is presented both from the standpoint of energy transfer from the electromagnetic field to the electron beam and from the beam to the field.

To simplify the analysis, the trajectory of a single electron is considered first. A single spiraling electron, unlike an electron beam, does not cause a significant change of the r-f field in the cavity, and does not extract an appreciable part of the power driving the cavity. The electron follows a helical trajectory with an increasing radius in a cavity driven by a linearly or by a circularly polarized field. Linear polarization is obtained when the cavity is driven through a single coupling iris; circular polarization is obtained when the cavity is driven through two coupling holes located at right angles in space with equal input-signal amplitudes in time quadrature.

For a given cavity, the two parameters that can be readily varied are the magnetic field strength which determines the cyclotron angular frequency, $\omega_c = eB_0/m$, and the axial velocity of the electron beam, v_0, which determines the transit time of the electron through the cavity. It is found that for a cavity of length $\lambda_g/2$, maximum energy is transferred to the electron when $\omega_c = \omega_0$, the resonant angular frequency of the cavity. For a cavity of length λ_g with $\omega_0 = \omega_c$, all or nearly all the energy gained by the beam during the first half-wave-length will be returned to the r-f field during the second half-wave-length; and there will be a negligible amount of rotational energy in the beam at exit. The deflection of the electron varies inversely with v_0.

The treatment of the trajectory of a single electron in a cavity excited in a linearly polarized mode is also valid for an electron beam if (1) the effect of space charge is neglected; (2) the degenerate mode at right angles to the driving mode is suppressed; (3) the de-

crease of the effective driving field to compensate for the energy transferred to the electron beam is taken into account.

The effect of space charge can be neglected because of the relatively low charge densities in the beam and the presence of the steady axial magnetic field. The beam in the cavity is not bunched as in a magnetron, but is a steady stream of electrons. Although the cross section of the beam is assumed to be small, the total beam currents considered are also small. For these reasons, high charge densities are not obtained. In any event, the presence of the strong axial magnetic field prevents defocusing of the beam.

Unless the perpendicular mode which is degenerate with the driving mode is suppressed, it will be excited by the spiraling electron beam. The r-f field in the cavity is, therefore, a superposition of a linear driving mode and a mode at right angles driven by the electron beam. This results in an elliptically polarized r-f field. If this degenerate mode is suppressed, the trajectory of the beam is the same as that of a single electron provided the decrease of effective driving field is considered.

The electron beam also excites a mode of oscillation in the original plane of polarization in phase opposition to the driving field. This "counter" E-field reduces the effective amplitude of the driving field and is analogous to the counter-e.m.f. in an electromechanical generator. With this reduced driving field, the losses in the cavity walls are also decreased. The remaining r-f input power is transferred by the beam to the other plane of polarization and appears as rotational energy in the beam at exit.

For the circularly polarized mode, there is a field driven through an iris by the external generator in each plane of polarization, and in each of these planes there are two counter-fields in phase opposition to the externally driven field. The first of these counter-fields is the same as that described for the linear case and is analogous to the counter-e.m.f. in an electromechanical generator. This is the "direct" counter-field which would exist even if the mode in the perpendicular plane were suppressed.

The second counter-field is cross-coupled by the electron beam from the driving field in the perpendicular plane of polarization. In the linear case this cross-coupled field drives the other degenerate mode and produces elliptical polarization. In the circular case, this cross-coupled field appears in opposition to the phase of the externally driven field if the latter has been chosen to add energy to the beam. The two counter-fields reduce the effective field more than the single counter-field in the linear case, and there is a correspondingly greater energy transfer to the beam for circular polarization.

If a spiraling beam of electrons is projected along the axis of the second TE_{11n_z} cavity, the cavity is excited, and energy is transferred from the beam to the r-f field. With the proper choice of parameters, it is possible to extract all the rotational energy from the beam. However, if the transit time is too long, the electron beam regains rotational energy from the r-f field in the cavity.

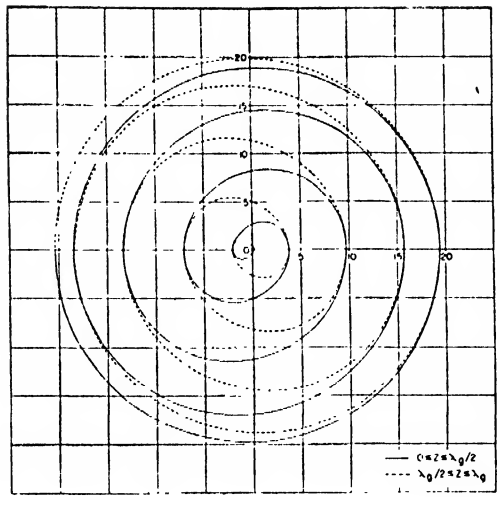

FIG. 2. Projection on the transverse plane of the trajectory of a single electron. TE_{11} cavity excited in a linearly polarized mode. $\kappa=1$, $\eta=0.1$, and $\phi=0$.

II. TRAJECTORY OF AN ELECTRON IN A TE_{11n_z} CAVITY IN A MAGNETIC FIELD

The transverse E-field in a perfectly conducting TE_{11n_z} cavity can be represented as $\mathbf{E}(r,\theta)\sin 2\pi z/\lambda_g \cos\omega_0 t$. For small deviations from the axis of the cavity $\mathbf{E}(r,\theta)$ can be written, by proper choice of the x axis, as $E_x=E_{0x}$, $E_y=0$, where E_{0x} is a constant. For velocities small in comparison with the velocity of light and for small r-f power inputs, the effect of the r-f magnetic field is negligible. The nonrelativistic equations of motion can be written† (see Fig. 1),

$$\left.\begin{aligned} \ddot{x} &= -e\mathcal{E}_x/m-(e/m)B_0\dot{y} \quad \text{(a)} \\ \ddot{y} &= -e\mathcal{E}_y/m+(e/m)B_0\dot{x} \quad \text{(b)} \\ \ddot{z} &= 0 \quad \text{(c)} \end{aligned}\right\} \tag{1}$$

where the dot notation indicates derivatives with respect to time, and e/m is the charge-to-mass ratio of the electron. The steady magnetic field, B_0, is directed along the positive z axis.

A linearly polarized mode as seen by the electron in its transit through the cavity can be written as

$$\left.\begin{aligned} \mathcal{E}_x &= E_{0x}\sin(2\pi z/\lambda_g)\cos(\omega_0 t+\phi) \\ \mathcal{E}_y &= \mathcal{E}_z = 0 \end{aligned}\right\} \tag{2}$$

for the interval $0\leq t\leq t_1$. Here, λ_g = wave-length in the cavity, $f_0=\omega_0/2\pi$ = resonant frequency of the cavity, t_1 = transit time of the electron through the cavity, and ϕ = phase angle of E-field at time of entrance.

† Rationalized M.K.S. units are used in this report.

The solution of Eq. (1c) is simply $z=v_0t$ where v_0 is the longitudinal velocity of the electron, and $z=0$ at $t=0$. Substituting this expression in the above equations will lead to solutions for $x(t)$ and $y(t)$ in terms of the parameters $\kappa=\omega_0/\omega_c$ and $\eta=v_0/v_p$, where $\omega_c=(e/m)B_0$ is the cylotron angular frequency, and v_p is the phase velocity of the r-f wave in the cavity. The solutions are for $\kappa=1$ (see Appendix A),

$$\left.\begin{aligned} x(t)=&-\frac{eE_{0x}}{2m\omega_0^2}\left\{\frac{\sin[(1+\eta)\omega_0t+\phi]}{\eta(2+\eta)}\right.\\ &-\frac{\sin[(1-\eta)\omega_0t+\phi]}{\eta(2-\eta)}+\frac{2}{\eta(4-\eta^2)}\\ &\left.\times[(2-\eta^2)\sin\omega_0t\cos\phi+2\cos\omega_0t\sin\phi]\right\}\\ y(t)=&-\frac{eE_{0x}}{2m\omega_0^2}\left\{-\frac{2\eta\cos}{1-\eta^2}+\frac{\cos[(1+\eta)\omega_0t+\phi]}{\eta(2+\eta)(1+\eta)}\right.\\ &+\frac{\cos[(1-\eta)\omega_0t+\phi]}{\eta(2-\eta)(1-\eta)}-\frac{2}{\eta(4-\eta^2)}\\ &\left.\times[(2-\eta^2)\cos\omega_0t\cos\phi-2\sin\omega_0t\sin\phi]\right\}\end{aligned}\right\}. \quad (3)$$

The electron traces a trajectory in the form of a helix with an expanding radius. Figure 2 shows a projection on the transverse (x, y) plane of the trajectory of the electron as it travels longitudinally through the cavity. For the chosen direction of the B-field, the electron spirals in a clockwise sense. The axes of the figures are

$$x'(t)=x(t)\Big/-\frac{eE_{0x}}{2m\omega_0^2}$$

and

$$y'(t)=y(t)\Big/-\frac{eE_{0x}}{2m\omega_0^2}.$$

This curve is plotted for $\eta=0.1$, which corresponds approximately to a 4000-volt electron. This high value of voltage was chosen to facilitate the calculation and plotting. For a more efficient transfer of energy to the beam, accelerating voltages of the order of 100 volts or less should be used.

Similarly, a circularly polarized mode as seen by the electron in the cavity can be written as

$$\left.\begin{aligned}\mathcal{E}_x&=E_{0x}\sin(2\pi/\lambda_g)z\cos\omega_0t\\ \mathcal{E}_y&=E_{0x}\sin(2\pi/\lambda_g)z\sin\omega_0t\\ \mathcal{E}_z&=0\end{aligned}\right\} \quad (4)$$

for the interval $0\leq t\leq t_1$. The direction of the B-field is taken the same as in the linearly polarized case. The circularly polarized field is chosen so that the E-field vector rotates in the clockwise sense. The solutions of the equations of motion for the same conditions are (see Appendix A),

$$\left.\begin{aligned} x(t)=&-\frac{eE_{0x}}{2m\omega_0^2}\left\{\frac{2}{\eta}\sin\omega_0t-\frac{1}{\eta(1+\eta)}\sin(1+\eta)\omega_0t\right.\\ &\left.-\frac{1}{\eta(1-\eta)}\sin(1-\eta)\omega_0t\right\}\\ y(t)=&-\frac{eE_{0x}}{2m\omega_0^2}\left\{-\frac{2\eta}{1-\eta^2}-\frac{2}{\eta}\cos\omega_0t\right.\\ &+\frac{1}{\eta(1+\eta)}\cos(1+\eta)\omega_0t\\ &\left.+\frac{1}{\eta(1-\eta)}\cos(1-\eta)\omega_0t\right\}\end{aligned}\right\}. \quad (5)$$

Figure 3, shows the projection on the transverse plane of the trajectory of a single electron for this case.

For $\kappa=\omega_0/\omega_c=1$, the maximum transverse deflection is obtained for both the linearly and circularly polarized fields. For a cavity of length λ_g, the electron gains energy during the first half-wave-length and loses it during the second half-wave-length.‡ If the transit time is chosen so that $1/\eta$ is an integer, all the rotational energy is lost during the second half wave-length. If $1/\eta$ is not an integer, there is a small amount of rotational energy left in the beam at exit. The deflection of the beam at $z=\lambda_g$ is of the order $1/\eta^2$ smaller than

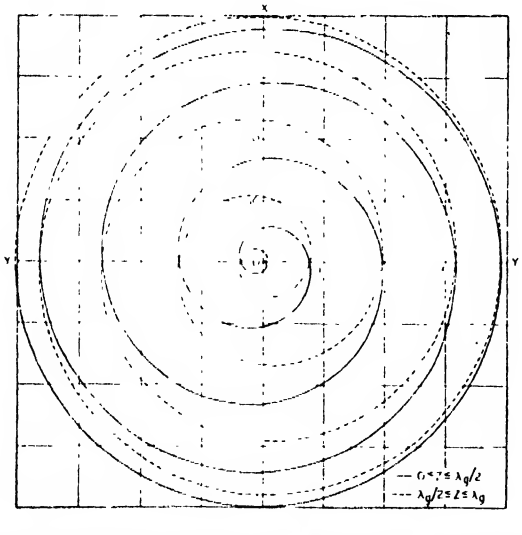

FIG. 3. Projection on the transverse plane of the trajectory of a single electron. TE_{11} cavity excited in a circularly polarized mode. $\kappa=1$, $\eta=0.1$.

‡ There are two unique cases, $\kappa=1/(1\pm\eta)$, for which there are equal increases in transverse deflection for each half wave-length traveled until relativistic effects become significant.

the deflection at $z=\lambda_g/2$. The deflection varies approximately as $1/\eta$. The transverse deflection for the circularly polarized case is approximately twice as great as the deflection for the linearly polarized case. For the same value of E_{0x}, it would require twice as much input power to drive the cavity in circular as in linear polarization.

For the $\kappa=1$ case, there are three sinusoidal terms in the expressions for $x(t)$ and $y(t)$ with frequencies $(1+\eta)\omega_0$, $(1-\eta)\omega_0$, and ω_0. The transit time, t_1, for a length $\lambda_g/2$ can be written as $\pi/\eta\omega_0$. Then, at time t_1 the arguments of these sinusoidal terms become

$$(1+\eta)\omega_0 t_1=\pi/\eta+\pi$$
$$(1-\eta)\omega_0 t_1=\pi/\eta-\pi$$
$$\omega_0 t_1=\pi/\eta.$$

The first two terms, $(1+\eta)\omega_0$ and $(1-\eta)\omega_0$, which describe the time dependence of the r-f driving E-field, differ by π-radians from their phase at $t=0$. Energy is gained by the electron in its transit from $z=0$ to $z=\lambda_g/2$ but is returned to the r-f field in the transit from $z=\lambda_g/2$ to $z=\lambda_g$.

By calculating the square root of the sum of x^2 and y^2 as given by Eq. (3), an expression is obtained for the radial deflection of the electron in terms of the entrance phase angle, ϕ, of the linearly polarized field. It is found that the terms independent of ϕ are of the order of $1/\eta^2$ larger than those containing ϕ. For values of $\eta\leq 0.1$, which are of the greatest practical interest, the radial deflection is effectively independent of ϕ. There is also a small spatial deviation of phase: while two electrons entering the cavity 90 degrees out-of-phase in time will still be 90 degrees out-of-phase in time at exit, they will not be 90 degrees out-of-phase in space. This bunching is negligible for values of $\eta\leq 0.1$.

For a circularly polarized mode, each electron has the same trajectory through the cavity except for the rotation of the coordinate system about the cylindrical axis.

In the solutions of the equations of motion for a single electron, the following approximations were made:

1. The E-field magnitude is constant for small deviations from the axis of the cavity.
2. The effect of the r-f B-field is negligible for velocities small with respect to the velocity of light and for small r-f power inputs.
3. The relativistic increase in electron mass is negligible.

For the choice of axes specified in Eqs. (2) for the linear mode, the expressions for the transverse E-field in a perfectly conducting TE_{11n_z} cavity are

$$\left.\begin{aligned} E_r&=-A_0(1/k_c r)J_1(k_c r)\cos\theta \\ E_\theta&=A_0 J_1'(k_c r)\sin\theta \end{aligned}\right\},$$

where J_1 = first-order Bessel function of first kind, J_1' = first derivative of J_1, $k_c=2\pi/\lambda_c$ where λ_c is the cut-off wave-length of the cavity, $A_0=2E_{0x}$ = amplitude constant.

Using the coordinate system of Fig. 1, the E-field can be written as

$$\left.\begin{aligned} E_x&=A_0\{[+(1/k_c r)J_1(k_c r) \\ &\qquad -\tfrac{1}{2}J_0(k_c r)]\cos 2\theta+\tfrac{1}{2}J_0(k_c r)\} \\ E_y&=A_0[-(1/k_c r)J_1(k_c r)+\tfrac{1}{2}J_0(k_c r)]\sin 2\theta. \end{aligned}\right\}$$

For small values of the argument $(k_c r)$,

$$(1/k_c r)J_1(k_c r)-\tfrac{1}{2}J_0(k_c r)\doteq 0$$

and these equations reduce to

$$E_x\doteq\tfrac{1}{2}A_0 J_0(k_c r)\doteq\tfrac{1}{2}A_0$$
$$E_y\doteq 0.$$

This approximation is valid to within 1.2 percent for values of the argument up to 0.3. Values of the argument up to 0.6 introduce errors of less than 5 percent. In a cavity designed to resonate at 9000 mc/sec., an argument of 0.5 corresponds to a deflection of one-quarter of the radius of the cavity, and, for $\omega_0=\omega_c$, corresponds to a tangential velocity of the electron roughly equal to the velocity of light.

The second approximation depends on the velocity of the electron and the r-f power input to the cavity. If the ratio of the transverse velocity of the electron is small with respect to c, the velocity of light, the force on the electron exerted by the E-field is large with respect to the force exerted by the B-field. If the power input to the cavity is large (above a kilowatt for an X band cavity), the magnitude of the r-f B-field approaches the magnitude of the steady B-field and therefore becomes appreciable.

The relativistic increase of mass is negligible if the ratio of the total velocity of the electron to the velocity of light is small with respect to one. For electrons of less than 5000 volts energy, relativistic effects introduce an error of less than 1 percent.

III. TRAJECTORY OF AN ELECTRON BEAM IN A TE_{11n_z} CAVITY IN A MAGNETIC FIELD

The theoretical treatment of the trajectory of a single electron in a cavity must be modified when a beam of electrons is considered. If the cavity is cylindrically symmetrical, two degenerate TE_{11n_z} modes can exist having mutually perpendicular orientations. The spiraling electron beam serves to couple energy between these two modes, and this coupling must be taken into account in the calculation of the beam trajectory.

The azimuthal position angle, θ, of the electrons in the cavity is related to the deflections by $\tan\theta=y/x$. For linear polarization with $\kappa=1$ and $\eta\ll 1$, the approximate expression for θ (after several r-f cycles) is

$$\theta\doteq\omega_c t+\phi+\pi/2.$$

In this expression each electron has its own local time which is taken to be zero when the electron enters the cavity.

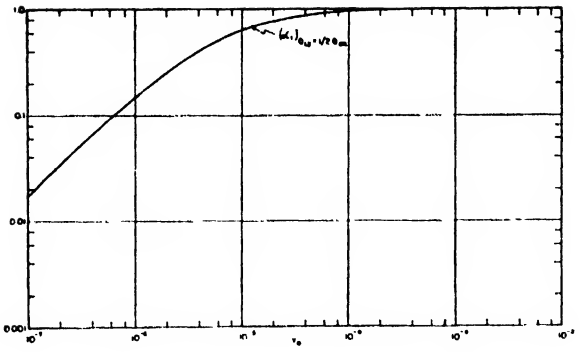

FIG. 4. $\alpha_1 = E_{2yx}/E_{1x}$ as a function of Y_0.
X band TE_{111} cavity with $\kappa = 1$.

If electron 1 enters at $\phi = 0$, its azimuthal angle (θ_1) is, after a time interval Δt_1, $\theta_1 = \omega_c \Delta t_1$. If electron 2 enters at $\phi = \phi_2$, its azimuthal angle (θ_2) is, after a time interval Δt_2, $\theta_2 = \omega_c \Delta t_2 + \phi_2$. Since $\phi_2 = \omega_c \Delta t_1 - \omega_c \Delta t_2$, $\theta_1 = \theta_2$. A projection on the transverse plane at any instant of a succession of electrons traversing the cavity would show a line of electrons each having the same azimuthal angle, but with greater radial deflections for the electrons which had been in the cavity for a longer interval of time. Accordingly, the beam of electrons has the form of a straight pencil at an angle to the axis of symmetry of the cavity rotating with an angular frequency ω_c.††

For circular polarization with $\kappa = 1$ and $\eta \ll 1$, the successive electrons will have the same azimuthal angle, as in the linear case. The beam has the same form of a straight pencil rotating around the axis of symmetry with an angular frequency ω_c.

For linear polarization, the spiraling electron beam drives a counter E-field in phase opposition to the original driving field. If the original r-f driving field is polarized in the plane containing the x axis, its amplitude E_{0x} is reduced by the counter E-field. This counter E-field is called E_{2xx} since it is directed along the x axis and is produced by the driving field in the plane of the x axis. With the reduction in the effective driving field, the losses in the cavity walls are decreased and the balance of the r-f input power appears in the rotational energy of the beam. The amplitude of the effective or reduced field is $|E_{1x}| = |E_{0x}| - |E_{2xx}|$.

The spiraling beam also excites the degenerate mode in the plane of the y axis. The amplitude of this cross-coupled field is called E_{2yx}. It is directed along the y axis, but is caused by the driving field in the plane of the x axis.

The differential equations of motion (1) for the electrons in the beam are unchanged, assuming the same approximations. For $\kappa = 1$ and $\eta^2 \ll 1$, the r-f field in the cavity as seen by the electron beam can be written as

$$\left.\begin{aligned} \mathcal{E}_{1x} &= E_{1x} \sin(2\pi z/\lambda_g) \cos\omega_0 t \\ \mathcal{E}_{2yx} &= -E_{2yx} \sin(2\pi z/\lambda_g) \sin\omega_0 t \\ \mathcal{E}_z &= 0 \end{aligned}\right\} \tag{6}$$

for the interval $0 \leq t \leq t_1$. The time dependence chosen for the E_{2yx} field is valid since the electron beam is a straight pencil beam rotating around the axis of symmetry. The phase angle of the E_{1x} field at entrance is omitted since $\eta^2 \ll 1$. The solution of the equations of motion is for $\kappa = 1$ (see Appendix A),

$$\left.\begin{aligned} x(t) = -\frac{eE_{1x}}{2m\omega_0^2}\Bigg[& \frac{4-2\eta^2}{\eta(4-\eta^2)} \sin\omega_0 t \\ & - \frac{\sin(1+\eta)\omega_0 t}{\eta(2+\eta)} - \frac{\sin(1-\eta)\omega_0 t}{\eta(2-\eta)} \\ & + \alpha_1 \Bigg\{ \frac{-4}{\eta(4-\eta^2)} \sin\omega_0 t + \frac{\sin(1+\eta)\omega_0 t}{\eta(2+\eta)(1+\eta)} \\ & \qquad + \frac{\sin(1-\eta)\omega_0 t}{\eta(2-\eta)(1-\eta)} \Bigg\} \Bigg] \\ y(t) = -\frac{eE_{1x}}{2m\omega_0^2}\Bigg[& \frac{-2\eta}{1-\eta^2} - \frac{4-2\eta^2}{\eta(4-\eta^2)} \cos\omega_0 t \\ & + \frac{\cos(1+\eta)\omega_0 t}{\eta(2+\eta)(1+\eta)} + \frac{\cos(1-\eta)\omega_0 t}{\eta(2-\eta)(1-\eta)} \\ & + \alpha_1 \Bigg\{ \frac{4}{\eta(4-\eta^2)} \cos\omega_0 t - \frac{\cos(1+\eta)\omega_0 t}{\eta(2+\eta)} \\ & \qquad - \frac{\cos(1-\eta)\omega_0 t}{\eta(2-\eta)} \Bigg\} \Bigg] \end{aligned}\right\} \tag{7}$$

This solution is written in terms of α_1 which is defined as the ratio of the E-field amplitudes, E_{2yx}/E_{1x}.

For a cavity excited in a circularly polarized mode, it is necessary to introduce E-field amplitudes for each plane of polarization corresponding to those defined for the linear case. The original driving fields in each plane have the amplitudes E_{0x} and E_{0y} when no energy is transferred to the beam. The reduced amplitudes are E_{1x} and E_{1y}.

There are two counter-fields in each plane: The first is the counter-field produced by the driving field in the same plane; the second is the counter-field cross-coupled from the driving field in the perpendicular plane. The first counter-field is analogous to the counter-e.m.f. in an electromechanical generator. The amplitude of this field is E_{2xx} in the x axis plane and E_{2yy} in the y axis plane. It acts in the same plane as the driving field by which it is produced.

The second type of counter-field, the cross-coupled field, acts in the plane perpendicular to the driving

†† A graphical analysis indicates that the $\eta \ll 1$ restriction is stronger then necessary and that a pencil beam is formed for $\eta^3 \ll 1$.

field by which it is produced. The field E_{2yx} acts in the y axis plane, but is caused by the driving field in the x axis plane. The field E_{2xy} acts in the x axis plane, but is caused by the driving field in the y axis plane.

Both types of counter-fields act in opposition to the phase of the driving fields if these original fields are chosen to add energy to the beam. Therefore

$$\begin{aligned} |E_{1x}| &= |E_{0x}| - |E_{2xx}| - |E_{2xy}| \\ |E_{1y}| &= |E_{0y}| - |E_{2yy}| - |E_{2yx}|. \end{aligned} \tag{8}$$

The differential equations of motion (1) are unchanged assuming the same approximations. For $\kappa=1$ and $\eta \ll 1$, the r-f field in the cavity as seen by the electron beam is

$$\left.\begin{aligned} \mathcal{E}_{1x} &= E_{1x} \sin(2\pi z/\lambda_g) \cos\omega_0 t \\ \mathcal{E}_{1y} &= E_{1x} \sin(2\pi z/\lambda_g) \sin\omega_0 t \\ \mathcal{E}_{1z} &= 0 \end{aligned}\right\} \tag{9}$$

for the interval $0 \leq t \leq t_1$. Except for the change in amplitude these expressions are identical with those for a single electron (4). Therefore, the solutions for a single electron (5) will be valid for the electron beam if E_{1x} is substituted for E_{0x}.

IV. TRAJECTORY OF A SPIRAL BEAM EXCITING A TE_{11n_z} CAVITY IN A MAGNETIC FIELD

If a spiraling beam of electrons is projected into a TE_{11n_z} cavity in the presence of a steady axial magnetic field, the cavity is excited, and energy is extracted from the electron beam. It is assumed in this discussion that a steady state condition has been reached. It is also assumed that the spiraling beam is a straight pencil of electrons rotating about the axis of symmetry at an angular frequency ω_c. The phase of the E-field in the cavity is determined by the phase of the electrons upon entrance ($t=0$). If the phase of the entering beam is chosen so that $x_0=0$, $\dot{y}_0=0$, $\dot{x}_0$ has its maximum negative value, and y_0 has its maximum positive value, then the r-f field as seen by the electron beam for $\kappa=1$ and $\eta^2 \ll 1$ is

$$\left.\begin{aligned} \mathcal{E}_{2x} &= -E_{2x} \sin(2\pi z/\lambda_g) \cos\omega_0 t \\ \mathcal{E}_{2y} &= -E_{2y} \sin(2\pi z/\lambda_g) \sin\omega_0 t \\ \mathcal{E}_{2z} &= 0 \end{aligned}\right\} \tag{10}$$

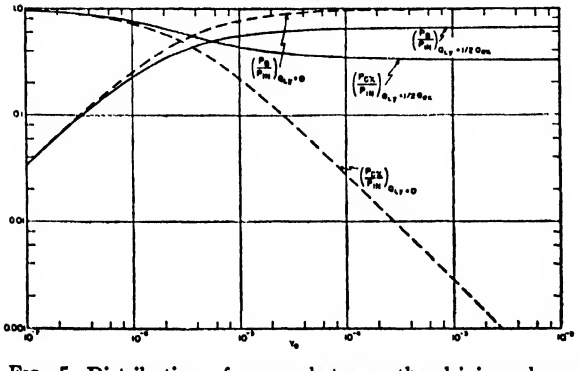

FIG. 5. Distribution of power between the driving plane of polarization and the electron beam. X band TE_{111} cavity with $\kappa=1$.

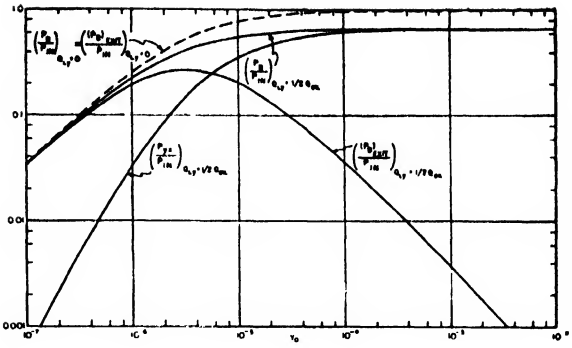

FIG. 6. Distribution of power between the electron beam and the driven plane of polarization. X band TE_{111} cavity with $\kappa=1$.

for the interval $0 \leq t \leq t_1$. The trajectory of the beam can be obtained from the solution of the differential equations of motion (1). The solution is for $\kappa=1$ (see Appendix B),

$$\begin{aligned} x(t) = {} & \frac{\dot{x}_0}{\omega_0} \sin\omega_0 t + \frac{eE_{2x}}{2m\omega_0^2} \left\{ \frac{4-2\eta^2}{\eta(4-\eta^2)} \sin\omega_0 t \right. \\ & \left. - \frac{\sin(1+\eta)\omega_0 t}{\eta(2+\eta)} - \frac{\sin(1-\eta)\omega_0 t}{\eta(2-\eta)} \right\} \\ & + \frac{eE_{2y}}{2m\omega_0^2} \left\{ \frac{4}{\eta(4-\eta^2)} \sin\omega_0 t \right. \\ & \left. - \frac{\sin(1+\eta)\omega_0 t}{\eta(1+\eta)(2+\eta)} - \frac{\sin(1-\eta)\omega_0 t}{\eta(1-\eta)(2-\eta)} \right\} \\ y(t) = {} & y_0 + \frac{\dot{x}_0}{\omega_0} - \frac{\dot{x}_0}{\omega_0} \cos\omega_0 t \\ & + \frac{eE_{2x}}{2m\omega_0^2} \left\{ -\frac{2\eta}{1-\eta^2} - \frac{4-2\eta^2}{\eta(4-\eta^2)} \cos\omega_0 t \right. \\ & \left. + \frac{\cos(1+\eta)\omega_0 t}{\eta(1+\eta)(2+\eta)} + \frac{\cos(1-\eta)\omega_0 t}{\eta(1-\eta)(2-\eta)} \right\} \\ & + \frac{eE_{2y}}{2m\omega_0^2} \left\{ \frac{-4}{\eta(4-\eta^2)} \cos\omega_0 t \right. \\ & \left. + \frac{\cos(1+\eta)\omega_0 t}{\eta(2+\eta)} + \frac{\cos(1-\eta)\omega_0 t}{\eta(2-\eta)} \right\} \end{aligned} \tag{11}$$

V. COUPLING BETWEEN OSCILLATIONS IN MUTUALLY PERPENDICULAR PLANES OF POLARIZATION IN A CAVITY DRIVEN IN LINEAR POLARIZATION

The power input (P_{in}) to the cavity excited in linear polarization in the x axis plane is partially dissipated in the walls of the cavity (P_{cx}) and partially transferred to the electron beam (P_B). P_B is determined from

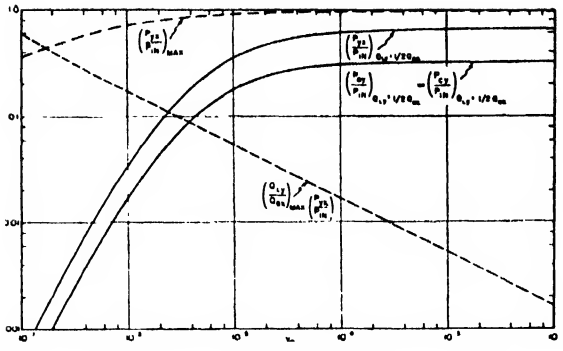

FIG. 7. Distribution of power in the plane of polarization driven by the electron beam. X band TE_{111} cavity with $\kappa=1$.

the beam current and the driving field along the trajectory of the beam,

$$P_B=\int \text{beam current} \times \text{driving field}.$$

The trajectory of the beam of electrons in a linearly excited cavity is given in Section III in terms of E_{1x} and $\alpha_1=E_{2yx}/E_{1x}$.

P_{cx} is obtained with the usual expression for Q,

$$Q=\omega_0\frac{\text{Energy stored}}{\text{Average power loss}},$$

in terms of P_{in}, E_{1x}, and the properties of the cavity. From these two expressions, P_B and P_{cx} can be written in terms of α_1 and the physical constants of the cavity.

To find α_1, the power coupled from the electron beam to the second plane of polarization, P_{yx}, must be evaluated. P_{yx} is found by taking the line integral of the product of the beam current and the driven E-field, E_{2yx}, along the trajectory of the beam. With the expression for the Q in the driven plane, another relation between E_{2yx} and P_{yx} is available. These two expressions can be solved simultaneously to give α_1 in terms of the beam admittance, $Y_0=I_0/V_0$, and cavity constants. With α_1 determined, P_B, P_{cx}, P_{yx}, and the rotational power left in the beam at exit can be written in terms of the r-f power input, P_{in}. If there is an iris coupled to the second plane of polarization, the power transmitted through the iris (P_{0y}) and the power dissipated in the cavity walls in the y axis plane (P_{cy}) can also be determined.

In the following treatment, α_1 is obtained first. The general power expressions are specialized to the case of a cavity of length $\lambda_g/2$ with $\kappa=1$ and $\eta^2\ll1$. The resulting expressions are plotted for a 9000-mc/sec. (X band) TE_{111} cavity.

The power coupled to the plane containing the y axis is given by

$$P_{yx}=Ne\int \boldsymbol{E}_2\cdot\mathbf{ds}, \tag{12}$$

where $N=$number of electrons entering per second,

$\boldsymbol{E}_2=-y'E_{2yx}\sin2\pi z/\lambda_g\sin\omega_0 t$,

$\mathbf{ds}=\boldsymbol{x}\dot{x}dt+\boldsymbol{y}\dot{y}dt+\boldsymbol{z}\dot{z}dt=$path element of the trajectory.

Since both ξ_2 and $\mathbf{s}$ can be written as functions of t only, using $z=v_0t$, the limits of integration can be taken as $t=0$ and $t=t_1$, where t_1 is the transit time of an electron through the cavity.

For the case of a cavity of length $\lambda_g/2$ with $\kappa=1$, expression (12) becomes with (7) since $\eta^2\ll1$,

$$P_{yx}=\frac{I_0eE_{2xy}{}^2}{2m\omega_0{}^2\eta^2}\frac{(1-\alpha_1)}{\alpha_1}=\frac{Y_0\lambda_g{}^2E_{2yx}{}^2}{16\pi^2}\frac{(1-\alpha_1)}{\alpha_1}, \tag{13}$$

where $I_0=Ne=$beam current, $Y_0=I_0/V_0=$beam admittance, and $V_0=mv_0{}^2/2e=$beam accelerating voltage. With the usual definition of the cavity Q,

$$\left.\begin{aligned}P_{yx}&=\omega_0\left(\tfrac{1}{2}\epsilon_0\int E_2{}^2d\tau/Q_{Ly}\right)\\&=\omega_0\epsilon_0E_{2yx}{}^2\tau_0/2Q_{Ly}\end{aligned}\right\}, \tag{14}$$

where $Q_{Ly}=$the y plane Q loaded by the coupling iris, $\epsilon_0=$dielectric constant of free space, $d\tau=$element of volume in the cavity, $\tau_0=$volume constant (see Appendix C). From expressions (13) and (14), the desired result is obtained:

$$\alpha_1=\frac{1}{1+(8\pi^2\omega_0\epsilon_0\tau_0)/(Y_0Q_{Ly}\lambda_g{}^2)}. \tag{15}$$

To relate P_{yx} to P_{in}, it is first necessary to evaluate the power coupled into the electron beam, P_B.

$$P_B=-Ne\int \boldsymbol{E}_1\cdot\mathbf{ds}, \tag{16}$$

where $E'=\boldsymbol{x}E_{1x}\sin(2\pi z/\lambda_g)\cos\omega_0t$. For the case of a cavity of length $\lambda_g/2$, with $\kappa=1$ since $\eta^2\ll1$,

$$P_B=\frac{I_0eE_{1x}{}^2}{2m\omega_0{}^2}\frac{1}{\eta^2}(1-\alpha_1)=\frac{Y_0\lambda_g{}^2E_{1x}{}^2}{16\pi^2}(1-\alpha_1). \tag{17}$$

The power driving the cavity, P_{in}, is partially dissipated in the walls of the cavity and the rest is converted into rotational energy of the electrons. The power dissipated in the walls of the cavity in the x axis plane, P_{cx}, can be written as

$$P_{cx}=\omega_0\epsilon_0E_{1x}{}^2\tau_0/2Q_{0x}, \tag{18}$$

where $Q_{0x}=$unloaded Q of the mode in the x axis plane. Defining k_1 as the ratio P_B/P_{cx},

$$k_1=P_B/P_{cx}=Y_0Q_{0x}\lambda_g{}^2(1-\alpha_1)/8\pi^2\omega_0\epsilon_0\tau_0 \tag{19}$$

for the case of $\kappa=1$ and a cavity length of $\lambda_g/2$. Sub-

stituting the expression for α_1, (15) results in

$$k_1=(Q_{0x}/Q_{Ly})\alpha_1. \tag{20}$$

Since $P_{in}=P_{cx}+P_B$,

$$\left.\begin{aligned} P_B&=\frac{k_1}{1+k_1}P_{in}=\frac{1}{1+(Q_{Ly})/(Q_{0x}\alpha_1)}P_{in}\\ \text{and}\qquad\qquad&\\ P_{cx}&=\frac{1}{1+k_1}P_{in}=\frac{1}{1+(Q_{0x}/Q_{Ly})\alpha_1}P_{in}\end{aligned}\right\}. \tag{21}$$

By defining two more coupling coefficients

$$k_2=P_{yx}/P_B \quad \text{and} \quad k_3=P_{0y}/P_{yx},$$

where P_{0y} is the power coupled out through an iris in the y axis plane, it is possible to write P_{0y} in terms of P_{in}.

The coefficient k_3 depends on the properties of the coupling iris and can be written as

$$k_3=1-Q_{Ly}/Q_{0y}, \tag{22}$$

where Q_{0y} is the unloaded Q in the y axis plane. From expressions (13) and (17)

$$k_2=\alpha_1$$

and

$$\frac{P_{yx}}{P_{in}}=\frac{\alpha_1}{1+(Q_{Ly})/(Q_{0x}\alpha_1)}. \tag{23}$$

Then, by the definitions of the coupling coefficients

$$\frac{P_{0y}}{P_{in}}=\frac{k_1k_2k_3}{1+k_1}=\frac{\alpha_1}{1+(Q_{Ly})/(Q_{0x}\alpha_1)}\left(1-\frac{Q_{Ly}}{Q_{0y}}\right). \tag{24}$$

Thus, the ratio P_{0y}/P_{in} is specified in terms of the beam admittance and the physical characteristics of the cavity.

The rotational power remaining in the spiral beam at the cavity exit, $(P_B)_{exit}$, can be obtained by subtracting P_{yx} from P_B. It is also possible to obtain $(P_B)_{exit}$ from kinetic energy considerations:

$$\left.\begin{aligned}(P_B)_{exit}&=Nm/2[(\dot{x})^2_{t=t_1}+(\dot{y})^2_{t=t_1}]\\ &=\frac{I_0eE_{1x}^2}{2m\omega_0^2\eta^2}(1-\alpha_1)^2=\frac{1-\alpha_1}{1+(Q_{Ly})/(Q_{0x}\alpha_1)}P_{in}\end{aligned}\right\} \tag{25}$$

for a cavity of length $\lambda_0/2$ with $\kappa=1$ and $\eta^2\ll 1$.

The amplitudes of the E-fields defined in Section III can now be readily evaluated in terms of P_{in} for a cavity of length $\lambda_0/2$ with $\kappa=1$. By definition of Q_{0x},

$$E_{0x}=(2Q_{0x}P_{in}/\omega_0\epsilon_0\tau_0)^{\frac{1}{2}}. \tag{26}$$

From (18) and (21),

$$E_{1x}=\left[\frac{2Q_{0x}}{\omega_0\epsilon_0\tau_0}\frac{P_{in}}{1+(Q_{0x}/Q_{Ly})\alpha_1}\right]^{\frac{1}{2}}. \tag{27}$$

From (27) and the definition of α_1,

$$E_{2yx}=\left[\frac{2Q_{0x}}{\omega_0\epsilon_0\tau_0}\frac{\alpha_1^2P_{in}}{1+(Q_{0x})/(Q_{Ly})\alpha_1}\right]^{\frac{1}{2}}. \tag{28}$$

The "counter" E-field, E_{2xx} defined in Section III, is obtained from (26) and (27),

$$E_{2xx}=\left\{\frac{2Q_{0x}P_{in}}{\omega_0\epsilon_0\tau_0}\left[1-\frac{1}{1+(Q_{0x}/Q_{Ly})\alpha_1}\right]\right\}^{\frac{1}{2}}. \tag{29}$$

The actual field present in the cavity is elliptically polarized and rotates in the sense opposite to that of the electrons.

In order to plot some of the foregoing expressions as functions of Y_0, the following values are assumed for an X band TE_{111} cavity with two coupling holes:

$$\begin{aligned}\omega_0&=2\pi\times 9\times 10^9 \text{ c.p.s.},\\ \lambda_g&=4\times 10^{-2} \text{ meter},\\ Q_{0x}&=Q_{0y}=2\times 10^4,\\ Q_{Ly}&=10^4,\\ \tau_0&=2.28\times 10^{-6} \text{ meter}^3\end{aligned}$$

(see Appendix C). All plots are for $\eta^2\ll 1$ and $\kappa=1$, which corresponds to a B-field of 0.32 weber/meter^2 (3200 gauss). A practical range of values for the beam admittance, Y_0, is 10^{-2} to 10^{-7}: $Y_0=10^{-2}$ mhos corresponds to currents of the order of 10 or 100 ma, and voltages of the order of 1 to 10 volts; $Y_0=10^{-7}$ mhos corresponds to currents of the order of 10μa, and voltages of the order of 100 volts.

Figure 4 shows a plot of $\alpha_1=E_{2yx}/E_{1x}$ as a function of Y_0, Eq. (15).

Figure 5 shows a plot of the distribution of power ($P_{in}=P_B+P_{cx}$) between the driving (x axis) plane of polarization and the electron beam as a function of Y_0.

If the mode in the y axis plane is suppressed ($Q_{Ly}=0$), the approximate expressions (21) become indeterminate and it is necessary to let α_1 vanish in the expression for P_B (17). Then

$$P_B=Y_0\lambda_g^2E_{1x}^2/16\pi^2. \tag{30}$$

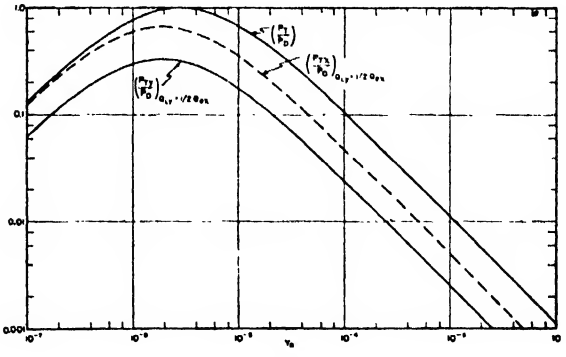

FIG. 8. Power transfer from a spiraling beam of electrons to an X band TE_{111} cavity. $\kappa=1$ and $Q_{Lx}\neq Q_{Ly}$.

Since P_{cx} remains the same,

$$\left.\begin{aligned}\frac{P_B}{P_{\text{in}}}&=\frac{1}{1+(8\pi^2\omega_0\epsilon_0\tau_0)/(Y_0\lambda_g^2Q_{0x})}\\ \text{and}\qquad\\ \frac{P_{cx}}{P_{\text{in}}}&=\frac{1}{1+(Y_0\lambda_g^2Q_{0x})/(8\pi^2\omega_0\epsilon_0\tau_0)}\end{aligned}\right\}. \tag{31}$$

These curves are also shown on Fig. 5.

Figure 6 shows the distribution of the power coupled into the beam ($P_B=P_{yx}+P_B$) as a function of Y_0. If the mode in the y axis plane is suppressed, ($Q_{Ly}=0$), $P_{yx}=0$, and $(P_B)_{\text{exit}}=P_B$.

Figure 7 shows the distribution of power in the driven (y axis) plane of polarization ($P_{yx}=P_{cy}+P_{0y}$) as a function of Y_0. P_{cy} is the power dissipated in the walls of the cavity by the oscillation in the y axis plane and can be written

$$\left.\begin{aligned}P_{cy}&=\frac{\omega_0\epsilon_0\tau_0E_{2yx}^2}{2Q_{0y}}\\ &=\frac{\alpha_1}{1+((Q_{Ly})/(Q_{0x}\alpha_1)}\frac{Q_{Ly}}{Q_{0y}}P_{\text{in}}\end{aligned}\right\} \tag{32}$$

by making use of (28). Since critical coupling ($Q_{0y}=2Q_{Ly}$) was chosen, $P_{0y}=P_{cy}$. It is of interest to determine the dependence of P_{yx} as a function of Q_{Ly}. Using expression (15) for α_1 and differentiating the power ratio P_{yx}/P_{in} (23), with respect to Q_{Ly}/Q_{0x}, the following condition results for maximum P_{yx}/P_{in},

$$\frac{Q_{Ly}}{Q_{0x}}=\left[\frac{8\pi^2\omega_0\epsilon_0\tau_0}{\lambda_g^2Y_0Q_{0x}}+\left(\frac{8\pi^2\omega_0\epsilon_0\tau_0}{\lambda_g^2Y_0Q_{0x}}\right)^2\right]^{\frac{1}{2}}. \tag{33}$$

Substituting this expression in (23), the optimum power ratio P_{yx}/P_{in} is obtained. This optimum power ratio and the ratio Q_{Ly}/Q_{0x} are also plotted in Fig. 7.

The value of Q_{Ly} can be decreased by increasing the size of the coupling hole in the y axis plane. Since it is not possible to enlarge the hole very much beyond critical coupling without materially decreasing the values of Q_{0y} and Q_{0x}, the maximization condition (33) has a limited validity.

VI. COUPLING BETWEEN OSCILLATIONS IN MUTUALLY PERPENDICULAR PLANES OF POLARIZATION IN A CAVITY DRIVEN IN CIRCULAR POLARIZATION

Since all the power in the beam appears at exit for the case of circular polarization, $P_B=(P_B)_{\text{exit}}$. From kinetic energy considerations,

$$P_B=Nm/2[(\dot{x})^2{}_{t=t_1}+(\dot{y})^2{}_{t=t_1}],$$

where $\dot{x}$ and $\dot{y}$ are found by differentiating expressions (5) with E_{1x} substituted for E_{0x}. For a cavity of length $\lambda_g/2$ with $\kappa=1$ for $\eta\ll1$,

$$P_B=(Y_0E_{1x}^2\lambda_g^2)/4\pi^2. \tag{34}$$

For a cylindrically symmetrical cavity, one-half of the power in the beam is coupled from the driving field in each of the two planes of polarization. Thus it is possible to define coefficients, similar to k_1 (19),

$$k_{1x}=P_{Bx}/P_{cx}$$

and

$$k_{1y}=P_{By}/P_{cy},$$

where $P_{Bx}=P_{By}=\frac{1}{2}P_B$. Then $k_{1x}=k_{1y}$. Using (18) for P_{cx}

$$k_{1x}=\frac{Y_0\lambda_g^2Q_{0x}}{4\pi^2\omega_0\epsilon_0\tau_0} \tag{35}$$

is obtained. By analogy with the expressions (21),

$$\left.\begin{aligned}P_{Bx}&=[k_{1x}/(1+k_{1x})](P_{\text{in}})_x\\ P_{cx}&=[1/(1+k_{1x})](P_{\text{in}})_x\end{aligned}\right\}. \tag{36}$$

Similar expressions hold for the y axis plane.

From (36) and (18), E_{1x} can be written explicitly as

$$E_{1x}=\left[\frac{2Q_{0x}}{\omega_0\epsilon_0\tau_0}\frac{(P_{\text{in}})_x}{1+k_{1x}}\right]^{\frac{1}{2}} \tag{37}$$

and by definition

$$E_{0x}=\left[\frac{2Q_{0x}}{\omega_0\epsilon_0\tau_0}(P_{\text{in}})_x\right]^{\frac{1}{2}}.$$

From expression (8),

$$E_{2xx}+E_{2xy}=E_{0x}-E_{1x}=\left[\frac{2Q_{0x}(P_{\text{in}})_x}{\omega_0\epsilon_0\tau_0}\left(\frac{k_{1x}}{1+k_{1x}}\right)\right]^{\frac{1}{2}}. \tag{38}$$

Similar expressions hold for the y axis plane.

VII. EXCITATION OF A TE_{11n_z} CAVITY BY A SPIRALING BEAM OF ELECTRONS

Since the transient case is of little practical interest, it is assumed that steady-state conditions have been reached.

In Section IV, the expressions for the trajectory of the electron beam were determined for the case of a cavity excited by a spiraling beam. The power transferred to the cavity is found by taking the line integral of the product of the beam current and the E-field along the trajectory of the beam through the cavity. If the Q's of the two modes are not the same, it is convenient to evaluate separately the line integrals of the x and y components of the r-f field. The general expressions are specialized to the case of a cavity of length $\lambda_g/2$ with $\kappa=1$ and $\eta^2\ll1$.

The power transferred to the cavity, P_T, is given by the integral

$$P_T = +Ne\int \boldsymbol{E}_2\cdot\mathbf{ds}, \tag{39}$$

where

$$\boldsymbol{E}_2 = -\boldsymbol{x}E_{2x}\sin(2\pi z/\lambda_g)\cos\omega_0 t - \boldsymbol{y}E_{2y}\sin(2\pi z/\lambda_g)\sin\omega_0 t$$

and

$$\mathbf{ds} = \boldsymbol{x}\dot{x}dt + \boldsymbol{y}\dot{y}dt.$$

Considering first the case where $Q_{Lx}\neq Q_{Ly}$, it is convenient to write P_T as the sum $(P_{Tx}+P_{Ty})$ of the powers transferred to the two modes. Then

$$\left.\begin{aligned} P_{Tx} &= -Ne\int \boldsymbol{x}E_{2x}\cdot\mathbf{ds} \\ \text{and} \\ P_{Ty} &= -Ne\int \boldsymbol{y}E_{2y}\cdot\mathbf{ds} \end{aligned}\right\}. \tag{40}$$

The evaluation of the first of these integrals for a cavity of length $\lambda_g/2$ with $\kappa=1$ results in since $\eta^2\ll 1$,

$$P_{Tx} = -\frac{NeE_{2x}}{\omega_0\eta}\dot{x}_0 - \frac{Ne^2E_{2x}^2}{2m\omega_0^2\eta^2} - \frac{Ne^2E_{2x}E_{2y}}{2m\omega_0^2\eta^2}. \tag{41}$$

With the usual expression for the cavity Q,

$$P_{Tx} = \omega_0\epsilon_0\tau_0 E_{2x}^2/2Q_{Lx}. \tag{42}$$

These expressions determine E_{2x},

$$E_{2x} = \frac{-2I_0\dot{x}_0/\omega_0\eta}{(\omega_0\epsilon_0\tau_0/Q_{Lx}) + (Y_0\lambda_g^2/8\pi^2)(1+Q_{Ly}/Q_{Lx})} \tag{43}$$

where $\dot{x}_0$ is negative. Using (42)

$$P_{Tx} = \frac{\omega_0\epsilon_0\tau_0}{2Q_{Lx}} \times\left[\frac{-2I_0\dot{x}_0/\omega_0\eta}{(\omega_0\epsilon_0\tau_0/Q_{Lx}) + (Y_0\lambda_g^2/8\pi^2)(1+Q_{Ly}/Q_{Lx})}\right]^2. \tag{44}$$

Defining the driving power as

$$P_D = (Nm/2)\dot{x}_0^2, \tag{45}$$

it is possible to write (44) as the power ratio,

$$\frac{P_{Tx}}{P_D} = \frac{Q_{Lx}Y_0\lambda_g^2}{2\pi^2\omega_0\epsilon_0\tau_0} \times\left[\frac{1}{1+[Y_0\lambda_g^2(Q_{Lx}+Q_{Ly})]/[8\pi^2\omega_0\epsilon_0\tau_0]}\right]^2. \tag{46}$$

Similar expressions hold for the y axis plane.

If the cavity has one iris which couples to the y axis plane, Q_{Lx} will be greater than Q_{Ly}, and more power is coupled to the unloaded plane of polarization.

For the special case where $Q_{Lx}=Q_{Ly}$, $E_{2x}=E_{2y}$ and the total power transferred is $2P_{Tx}$,

$$\frac{P_T}{P_D} = \frac{Q_{Lx}Y_0\lambda_g^2}{\pi^2\omega_0\epsilon_0\tau_0}\left[\frac{1}{1+[Q_{Lx}Y_0\lambda_g^2]/[4\pi^2\omega_0\epsilon_0\tau_0]}\right]^2. \tag{47}$$

Figure 8 shows the power ratio P_T/P_D (47) as a function of Y_0 for a cylindrically symmetrical X band cavity having the same physical constants as used in Section V with Q_{Lx} taken equal to Q_{Ly}. Above the critical value of Y_0 for which P_T/P_D equals unity, the power transferred to the cavity drops off rapidly. The physical explanation is that for higher values of Y_0, the electrons lose all their rotational energy to the r-f field before they complete their transit through the cavity, and start to regain rotational energy from the field.

Figure 8 also shows P_{Tx}/P_D (46) and P_{Ty}/P_D (46) plotted as functions of Y_0 for the case where there is a single iris critically coupled to the y axis plane. Then

$$Q_{Lx} = Q_{0x} = 2Q_{Ly}.$$

The total power transferred to the beam $(P_{Tx}+P_{Ty})$ is

$$\frac{P_T}{P_D} = (Q_{Lx}+Q_{Ly})\frac{Y_0\lambda_g^2}{2\pi^2\omega_0\epsilon_0\tau_0} \times\left[\frac{1}{1+[Y_0\lambda_g^2(Q_{Lx}+Q_{Ly})]/[8\pi^2\omega_0\epsilon_0\tau_0]}\right]^2.$$

Maximizing this ratio with respect to Y_0 determines the critical value of Y_0,

$$Y_0 = \frac{8\pi^2\epsilon_0\omega_0\tau_0}{\lambda_g^2(Q_{Lx}+Q_{Ly})}.$$

VIII. CONCLUSIONS

Several possible applications of the interaction between the resonant cavity oscillations and the spiral beam of electrons are evident. First, this interaction could be used as the basic energy interchange mechanism in a microwave generator. Second, the coupling between oscillations in the two planes of polarization in a single cavity or the coupling between two cavities by an electron beam could serve as a method of amplitude modulating a microwave signal. Modulation could be effected by varying either the beam current or voltage. A tube called the Electron Coupler, which uses a two-cavity system for amplitude modulation, has

recently been described in the literature.[7] Third, the resonant cavity driven by an external oscillator could be used as a microwave circular sweep generator. This sweep would be particularly useful for measuring extremely short pulses. For example, a spiral beam formed in the X band cavity described would make one complete revolution in about 10^{-10} second and could therefore be used to measure time intervals up to the order of 10^{-11} second.

Experimental X band tubes have been constructed in this Laboratory. The experimental results obtained will be published in a later paper.

APPENDIX A

Solution of the Equations of Motion in a TE_{11n_z} Cavity

The equations of motion (1) can be written using the Laplace transform notation[8] for $0 \leq t \leq t_1$,

$$\left.\begin{aligned} s^2X(s)+\omega_c sY(s) &= -(e/m)\mathfrak{L}(\mathcal{E}_x) \\ s^2Y(s)-\omega_c sX(s) &= -(e/m)\mathfrak{L}(\mathcal{E}_y) \end{aligned}\right\},$$

where s=variable in the complex plane, $\mathfrak{L}$=Laplace transform of, $X(s)$=Laplace transform of $x(t)$, $Y(s)$=Laplace transform of $y(t)$.

The initial conditions assumed are that $x=0$, $\dot{x}=0$, $y=0$, and $\dot{y}=0$ at $t=0$. Then

$$\left.\begin{aligned} X(s) = &-\frac{eE_{0x}}{2m}\frac{\omega_c}{s(s^2+\omega_c^2)} \\ &\times\mathfrak{L}\{\cos[(1+\eta)\omega_0 t+\phi]-\cos[(1-\eta)\omega_0 t+\phi]\} \\ &-\frac{eE_{0y}}{2m}\frac{1}{s^2+\omega_c^2} \\ &\times\mathfrak{L}\{\sin[(1+\eta)\omega_0 t+\phi]-\sin[(1-\eta)\omega_0 t+\phi]\} \end{aligned}\right\}$$

and

$$\left.\begin{aligned} Y(s) = &-\frac{eE_{0x}}{2m}\frac{\omega_c}{s(s^2+\omega_c^2)} \\ &\times\mathfrak{L}\{\sin[(1+\eta)\omega_0 t+\phi]-\sin[(1-\eta)\omega_0 t+\phi]\} \\ &+\frac{eE_{0y}}{2m}\frac{1}{s^2+\omega_c^2} \\ &\times\mathfrak{L}\{\cos[(1+\eta)\omega_0 t+\phi]-\cos[(1-\eta)\omega_0 t+\phi]\} \end{aligned}\right\}.$$

For the linearly polarized mode, $E_{0y}=0$. Then, for $\omega_0 \neq (1\pm\eta)\omega_0$,

$$\left.\begin{aligned} x(t) = &-\frac{eE_{0x}}{2m}\mathfrak{L}^{-1}\left[\frac{(1+\eta)\omega_0\cos\phi+s\sin\phi}{(s^2+\omega_c^2)(s^2+(1+\eta)^2\omega_0^2)}\right. \\ &\left.-\frac{(1-\eta)\omega_0\cos\phi+s\sin\phi}{(s^2+\omega_c^2)(s^2+(1-\eta)^2\omega_0^2)}\right] \\ y(t) = &-\frac{eE_{0x}}{2m}\omega_c\mathfrak{L}^{-1}\left[\frac{(1+\eta)\omega_0\cos\phi+s\sin\phi}{s(s^2+\omega_c^2)(s^2+(1+\eta)^2\omega_0^2)}\right. \\ &\left.-\frac{(1-\eta)\omega_0\cos\phi+s\sin\phi}{s(s^2+\omega_c^2)(s^2+(1-\eta)^2\omega_0^2)}\right] \end{aligned}\right\},$$

where $\mathfrak{L}^{-1}$ means the inverse Laplace transform. By taking the inverse and letting $\omega_0=\omega_c$, i.e., $\kappa=1$, the Eqs. (3) are obtained.

For the circularly polarized driving field, $E_{0y}\neq 0$ and $\phi=0$, then

$$\left.\begin{aligned} x(t) = &-\frac{eE_{0x}}{2m}\mathfrak{L}^{-1}\left[\frac{(1+\eta)\omega_0}{(s^2+\omega_c^2)(s^2+(1+\eta)^2\omega_0^2)}\right. \\ &\left.-\frac{(1-\eta)\omega_0}{(s^2+\omega_c^2)(s^2-(1-\eta)^2\omega_0^2)}\right] \\ &-\frac{eE_{0y}}{2m}\mathfrak{L}^{-1}\left[\frac{\omega_c}{(s^2+\omega_c^2)(s^2+(1+\eta)^2\omega_0^2)}\right. \\ &\left.-\frac{\omega_c}{(s^2+\omega_c^2)(s^2+(1-\eta)^2\omega_0^2)}\right] \\ y(t) = &-\frac{eE_{0x}}{2m}\mathfrak{L}^{-1}\left[\frac{\omega_c(1+\eta)\omega_0}{s(s^2+\omega_c^2)(s^2+(1+\eta)^2\omega_0^2)}\right. \\ &\left.-\frac{\omega_c(1-\eta)\omega_0}{s(s^2+\omega_c^2)(s^2+(1-\eta)^2\omega_0^2)}\right] \\ &-\frac{eE_{0y}}{2m}\mathfrak{L}^{-1}\left[\frac{s}{(s^2+\omega_c^2)(s^2+(1+\eta)^2\omega_0^2)}\right. \\ &\left.+\frac{s}{(s^2+\omega_c^2)(s^2+(1-\eta)^2\omega_0^2)}\right] \end{aligned}\right\}.$$

By taking the inverse of these expressions, and letting $\omega_0=\omega_c$, i.e., $\kappa=1$, and $E_{0x}=E_{0y}$, Eqs. (5) are obtained. Equations (7) are obtained when E_{1x} is substituted for E_{0x} and $-E_{2yx}$ is substituted for E_{0y}.

APPENDIX B

Solution of the Equations of Motion in a TE_{11n_z} Cavity Driven by a Spiraling Electron Beam

The equations of motion (1) can be written in Laplace transform notation[8] for $0 \leq t \leq t_1$,

$$\left.\begin{aligned} s^2X(s)-\dot{x}_0+\omega_c sY(s)-\omega_c y_0 &= -(e/m)\mathfrak{L}(\mathcal{E}_x) \\ s^2Y(s)-y_0 s-\omega_c sX(s) &= -(e/m)\mathfrak{L}(\mathcal{E}_y) \end{aligned}\right\},$$

[8] M. F. Gardner and J. L. Barnes, *Transients in Linear Systems* (John Wiley and Sons, Inc., New York, 1942).

where the initial conditions at $t=0$ are: $x=0$, $y=y_0$, $\dot{x}=\dot{x}_0$, $\dot{y}=0$. Then,

$$x(t)=\mathfrak{L}^{-1}\left\{\frac{\dot{x}_0}{s^2+\omega_c^2}+\frac{eE_{2x}}{2m}\left[\frac{(1+\eta)\omega_0}{(s^2+\omega_c^2)(s^2+(1+\eta)^2\omega_0^2)}-\frac{(1-\eta)\omega_0}{(s^2+\omega_c^2)(s^2+(1-\eta)^2\omega_0^2)}\right]\right.$$
$$\left.+\frac{eE_{2y}}{2m}\left[\frac{\omega_c}{(s^2+\omega_c^2)(s^2+(1+\eta)^2\omega_0^2)}-\frac{\omega_c}{(s^2+\omega_c^2)(s^2+(1-\eta)^2\omega_0^2)}\right]\right\}$$

$$y(t)=\mathfrak{L}^{-1}\left\{\frac{y_0 s}{s^2+\omega_c^2}+\frac{\omega_c^2 y_0+\omega_c\dot{x}_0}{s(s^2+\omega_c^2)}-\frac{eE_{2x}}{2m}\left[\frac{\omega_c(1+\eta)\omega_0}{s(s^2+\omega_c^2)(s^2+(1+\eta)^2\omega_0^2)}-\frac{\omega_c(1-\eta)\omega_0}{s(s^2+\omega_c^2)(s^2+(1-\eta)^2\omega_0^2)}\right]\right.$$
$$\left.+\frac{eE_{2y}}{2m}\left[\frac{s}{(s^2+\omega_c^2)(s^2+(1+\eta)^2\omega_0^2)}-\frac{s}{(s^2+\omega_c^2)(s^2+(1-\eta)^2\omega_0^2)}\right]\right\}.$$

By taking the inverse and letting $\omega_0=\omega_c$, i.e., $\kappa=1$, Eqs. (11) are obtained.

APPENDIX C

Evaluation of $\frac{1}{2}\epsilon_0\int E^2 d\tau$ in TE_{11n_z} Cavity

The E-field in a TE_{11n_z} cavity is given by[9]

$$\left.\begin{aligned}E_r&=-A_0\frac{1}{k_c r}J_1(k_c r)\sin\theta\sin\frac{2\pi n_z z}{\lambda_g}\\ E_\theta&=A_0 J_1'(k_c r)\cos\theta\sin\frac{2\pi n_z z}{\lambda_g}\end{aligned}\right\},\qquad\text{(C-1)}$$

where n_z is an integer. Then

$$\frac{1}{2}\epsilon_0\int E^2 d\tau=\frac{\epsilon_0 A_0^2}{2}\int_0^{(n_z\lambda_g/2)}\sin^2\frac{2\pi n_z z}{\lambda_g}dz\times\int_0^a\int_0^{2\pi}\left[\frac{1}{k_c^2 r^2}J_1^2(k_c r)\sin^2\theta+J_1'^2(k_c r)\cos^2\theta\right]r\,dr\,d\theta$$
$$=\frac{\epsilon_0 A_0^2}{2}\frac{n\lambda_g\pi}{4k_c^2}\left[\int_0^{k_c a}\frac{1}{\rho}J_1^2(\rho)d\rho+\int_0^a\rho J_1'^2(\rho)d\rho\right],\qquad\text{(C-2)}$$

[9] S. Ramo and J. R. Whinnery, *Fields and Waves in Modern Radio* (John Wiley and Sons, Inc., New York, 1944).

where a is the radius of the cavity, and $\rho=k_c r$. The last integral in (C-2) becomes

$$\int_0^{k_c a}\rho J_1'^2(\rho)d\rho=-\frac{J_1^2(k_c a)}{2}+k_c a J_0(k_c a)J_1(k_c a)+\frac{J_0^2(k_c a)}{2}-\frac{1}{2}-\frac{k_c^2 a^2}{2}[J_1^2(k_c a)-J_0(k_c a)J_2(k_c a)].\qquad\text{(C-3)}$$

The first integral in (C-2) cannot be integrated in a closed form, but the integrand can be expanded in a series and then integrated. For an upper limit of integration less than 2, only the first six terms are required for three-place accuracy. Thus

$$\int_0^{k_c a}\frac{1}{\rho}J_1^2(\rho)d\rho\doteq\left[\frac{\rho^2}{8}-\frac{\rho^4}{64}+\frac{5\rho^6}{4608}-\frac{7\rho^8}{147456}+\frac{\rho^{10}}{737{,}280}\right]_0^{k_c a}.\qquad\text{(C-4)}$$

Then the stored energy integral can be written

$$\frac{1}{2}\epsilon_0\int E^2 d\tau=\frac{1}{2}\epsilon_0 A_0^2\tau_0'=\frac{1}{2}\epsilon_0 E_0^2\tau_0$$

where τ_0' is found from the evaluation of (C-2) using expressions (C-3) and (C-4). Then $\tau_0=4\tau_0'$ because $A_0=2E_0$.

For an X band TE_{111} cavity, where $f_0=9000$ mc, $a=1.75\times10^{-2}$ meter, and $\lambda_g=4\times10^{-2}$ meter. Then $k_c a=1.85$, and the approximation condition is satisfied. For these numerical values, $\tau_0=2.28\times10^{-6}$ meter.[3]

Geometrical Factors Affecting the Contours of X-Ray Spectrometer Maxima. II. Factors Causing Broadening*

LEROY ALEXANDER
Department of Research in Chemical Physics, Mellon Institute, Pittsburgh, Pennsylvania
(Received July 25, 1949)

By applying Stokes' Fourier transform method for the analysis of diffraction maxima it is shown that the pure diffraction contour generated by a crystallite size distribution is apt to be approximated rather closely by the function $1/(1+k^2\phi^2)$. In the case of the x-ray spectrometer this pure diffraction contour is broadened significantly by the action of the following five geometrical factors: (I) the x-ray source width, (II) flat rather than curved sample surface, (III) vertical divergence of the x-ray beam, (IV) penetration of the sample by the beam, and (V) the receiving slit width.

The broadening of the pure diffraction contour due to the action of each of the five factors and the breadth of the final contour generated by the instrument can be deduced by employing the convolution approach suggested by Spencer. The effect of each instrumental factor is expressed by a convolution equation of the form

$$f_i(\phi)=\int_{-\infty}^{+\infty} W_i(\xi)f_{i-1}(\phi-\xi)d\xi,$$

in which ϕ is the angular displacement from twice the ideal Bragg angle, 2θ, f_{i-1} is the contour before the action of the ith geometrical factor, W_i is the form of the ith geometrical factor, and f_i is the contour after the action of W_i on f_{i-1}. Starting with a pure diffraction contour of the form $1/(1+k^2\phi^2)$, generalized broadening curves are derived for the effect of each of the five geometrical factors. Using these curves it is possible to predict the breadth of the final diffraction contour generated by the spectrometer from an initial contour of any breadth.

I. INTRODUCTION

IN addition to its theoretical interest this subject commands attention because of the very general employment of the diffraction contour width as a criterion of crystalline size. The problem is essentially that of deducing the nature of the pure diffraction contour free of instrumental contributions. Several investigators have suggested methods of attacking the problem,[1–6] the most directly applicable one being that of Stokes.[5]

In the present paper each of the geometrical factors causing significant broadening will be discussed separately, and it will be indicated how the net broadening can be estimated as a result of the combined action of the several factors. In the following paper (this issue) these findings are applied to the problem of more accurately determining the crystallite sizes of powders from contour broadening measurements.

When freed of instrumental effects, the breadth of a contour approaches zero for the case of crystallite dimensions greater than 1000A and for moderate Bragg angles (such as must be resorted to in conventional spectrometers). However, at Bragg angles close to 90° the pure contour breadth is measurable for crystallite dimensions as large as 2000A.

For a powder spectrometer in good adjustment the instrumental factors causing appreciable broadening are the following: (I) width of x-ray source (or "source" slit if two slits are used), (II) flat rather than curved sample surface, (III) vertical divergence, (IV) penetration of the sample by the beam, and (V) width of the receiving slit. In the older Norelco model in which Soller slits are not employed, factor (I) is usually dominant while (IV) and (V) may or may not be important. In the newer models vertical divergence is practically eliminated by the use of Soller slits, while at the same time very narrow sources are employed. For this case factor (I) becomes less important and (III) can be neglected.

II. THE MATHEMATICAL EXPRESSION OF INSTRUMENTAL EFFECTS

Spencer[2,3] has pointed out that the effect of an apparatus is to transform a function $f(x)$ into a function $F(x)$ which is directly observable. Assuming that the superposition theorem holds, $F(x)$ is the convolution (*Faltung*) of $f(x)$ and the weight function, $W(x)$, of the apparatus, *viz.*,

$$F(x)=\int_{-\infty}^{+\infty} W(u)f(x-u)du. \qquad (1)$$

This expression has also been derived by Jones[7] for the special case of Debye-Scherrer powder diffraction con-

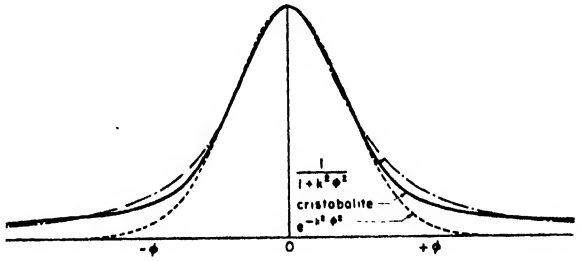

FIG. 1. Comparison of the pure diffraction contour of cristobalite with the functions $1/(1+k^2\phi^2)$ and $\exp(-k^2\phi^2)$.

* Presented in part before the American Society for X-Ray and Electron Diffraction at Cornell University, Ithaca, New York, on June 25, 1949. For Paper No. I, "Factors Causing Asymmetry," see J. App. Phys. **19**, 1068 (1948).

tours. The auxiliary variable u has the same dimensions as x and its introduction in Eq. (1) is a characteristic feature of the superposition theorem. The weight function, $W(x)$, is to be regarded as a function which expresses the sum total of the apparatus effects upon the pure function which is being measured. Alternately, the instrumental weight function may be split up into each of the several instrumental factors, which it may be more convenient to analyze separately. The ultimate response curve of the apparatus may then be obtained by the successive operation of each specific weight function upon the response curve generated by the action of the preceding specific function. Thus, for n instrumental factors and weight functions W_I, W_{II}, $W_{III}, \cdots W_n$, we would have the generation of the respective contours $f_1, f_2, f_3, \cdots, f_n = F$, according to the successive action of these weight functions:

$$\left.\begin{aligned} f_1(x) &= \int_{-\infty}^{+\infty} W_I(u) f(x-u)\,du, \\ f_2(x) &= \int_{-\infty}^{+\infty} W_{II}(u) f_1(x-u)\,du, \\ f_3(x) &= \int_{-\infty}^{+\infty} W_{III}(u) f_2(x-u)\,du, \\ f_n(x) = F(x) &= \int_{-\infty}^{+\infty} W_n(u) f_{n-1}(x-u)\,du. \end{aligned}\right\} \quad (2)$$

It should be borne in mind that in Eqs. (1) and (2), $f(x-u)$ is the pure function which we are seeking to measure and which was originally written simply as $f(x)$. It must be kept in mind that the symbol f denotes a specific function, regardless of the notation used for the independent variable (x or $x-u$).

The elucidation of contour broadening in an x-ray powder spectrometer, then, resolves itself into the twofold task of (a) deducing or assuming satisfactorily the nature of the pure diffraction contour, $f(x)$, and (b) determining the proper forms of the five instrumental weight functions W_I, W_{II}, W_{III}, W_{IV}, and W_V, corresponding to the five factors listed above which contribute to contour breadth. Once this has been done, Eqs. (2) can be employed to synthesize the final contour generated by the instrument starting from any original pure diffraction contour.

III. THE PURE DIFFRACTION CONTOUR

Case I. Crystallite Size > 1000A

For moderate Bragg angles the pure contour width is imperceptible and may be neglected. Hence, in Eq. (2) $f(x-u)$ is effectively a constant and $f_1(x) = W_I(x)$, so that for this case the first convolution equation drops out and we start with the action of W_{II}, the flat sample factor, on W_I, the x-ray source contour.

TABLE I. Pure diffraction contours of miscellaneous materials showing crystallite size broadening. The first five were analyzed by the Fourier method of Stokes. Degree of resemblance to $e^{-k^2\phi^2}$ or $1/(1+k^2\phi^2)$ is indicated as an approximate percentage.

No.	Material	Origin	Percentage resemblance to $e^{-k^2\phi^2}$	Percentage resemblance to $1/(1+k^2\phi^2)$
1	MgO	Decomposition of magnesium carbonate at 600°C.	20	80
2	CaF_2	Presumably precipitated from aqueous solution.	50	50
3	Cristobalite	Thermal treatment of diatomaceous earth (amorphous SiO_2).	20	80
4	Basic calcium phosphate	Precipitated from aqueous solution.	10	90
*5	Cold worked copper	Specific information not published.	20	80
**6	Nickel catalyst	Alkaline treatment of Raney alloy.	10	90

* This contour published by Stokes.
** This contour not analyzed by the Fourier method because its width was so great as to render the instrumental contributions negligible.

Case II. Crystallite Size < 1000A

The pure diffraction contour is a function of the mean crystallite shape[8] and of the size distribution. Obviously these factors will vary widely with the chemical constitution and origin of any particular powder sample. The investigations of Jones[7] tend to show that for a crystallite size distribution, the diffraction contour is given more closely by the function $1/(1+k^2x^2)$ than by a normal distribution curve ($e^{-k^2x^2}$). Stokes[5] has recently described a Fourier transform method for deducing the nature of the pure diffraction contour free of instrumental contributions. This method makes it possible for the first time to replace the somewhat speculative notions of the past with dependable information about the nature of the pure diffraction contour.

Using a Patterson-Tunell[9] set of strips and stencils for the rapid summation of Fourier series, the pure diffraction contours of a number of materials have been determined by the procedure of Stokes with the results summarized in Table I. In Fig. 1 the rather typical case of the cristobalite contour is portrayed. Its comparatively close coincidence with the function $1/(1+k^2\phi^2)$ is evident, and it will be noted from Table I that five of the six materials showed equally good or even better agreement with this function. Only in the case of CaF_2 was the agreement poorer, and even then the pure diffraction contour did not resemble $e^{-k^2\phi^2}$ more closely than $1/(1+k^2\phi^2)$. The most fundamental point of difference between these two mathematical functions is the much more gradual decrease in magnitude of the latter as ϕ becomes large. As suggested by Jones,[7] it is not surprising that this function should more accurately fit the case of the diffraction contour of a crystallite size distribution. There are theoretical reasons for $e^{-k^2\phi^2}$ being the better choice if all the

[8] A. R. Stokes and A. J. C. Wilson, Proc. Camb. Phil. Soc. 38, 313 (1942).
[9] A. L. Patterson and G. Tunell, Am. Mineralogist 27, 655 (1942).

crystallites are of the same size, whereas for a distribution of sizes the large crystallites will tend to sharpen the peak while the small ones will broaden the base of the contour.

In view of the above considerations together with the experimental data of Table I, there appears to be good justification for choosing the simple mathematical function $1/(1+k^2\phi^2)$ to approximate the pure diffraction contour generated by a typical crystallite size distribution.

Having thus decided on a suitable form for the pure contour function, $f(x-u)$, of Eqs. (2), we now proceed to evaluate each of the five weight functions corresponding to the five geometrical factors which act to modify it. In order to retain maximum generality in the following analysis, we shall discuss Case II, in which the pure diffraction contour possesses appreciable breadth. In the ensuing treatment as well as in the preceding three paragraphs the generalized parameter x of Eqs. (1) and (2) is replaced by the appropriate quantity ϕ, which is the angular displacement from the theoretical angle, 2θ, of a given reflection. Unless otherwise indicated the term *width*, or *breadth*, of a contour will refer to the width at half maximum intensity.

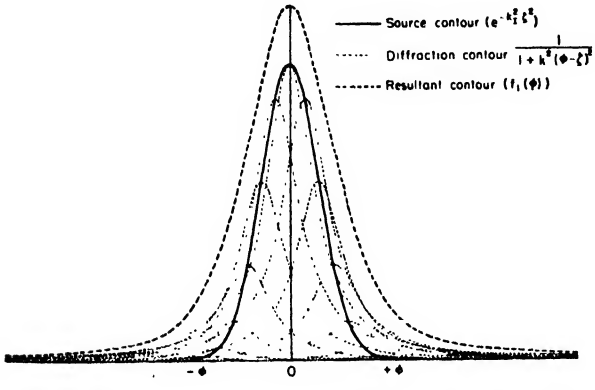

FIG. 2. Schematic representation of the convolution of the source contour and a pure diffraction contour:

$$f_1(\phi)=\int_{-\infty}^{+\infty}\frac{\exp(-k_I^2\zeta^2)d\zeta}{1+k^2(\phi-\zeta)^2}.$$

The case pictured is that of $w/w_I=0.85$ and $w_1/w=1.80$.

IV. EFFECT OF THE X-RAY SOURCE WIDTH (W_I)

In the past it has been customary to assume that the distribution of energy across the focus of the x-ray tube is either uniform or of the form $e^{-k^2\phi^2}$.[10] Pinhole photographs of tube foci usually reveal a more or less irregular intensity distribution which does not conform to either of these assumptions, although it commonly approaches the exponential state more or less closely. With a focusing powder spectrometer possessing a relatively wide source (of the order of $0.20°2\theta$), it is possible to observe the effective source contour with little distortion by scanning a diffraction contour produced by some material of large crystallite size in order to eliminate the pure contour breadth. At the same time it is necessary to keep the x-ray beam divergence small and to employ a narrow receiving slit. Under these conditions the factors other than source width become of minor importance in influencing the observed contour. Using a Norelco Geiger-Counter Spectrometer Type No. 12021, the copper and iron anode tubes used in the present investigation were thus shown to possess source configurations approaching the normal distribution curve, $e^{-k^2\phi^2}$, very closely. Such an intensity distribution will be assumed in the present paper, although it must be remembered that a radical departure from this type of configuration, which might well be found for some particular x-ray tubes, would lead to a corresponding modification of the analysis to follow.

We may write for the weight function of the source contour

$$W_I(\phi)=\exp(-k_I^2\phi^2), \tag{3}$$

in which the value of k_I determines the width of the contour and from which we have eliminated any amplitude coefficient since it has no bearing on the contour shape. The pure contour is assumed to be of the form

$$f(\phi)=1/(1+k^2\phi^2), \tag{4}$$

so that we obtain for the convolution of W_I and f

$$_1(\phi)=\int_{\infty}^{+\infty}W_I(\zeta)f(\phi-\zeta)d\zeta$$

$$=\int_{-\infty}^{+\infty}\frac{\exp(-k_I^2\zeta^2)d\zeta}{1+k^2(\phi-\zeta)^2}. \tag{5}$$

In terms of the widths of the W_I and f contours at half maximum intensity, w_I and w, we find for k_I and k respectively:

$$(W_I)_{\frac{1}{2}}=(W_I)_0/2=\tfrac{1}{2}=\exp(-k_I^2\phi_{\frac{1}{2}}^2)$$

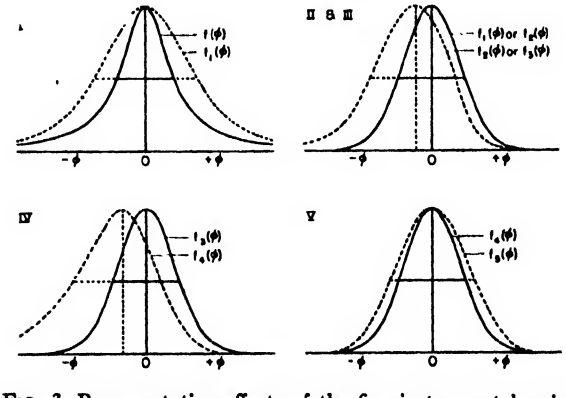

FIG. 3. Representative effects of the five instrumental weight functions upon a diffraction contour. The solid and dashed lines respectively depict the diffraction contour before and after the action of each weight function. The effects of the following functions are portrayed: (I) the x-ray source, (II) flat rather than curved sample surface, (III) vertical divergence, (IV) penetration of the sample by the beam, and (V) the receiving slit.

[10] A. Taylor and H. Sinclair, Proc. Phys. Soc. 57, 108 (1945).

or

$$k_I=(\log_e 2)^{\frac{1}{2}}/\phi_{\frac{1}{2}}=2(\log_e 2)^{\frac{1}{2}}/w_I=1.67/w_I, \quad (6)$$

and

$$f_{\frac{1}{2}}=f_0/2=\tfrac{1}{2}=1/(1+k^2\phi_{\frac{1}{2}}^2)$$

or

$$k=1/\phi_{\frac{1}{2}}=2/w. \quad (7)$$

Using the procedure described above for determining the approximate form of the source intensity distribution, it was found that w_I for the copper anode tube was about 0.20° (in $\Delta 2\theta$, or ϕ, units). This agreed substantially with a geometrical deduction of the angular source width from the manufacturer's specifications for the size of the focus. In the improved spectrometers with Soller slits and vertical focal spots, W_I is ordinarily very much smaller.

An attempt has been made in Fig. 2 to picture the meaning of the convolution equation, (5). The source contour acts as the envelope for an infinite number of diffraction contours (represented by a finite number in Fig. 2) all of the same shape but differing in amplitude. The resultant intensity at any point ϕ is the sum of the intensities of the various diffraction contours at this point. In Fig. 2 the amplitude of the resultant contour has been greatly scaled down to permit plotting it in the same diagram with the source and diffraction contours. It will be observed that the resultant contour is much broader than the original diffraction contour.

Equation (5) cannot be integrated readily, but sufficiently accurate solutions can be obtained by evaluating the equivalent summation at small intervals:

$$f_1(\phi)=\sum_{-\infty}^{+\infty}\frac{\exp(-k_I^2\zeta^2)}{1+k^2(\phi-\zeta)^2}\Delta\zeta. \quad (8)$$

The calculations are facilitated by graphing the denominator function for values of $(\phi-\zeta)$ and by utilizing standard tables of the normal distribution function, $(2\pi)^{-\frac{1}{2}}e^{-(\frac{1}{2})x^2}$, for obtaining the numerator. This is accomplished by converting the exponential function from $\exp(-k_I^2\zeta^2)$ to $\exp[-\frac{1}{2}(2^{\frac{1}{2}}k_I\zeta)^2]$, permitting the value of the numerator to be obtained as a function of the argument $2^{\frac{1}{2}}k_I\zeta$. When $w_I=0.20°$ the interval $\Delta\zeta$ should be about 0.01°. Figure 3(I) depicts the action of a source of breadth $w_I=0.20°$ in broadening a pure diffraction contour of breadth $w=0.20°$ to a resultant contour for which $w_1=0.327°$.

The relative broadening of the pure contour is a function only of the ratio of the breadth of the pure contour to the breadth of the x-ray source contour, w/w_I. The relative broadening is the ratio of the breadth of the contour after the action of the source factor, which we may denote by w_1, to its original breadth, w. Figure 4(I) shows this broadening ratio, w_1/w, as a function of w/w_I, the location of the curve having been precisely determined by the application of Eq. (8) to a number of pairs of values of w and w_I [and, therefore, also of k and k_I by Eqs. (6) and (7)].

V. EFFECT OF FLAT RATHER THAN CURVED SAMPLE SURFACE (W_{II})

From Fig. 5 it is seen that an x-ray beam of horizontal divergence angle α and impinging upon a flat sample surface at the angle θ (as in conventional spectrometers) will irradiate a length of sample which is approximately given by

$$2s=\alpha d/\sin\theta, \quad (9)$$

where d is the distance from source to sample. This formula is very accurate for the usual small values of α of not more than 2° or 3°. In actual practice the effective beam divergence at low Bragg angles is limited by the length of the sample, l, so that for $\sin\theta<\alpha d/l$ the effective divergence is $\alpha=(l/d)\sin\theta$. To simplify the present discussion, however, the sample surface will be assumed to be very large so that (9) holds at all values of θ. We shall first investigate the effect of sample flatness in broadening the focus of the diffracted rays at the receiving slit.

Figure 6 shows how this happens. The flat sample, S_1-S_2, is tangent to the focusing circle at its midpoint, S_0. A central ray FS_0, which impinges at the Bragg angle θ upon the surface, is diffracted (also at the Bragg angle θ) to the theoretical focus at G. But a non-central ray, FS', impinging at an angle $\theta+\Delta\theta$, is diffracted at

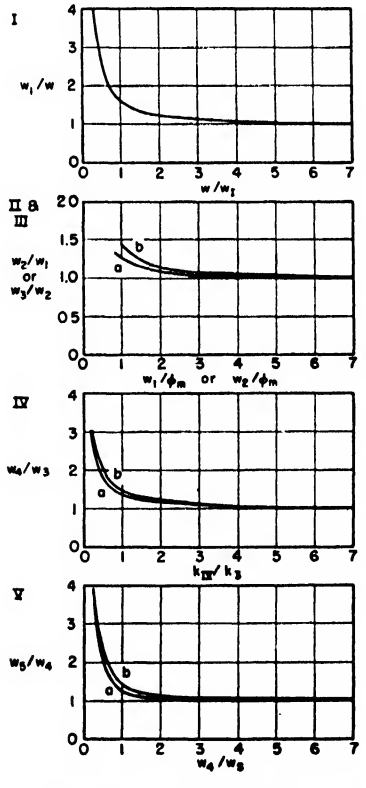

FIG. 4. Broadening ratios for the five instrumental weight functions, including (I) the x-ray source, (II) flat rather than curved sample surface, (III) vertical divergence, (IV) penetration of the sample by the beam, and (V) the receiving slit. Curves (a) and (b) apply respectively to $\exp(-k^2\phi^2)$ and $1/(1+k^2\phi^2)$ contours.

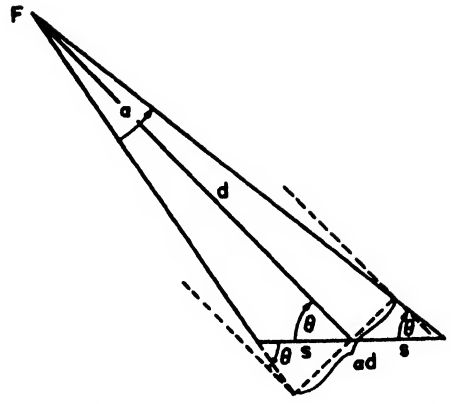

FIG. 5. Irradiation of a flat sample surface by a beam of divergence angle α.

the angle $\theta-\Delta\theta$, and arrives at some point G_1 which is displaced from the ideal focus by the linear interval GG_1. This displacement is proportional to z, the displacement of the point S' on the flat sample surface from the focusing circle. We now employ the approximate formula which expresses the length of the sagitta in terms of the circle radius r and the ordinate h (see Fig. 6, insert)

$$x=h^2/2r, \tag{10}$$

which is rather accurate for $h\ll r$. Applying this relationship to the situation of Fig. 6, we find that

$$z=h^2/2R, \tag{11}$$

where h is the distance S_0S' and R is the radius of the focusing circle. Since $R=d/2\sin\theta$,[11] this gives for z

$$z=h^2\sin\theta/d. \tag{12}$$

The displacement GG_1 from the ideal focus is then

$$GG_1=2z\cos(\theta+\Delta\theta)=(h^2/d)\sin2\theta, \tag{13}$$

or in terms of the angular deviation from the theoretical diffraction angle 2θ

$$\phi_{GG_1}=-(h^2/d^2)\sin2\theta \text{ radians}$$
$$=-57.3(h^2/d^2)\sin2\theta \text{ degrees}. \tag{14}$$

The minus sign indicates that the displacement ϕ is in the -2θ direction.

The limiting displacement of the diffracted rays from the ideal focus G corresponds to rays diffracted from the points S_1 and S_2, for which $h=s$. Then

$$\phi_m=-(s^2/d^2)\sin2\theta \text{ radians},$$

or, since $s\cong\alpha d/2\sin\theta$,

$$\phi_m=-\frac{\alpha^2}{4\sin^2\theta}\cdot 2\sin\theta\cos\theta$$
$$=-\tfrac{1}{2}\alpha^2\cot\theta \text{ radians}. \tag{15}$$

[11] L. Alexander, J. App. Phys. 19, 1068 (1948).

For ϕ and α in degrees this becomes

$$\phi_m=-\frac{\alpha^2\cot\theta}{114.6} \text{ degrees}. \tag{16}$$

This equation shows that the sharpness of focus (as affected by the flat sample factor) improves rapidly with decreasing beam divergence and increasing diffraction angle. If the finite length, l, of the sample surface is also taken into account, at angles for which $\sin\theta<\alpha d/l$ the limiting displacement of the diffracted rays from the ideal focus G is

$$\phi_m=-\tfrac{1}{2}(l^2/114.6d^2)\sin2\theta \text{ degrees}. \tag{17}$$

In practice, then, the sharpness of focus as a result of the flat sample effect is poorest (ϕ_m is a maximum) when $\sin\theta=\alpha d/l$ and it improves at both smaller and larger angles. We now need to determine the flat sample weight function, $W_{II}(\phi)$. From Eq. (13) or from an inspection of Fig. 6 it is seen that a displacement GG_1 (or ϕ_{GG_1}) is proportional to the sagitta variable z. But the intensity at a displacement ϕ from the theoretical focus is proportional to the energy diffracted in the interval Δz_ϕ (or $\Delta\phi_\phi$). This energy is proportional to the amount of sample surface diffracting into the increment Δz (or $\Delta\phi$), which is Δh_z (or Δh_ϕ). It follows, therefore, that the $W_{II}(\phi)$ function is proportional to $(\Delta h/\Delta z)$. But it has already been shown that we make negligible error in using the sagitta relationship for z [Eq. (11)], so that in the limit

$$W_{II}(\phi)\propto dh/dz=R/h=(R/2z)^{\frac{1}{2}}.$$

Since we are not interested in the absolute magnitude of the amplitude but only in the nature of the contour, and remembering that ϕ is proportional to z, we may dispense with a proportionality constant and write

$$W_{II}(\phi)=\phi^{-\frac{1}{2}}. \tag{18}$$

This function has the objection of an infinite ordinate at $\phi=0$, but the difficulty can be circumvented by evaluating the resulting convolution integral as a summation and omitting the zero term. For the convolution of $f_1(\phi)$ and $W_{II}(\phi)$ we then have

$$f_2(\phi)=\int_{-\infty}^{+\infty}W_{II}(\zeta)f_1(\phi-\zeta)d\zeta$$
$$=\int_{\phi_m}^{0}|\zeta|^{-\frac{1}{2}}\exp[-k_1^2(\phi-\zeta)^2]d\zeta, \tag{19}$$

assuming the f_1 contour to approximate an error curve. To evaluate $f_2(\phi)$ we go to the equivalent summation

$$f_2(\phi)=\sum_{\zeta=\phi_m}^{\zeta=\phi_1}|\zeta|^{-\frac{1}{2}}\exp[-k_1^2(\phi-\zeta)^2]\Delta\zeta \tag{20}$$

and sum at a relatively large number of ζ values (small

$\Delta\zeta$), omitting the $\zeta=0$ term. This omission has the effect of shifting the center of gravity of the contour slightly, but it will furnish a rather accurate contour shape provided $\Delta\zeta$ is kept small, e.g., of the order of $\phi_m/40$ or less. It will be noticed that ζ has been assigned to a range of negative rather than positive values. This is consistent with the sign convention of Eqs. (15) and (16) and is correct because the function W_{II} distorts a diffraction contour in the -2θ direction.

As in Part IV, the computations for actual experimental conditions are facilitated by graphing one function, this time $W_{II}(\zeta)=|\zeta|^{-\frac{1}{2}}$, and utilizing standard tables of the normal distribution function to evaluate $\exp[-k_1^2(\phi-\zeta)^2]$, after first writing the exponent as $-\frac{1}{2}[2^{\frac{1}{2}}k_1(\phi-\zeta)]^2$. For illustration we may outline briefly the computations for a rather extreme case of broadening, which portrays the nature of the results to be expected in a striking manner. The case is one of large beam divergence ($\alpha=1.41°$) and low Bragg angle ($\theta=5°$). From Eq. (16) we find for the greatest displacement of the diffracted rays from the theoretical focus:

$$\phi_m=-(\alpha^2\cot\theta)/114.6=-2\times11.43/114.6=-0.200°.$$

Assuming that the contour of the x-ray source is an error curve in form and that the width at half maximum intensity is 0.200° (there being no pure diffraction broadening assumed in this case), we find for k_1 by applying Eq. (6):

$$k_1=1.67/w_1=1.67/w_I=1.67/0.200=8.35 \text{ degrees}^{-1}.$$

When summed at intervals of $\Delta\zeta=0.005°$, Eq. (20) becomes

$$f_2(\phi)=\sum_{\zeta=-0.200°}^{\zeta=-0.005°}|\zeta|^{-\frac{1}{2}}\exp[-8.35^2(\phi-\zeta)^2]\times0.005°.$$

Dropping the constant factor 0.005° since it does not affect the nature of the contour, and converting the exponent into the standard error curve form, we have

$$f_2(\phi)=\sum_{\zeta=-0.200°}^{\zeta=-0.005°}|\zeta|^{-\frac{1}{2}}\exp[-\tfrac{1}{2}\{11.8(\phi-\zeta)\}^2]. \quad (21)$$

Figure 3(II) shows the $f_2(\phi)$ contour as computed with Eq. (21) and compares it with the original contour $f_1(\phi)=\exp(-8.35^2\phi^2)$. The peak has been broadened from $w_1=0.200°$ to $w_2=0.249°$, which means a broadening ratio of $w_2/w_1=1.245$. In addition the resulting peak is seen to be decidedly asymmetric and the center of gravity and maximum point have been shifted in the -2θ direction by appreciable amounts.

A consideration of Eq. (21) shows that the broadening ratio w_2/w_1 is a function only of the relative sizes of w_1 and ϕ_m. Accordingly if the $f_2(\phi)$ function is computed for a number of values of the ratio w_1/ϕ_m which cover all anticipated experimental situations, another curve of perfectly general applicability is obtained which is analogous to the curve of Fig. 4(I) developed in Part IV. This curve of w_2/w_1 as a function of w_1/ϕ_m is shown in Fig. 4(II,a). When the function $f_1(\phi-\zeta)$ of Eq. (19) has the form $1/[1+k_1^2(\phi-\zeta)^2]$, curve (b) is obtained. Curve (b) is more appropriate than (a) for cases in which the pure diffraction contour is much wider than the x-ray source contour. When w and w_I do not differ very greatly the broadening will be intermediate between the values predicted by curves (a) and (b).

For moderate values of the beam divergence, and Bragg angles of 10° or more, it is found that the broadening ratio seldom exceeds 1.02. This permits us to conclude that for ordinary experimental conditions the effect of flat sample surface is very minor.

VI. EFFECT OF VERTICAL DIVERGENCE OF THE X-RAY BEAM (W_{III})

In a preceding paper[11] the effect of vertical divergence and other third-dimensional properties of the spectrometer in producing asymmetry was discussed in detail. Referring to Fig. 2 of this reference, in the older spectrometers without Soller slit collimators the usual working value of the x-ray slit height, h_x, is considerably larger than the source height, h_f. Under these conditions we make but little error in assuming that the x-ray source has negligible height and that the centers of the diffraction halos in the plane $G'G$ (refer to Figs. 1 and 3 of the above reference) are uniformly distributed over a vertical interval

$$L=(h_x d/b)(1+\cos2\theta),$$

b and d being respectively the distances from the x-ray source to the x-ray slit and sample. Defining the vertical divergence angle β by h_x/b, this becomes

$$L=\beta d(1+\cos2\theta), \quad (22)$$

β being expressed in radians.

As a first approximation we may assume negligible receiving slit height. In that case, referring to Fig. 3 of the above reference, the maximum displacement of a diffracted ray from the ideal receiver focus is given by the sagitta of the arc of height $\frac{1}{2}L$ and radius r. Em-

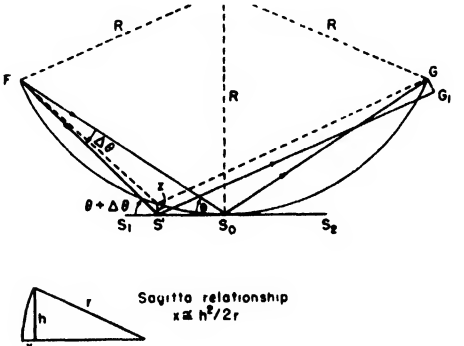

FIG. 6. Displacement of a diffracted ray from the theoretical focus G because of the use of a flat rather than curved sample surface.

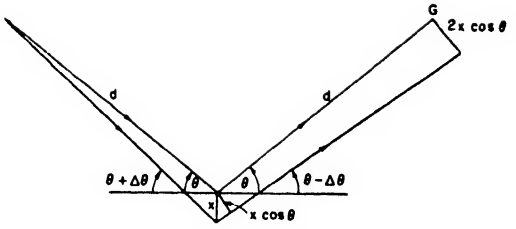

FIG. 7. Displacement of a diffracted ray from the theoretical focus G due to penetration of the sample to a depth x.

ploying the approximate sagitta formula as was done in Part V, we find for this displacement

$$x\ (\text{cm}) = (L/2)^2/2r = L^2/8r; \qquad (23)$$

but from Fig. 1 of reference 11 it can be seen that a displacement x in the direction GG' equals an angular displacement ϕ tangent to the spectrometer arc of

$$\phi = x\ (\text{cm}) \times (\cos 2\theta)/d \text{ radians}.$$

Combining this with Eqs. (22) and (23) and noting that $r = d \sin 2\theta$, we obtain

$$\phi_m = -(\beta^2/8)(1+\cos 2\theta)^2 \cot 2\theta \text{ radians}, \qquad (24)$$

the negative sign indicating that the displacement from the theoretical angle 2θ is in the negative direction. For ϕ_m and β in degrees Eq. (24) becomes

$$\phi_m = -(\beta^2/8 \times 57.3)(1+\cos 2\theta)^2 \cot 2\theta \text{ degrees}. \qquad (25)$$

The preceding analysis demonstrates that, as in Part V, we are again dealing with an instrumental weight function, this time $W_{III}(\phi)$, which varies as the inverse square root of the displacement, ϕ, from the ideal angle of deviation, 2θ. This follows in a manner parallel to that involved in the development of Eq. (18) since the intensity corresponding to a displacement ϕ from the theoretical focus is proportional to the energy diffracted in the interval Δx_ϕ [or $(\Delta\phi)_\phi$], and this energy is proportional to $(\Delta L)_\phi$. Thereupon in the limit

$$W_{III}(\phi) \propto \frac{dL}{dx} = \left(\frac{2r}{x}\right)^{\frac{1}{2}},$$

and, neglecting the constant factor as in Part V, and remembering that x is proportional to ϕ, we again arrive at the weight function,

$$W_{III}(\phi) = \phi^{-\frac{1}{2}}. \qquad (26)$$

Assuming $f_2(\phi)$ to approximate an error curve, we then find for the convolution, $f_3(\phi)$, of $W_{III}(\phi)$ and $f_2(\phi)$

$$f_3(\phi) = \int_{-\infty}^{+\infty} W_{III}(\zeta) f_2(\phi-\zeta)\, d\zeta,$$

or

$$f_3(\phi) = \sum_{\zeta=\phi_m}^{\zeta=\phi_1} |\zeta|^{-\frac{1}{2}} \exp[-k_2^2(\phi-\zeta)^2]\Delta\zeta, \qquad (27)$$

which is identical in form to Eq. (20).

It is evident that the remarks made in connection with Eq. (20) apply here, and also that curves (a) and (b) of Fig. 4 (II and III) apply directly in the present case for w_3/w_2 as a function of w_2/ϕ_m. The only difference is that Eq. (25) instead of Eq. (16) is to be used to determine ϕ_m for the particular experimental conditions under consideration.

For Bragg angles of 10° or more and for vertical divergence angles less than 2.4° it is found that the broadening ratio is seldom greater than 1.10 and more commonly it is of the order of 1.05. Evidently vertical divergence is much more important than flat sample surface in producing contour broadening.

VII. EFFECT OF PENETRATION OF THE SAMPLE BY THE X-RAY BEAM (W_{IV})

Consider a ray incident upon the sample at the angle $\theta+\Delta\theta$ and diffracted from a crystallite at a depth x (Fig. 7). If $\Delta\theta$ is neglected because it is very small, the intensity of the emergent diffracted ray, I, relative to that of a ray diffracted under conditions of non-absorption, I_0, is

$$I/I_0 = \exp(-2\mu x/\sin\theta), \qquad (28)$$

μ being the linear absorption coefficient of the powder. The linear displacement of this diffracted ray from the theoretical focus at the receiver is evidently $2x\cos\theta$, and the corresponding angular displacement, ϕ_x, is

$$\phi_x = -(114.6x\ \cos\theta)/d \text{ degrees}, \qquad (29)$$

the negative sign denoting a displacement in the -2θ direction. Equation (28), then, is an expression of the instrumental weight function, W_{IV}, due to penetration of a thick powder sample by the x-ray beam, and when this is combined with Eq. (29) we obtain W_{IV} expressed as a function of ϕ:

$$W_{IV}(\phi) = e^{k_{IV}\phi}, \qquad (30)$$

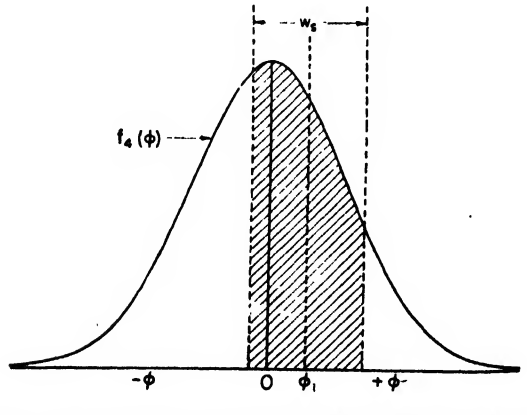

FIG. 8. Representation of a receiving slit of width w_s scanning a diffraction contour $f_4(\phi)$. The resulting intensity is proportional to the area of the contour intercepted (shaded zone).

in which

$$k_{IV}=4\mu d/114.6\sin 2\theta, \tag{31}$$

and ϕ varies between the limits 0 and $-\infty$.

Assuming first that $f_3(\phi)$ approximates an error curve (i.e., that the pure diffraction broadening is slight and that the preceding convolution sequence has not greatly modified the original error curve contour of the x-ray source), we obtain for the convolution, $f_4(\phi)$, of $W_{IV}(\phi)$ and $f_3(\phi)$

$$f_4(\phi)=\int_{-\infty}^{+\infty} W_{IV}(\zeta)f_3(\phi-\zeta)d\zeta,$$

or

$$f_4(\phi)=\int_0^{-\infty} e^{k_{IV}\zeta}\exp[-k_3^2(\phi-\zeta)^2]d\zeta. \tag{32}$$

By combining the two exponential factors and removing a constant factor from the integral, Eq. (32) can be put in the form

$$f_4(\phi)=\exp\left[k_{IV}\left(\phi+\frac{k_{IV}}{4k_3^2}\right)\right]\times\int_0^{-\infty}\exp\left[-\left(k_3\zeta-\frac{k_{IV}+2k_3^2\phi}{2k_3}\right)^2\right]d\zeta.$$

A change of variable from ζ to

$$u=2^{\frac{1}{2}}\left(k_3\zeta-\frac{k_{IV}+2k_3^2\phi}{2k_3}\right)$$

then leads to the result

$$f_4(\phi)=\exp\left[\left(k_{IV}\phi+\frac{k_{IV}^2}{4k_3^2}\right)\Big/2^{\frac{1}{2}}k_3\right]\times\int_l^{-\infty}\exp[-(u^2/2)]du, \tag{33}$$

in which the lower limit of the integral, l, is given by

$$l=(k_{IV}/2^{\frac{1}{2}}k_3)+2^{\frac{1}{2}}k_3\phi. \tag{34}$$

The expression for the convolution $f_4(\phi)$ has thus been reduced to the state of an integral (Eq. (33)) which can be evaluated directly by reference to tables of the normal curve of error. For any particular sample material of linear absorption coefficient μ and for a given spectrometer setting 2θ the value of k_{IV} can be calculated with Eq. (31), while k_3 depends upon the width at half maximum intensity of the error curve contour $f_3(\phi)$ according to a relationship identical with Eq. (6), or

$$k_3=1.67/w_3. \tag{35}$$

Figure 3(IV) depicts the effect of sample penetration upon a contour of the form $f_3(\phi)=\exp[-(k_3^2\phi^2)]$ for the particular case of $k_{IV}/k_3=1$. This case was chosen because it is typical of experimental conditions under which the effects of sample penetration are conspicuous. The given values of k are satisfied by either of the following sets of experimental conditions, the first corresponding to the old Norelco spectrometer with wide source ($w_I=0.20°$) and the second to a spectrometer with a relatively narrow source ($w_I=0.07°$):

I. Width of source contour: $w_I=0.20°$
Bragg angle : $\theta=15°$
Linear absorption coefficient of powder : $\mu=9$ or $\begin{cases}\theta\to 45°\\ \mu=18\end{cases}$

(CuKα radiation and powders consisting of metal-organic compounds or mixtures of organic compounds and common siliceous minerals)

II. Width of source contour: $w_I=0.07°$
Bragg angle : $\theta=15°$
Linear absorption coefficient of powder : $\mu=27$ or $\begin{cases}\theta\to 45°\\ \mu=54\end{cases}$

(CuKα radiation and powders prepared from common siliceous minerals)

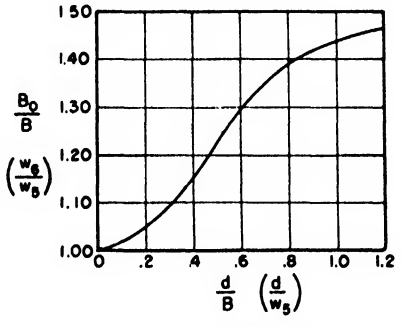

FIG. 9. Inverse of Jones' curve for correcting an observed contour breadth for Kα doublet broadening. B_0=observed breadth, B=breadth corrected for Kα doublet, d=angular separation of α_1 and α_2.

The broadening ratio for this case, w_4/w_3, is a function only of the ratio of the contour constants, k_{IV}/k_3. Curve (a) of Fig. 4(IV) depicts this function for the case just discussed wherein the $f_3(\phi)$ contour is given by $\exp[-(k_3^2\phi^2)]$. When $f_3(\phi)$ is given by $1/(1+k_3^2\phi^2)$, a condition approached by materials giving considerable pure diffraction broadening, the convolution integral cannot be evaluated directly as in the case of Eq. (32) but must be treated as the equivalent summation in the manner described in earlier sections. In this case curve (b) of Fig. 4(IV) is obtained.

If the absorption coefficient of the sample is low and if θ is not very small, sample penetration can evidently be an important source of contour broadening. Thus, in the example cited above for a powder of large crystallite size the broadening ratio was found to be 1.40. In the newer spectrometers with narrow sources this instrumental factor is relatively much more important than in the old Norelco instrument. For example, if $k_{IV}/k_3=2.86$ for $w_I=0.20°$, it will be decreased to 1.00 for $w_I=0.07°$, and reference to curve (a) of Fig. 4(IV) shows that this increases the broadening ratio from 1.14

TABLE II. Summarizing table of the effects of the instrumental weight functions upon the diffraction contour.*

Instrumental weight function	Contour function Initial	Contour function Final	Contour width Initial	Contour width Final	Form of convolution expression General	Form of convolution expression Spectrometer case	Constants Instrumental	Constants Diffraction contour	Integral limits
W_I Source	$f(\phi)$	$f_1(\phi)$	w	w_1	$f_1(\phi)=\int_{-\infty}^{+\infty} W_I(\zeta)f(\phi-\zeta)d\zeta$	$\int_{-\infty}^{+\infty}\frac{\exp(-k_I^2\zeta^2)d\zeta}{1+k^2(\phi-\zeta)^2}$	$k_I=\frac{1.67}{w_I}$	$k=\frac{2}{w}$	
W_{II} Flat sample	$f_1(\phi)$	$f_2(\phi)$	w_1	w_2	$f_2(\phi)=\int_{-\infty}^{+\infty} W_{II}(\zeta)f_1(\phi-\zeta)d\zeta$	(A) $\int_{\phi_m}^{0}\lvert\zeta\rvert^{-\frac{1}{2}}\exp[-k_1^2(\phi-\zeta)^2]d\zeta$ (B) $\int_{\phi_m}^{0}\frac{\lvert\zeta\rvert^{-\frac{1}{2}}d\zeta}{1+k_1^2(\phi-\zeta)^2}$		$k_1=\frac{1.67}{w_1}$ $k_1=\frac{2}{w_1}$	$\phi_m=-\frac{\alpha^2\cot\theta}{114.6}$

W_{VI} Kα doublet	$f_5(\phi)$	$f_6(\phi)$	w_5	w_6					

* ϕ = angular displacement from the theoretical diffraction angle, 2θ.
$f(\phi)$ = pure diffraction contour.
w = width at half maximum intensity of the pure diffraction contour.
(A) Form of the convolution expression for a $\exp[-(k^2\phi^2)]$ contour.
(B) Form of the convolution expression for a $1/(1+k^2\phi^2)$ contour.

to 1.40. When powders of moderate or large absorption coefficients are used, the broadening ratio for the old Norelco spectrometer using CuKα radiation is seldom in excess of 1.20 and it often is less than 1.10. Even so, this instrumental factor is more important, in general, than the flat sample or vertical divergence factor in causing contour broadening.

The present analysis of sample penetration has presupposed the use of an infinitely thick sample. This condition is effectively realized under spectrometer conditions if the sample thickness, t, is great enough to satisfy the condition[12]

$$t \geq \frac{3.2}{\mu} \cdot \frac{\rho}{\rho'} \sin\theta, \tag{36}$$

in which μ and ρ are respectively the linear absorption coefficient and density of the solid material composing the powder, and ρ' is the density of the powder including interstices. The contour distortion due to sample penetration can be minimized if necessary in special cases, but at the expense of reduced intensity, by mounting a very thin layer of powder on a suitable flat substrate.

VIII. EFFECT OF RECEIVING SLIT WIDTH (W_V)

Figure 8 illustrates diagrammatically the effect of the receiving slit upon the contour being scanned ($f_4(\phi)$ in our present notation). It is assumed that the sensitivity of all points within the slit area is uniform. When the center of the slit is set at an angle of deviation ϕ_1 from the peak maximum (ideally 2θ), the slit intercepts a portion of the contour extending between the limits $\phi_1 - w_s/2$ and $\phi_1 + w_s/2$, w_s being the angular width of the slit. The recorded intensity, $f_5(\phi_1)$, corresponding to this position is evidently proportional to the area intercepted. Hence, we can write directly

$$f_5(\phi) = K \int_{\phi - w_s/2}^{\phi + w_s/2} \exp[-(k_4^2\zeta^2)]d\zeta, \tag{37}$$

assuming $f_4(\phi)$ to be an error curve in form. If we assume it to be more closely represented by the function $1/(1+k^2\phi^2)$,

$$f_5(\phi) = K \int_{\phi - w_s/2}^{\phi + w_s/2} \frac{d\zeta}{1+k_4^2\zeta^2}. \tag{38}$$

In Eqs. (37) and (38) the weight function $W_V(\phi)$ may be interpreted as a constant, K, between the limits $\zeta = \phi - w_s/2$ and $\phi + w_s/2$. Equation (37) can be readily evaluated by transforming the exponent to $\frac{1}{2}(2^{\frac{1}{2}}k_4\zeta)^2$ and referring to tabulated values of the area of the standard error curve between definite limits. The proper value of k_4 is deduced, as explained earlier, by Eq. (6) or (7) depending upon which form of contour, $f_4(\phi)$, is assumed. The angular equivalent of the linear slit width, w_s (cm), is given by

$$w_s \text{ (degrees)} = w_s \text{ (cm)} \times 57.3/d,$$

d being the sample-to-receiving slit distance. This angular value of w_s is used in determining the integral limits $\phi + w_s/2$ and $\phi - w_s/2$.

Figure 3(V) shows the effect of a receiving slit of width $w_s = 0.045$ cm $= 0.20°$ upon an error curve diffraction contour for which $w_4 = 0.20°$ (corresponding to $k_4 = 1.67/w_4 = 8.35$). The width of the resulting contour, $f_5(\phi)$, is $w_5 = 0.25°$, which corresponds to a broadening ratio of $w_5/w_4 = 0.25/0.20 = 1.25$. Figure 4(V) shows plots of the broadening ratio w_5/w_4 for the two cases of (a) $f_4(\phi) = \exp[-(k_4^2\phi^2)]$ and (b) $f_4(\phi) = 1/(1+k_4^2\phi^2)$.

TABLE III. Application of the method of convolution analysis to four representative cases:* Case (a) $D > 1000$ A, $w = 0°$, $w_I = 0.20°$. Case (b) $D > 1000$ A, $w = 0°$, $w_I = 0.07°$, Soller slits. Case (c) $D = 300$ A, $w = 0.305°$ by Scherrer formula, $w_I = 0.20°$. Case (d) $D = 300$ A, $w = 0.305°$ by Scherrer formula, $w_I = 0.07°$, Soller slits.

Instrumental weight function	Quantity tabulated	Values of the quantities listed in column 2 Case (a)	Case (b)	Case (c)	Case (d)
I. Source	w	0	0	0.305°	0.305°
	w/w_I	0	0	1.53	4.36

	w_6/w_5	1.135	1.36	1.04	1.06
	w_6	0.254	0.151°	0.447°	0.369°

* D refers to the crystallite size. Other conditions assumed are: $\mu = 40$, $2\theta = 30°$, $\lambda = 1.542$A (CuKα), $w_s = 0.088°$.

IX. EFFECT OF UNRESOLVED Kα DOUBLET (W_{VI})

For Bragg angles to small to resolve the Kα doublet, the observed contour breadth will also be increased as a result of the superposition of the α_1 and α_2 contours. The width of either contour will be w_5 as a result of the action of the five instrumental factors (see Part VIII). The broadening due to an unresolved doublet has been thoroughly analyzed by Jones,[7] who developed a curve for correcting for this effect. For our purpose Jones' plot of B/B_0 as a function of d/B_0 can be more readily used if transformed to a plot of B_0/B as a function of d/B (w_6/w_5 against d/w_5 in the present notation). This curve is shown in Fig. 9. Here w_5 and w_6 represent respectively the contour widths before and after

[12] L. Alexander and H. P. Klug, Anal. Chem. 20, 886 (1948).

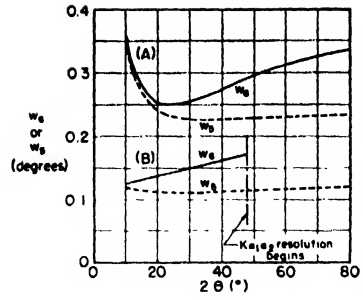

FIG. 10. Predicted dependence of contour breadth upon 2θ for spectrometers with x-ray source widths of (A) 0.20° and (B) 0.07° 2θ. w_b = width of a contour not resolving the Kα doublet; w_s = width of a resolved line of the doublet. Conditions assumed are: $\mu = 40$, $w_s = 0.088°$, crystallite size greater than 1000 A.

broadening due to the unresolved doublet, and d is the angular separation of the Kα doublet characteristic of the particular radiation and diffraction angle involved (see *Internationale Tabellen zur Bestimmung von Kristallstrukturen*, Vol. II, p. 588 ff.).

X. APPLICATION TO REPRESENTATIVE EXPERIMENTAL CASES

Table II summarizes the results of the analyses presented in the preceding sections. The five instrumental weight functions are presented in the order in which it is logical to apply them when making use of the broadening curves given in Fig. 4. Although not strictly an instrumental factor, the effect of Kα doublet broadening is included (W_{VI}) because of the necessity of taking it into account in arriving at the actually observed contour breadth at low angles. Table III illustrates with numerical data the application of the analysis to four representative experimental cases. In each case it is assumed that $\mu = 40$ (moderate absorbing power for x-rays), $2\theta = 30°$, $\lambda = 1.542$A (CuKα radiation), and the angular width of the receiving slit, w_s, is 0.088° (a relatively narrow slit). The four specific cases carried through in the four columns of the table are:

(a) Crystallite size > 1000A, $w \to 0°$, $w_I = 0.20°$ (older spectrometer).

(b) Crystallite size > 1000A, $w \to 0°$, $w_I = 0.07°$ (newer spectrometers with narrow source and Soller slits).

(c) Crystallite size 300A, $w = 0.305°$ by Scherrer formula, $w_I = 0.20°$.

(d) Crystallite size 300A, $w = 0.305°$ by Scherrer formula, $w_I = 0.07°$.

A few important observations can be made. With a relatively wide x-ray source contour (Cases (a) and (c)) and assuming the use of a narrow receiving slit, the dominant instrumental factor causing broadening is the source width. All the other instrumental factors are inappreciable or nearly so, and the Kα doublet becomes significant only for the larger crystallite sizes. In particular, the flat sample and vertical divergence effects are very slight. These become greater at small diffraction angles since the contour widening increases with the absolute magnitude of ϕ_m for both effects (see Eqs. (17) and (25)), although flat sample broadening diminishes again when $\sin\theta$ becomes less than $\alpha d/l$ (see Part V).

The same remarks apply to the case of a narrow source except that the source is relatively less significant and the other factors more significant as causes of contour broadening. Except at low Bragg angles the flat sample and vertical divergence effects remain very minor. Penetration of the sample and Kα doublet separation both become important at the angle considered ($2\theta = 30°$), particularly for contours displaying little crystallite size broadening.

In Fig. 10 the convolution analysis is applied to the problem of predicting the observed contour breadth as a function of 2θ (A) for the old Norelco spectrometer with a source width of 0.20° 2θ and (B) for newer spectrometers with an assumed source width of 0.07° 2θ and Soller slits to eliminate vertical divergence. The curves are plotted for the typical case of large crystallite size, moderately absorbing sample ($\mu = 40$), and a relatively narrow receiving slit width of 0.088° 2θ. It is also assumed that the length of sample is sufficient to receive the entire beam at the lowest angle indicated ($2\theta = 10°$). It will be noticed that resolution of the Kα doublet is obtained below 50° for the newer design whereas in the older design the doublet remains unresolved through the entire angular range. The failure of Curve B to make a sharp upturn below 20° such as occurs for Curve A is largely due to the absence of vertical divergence.

ACKNOWLEDGMENT

The author is appreciative of the interest and encouragement contributed by Dr. Harold P. Klug during the conduct of this investigation. He wishes to thank Mr. Douglas Pitman for valuable help in obtaining data and in performing calculations. He is also indebted to Dr. John R. Bowman for aid in evaluating the integral of Eq. (32).

Determination of Crystallite Size with the X-Ray Spectrometer*

LEROY ALEXANDER AND HAROLD P. KLUG
Department of Research in Chemical Physics, Mellon Institute, Pittsburgh, Pennsylvania
(Received July 25, 1949)

The accuracy of the Scherrer crystallite size equation is limited in part by the uncertainty in β, the experimentally deduced pure diffraction broadening. Currently used procedures for estimating β from the observed breadth of a Debye-Scherrer line are not, in general, applicable to the x-ray spectrometer.

By making use of a scheme of convolution analysis for analyzing the effect of geometrical factors in broadening the pure diffraction contour, a correction curve is developed for determining β from the experimentally measured line breadths b and B (Jones' notation). The degree of reliability of this correction procedure is ascertained by applying Stokes' direct Fourier transform procedure for determining the form of the pure diffraction contour free of instrumental effects.

Suggestive procedures are given for crystallite size determination with the x-ray spectrometer in different size ranges, and several examples are described.

I. INTRODUCTION

THE accuracy of the familiar Scherrer equation,

$$D=(K\lambda)/(\beta\cos\theta), \tag{1}$$

is limited by the uncertainties in K, the crystallite shape factor, and β, the pure diffraction broadening. Theoretical work by Stokes and Wilson[1] has elucidated the relationship between K and the crystal shape to a degree not previously attained. However, for the usual applications to crystallite size measurement a large degree of indeterminancy in K, as much as 20 percent or even more, remains, and it is customary to let $K=1$. To gain optimum accuracy it remains to reduce the uncertainty in β as much as possible, preferably to a value much less than 20 percent.

Considerable effort has been expended by a number of investigators in evolving expressions for readily deducing β from B, the observed breadth, for the case of Debye-Scherrer lines. The most widely applied are the procedures due to Warren[2] and Jones.[3] These published correction curves have also been applied to the analysis of spectrometer maxima, although no one has specifically demonstrated their applicability to the particular conditions governing the generation of spectrometer contours. The formula of Warren,

$$\beta^2=B^2-b^2, \tag{2}$$

where b is the observed breadth of a line produced by crystallites of sufficient size to give no diffraction broadening, applies only to the case in which the β and b contours are both true "error" curves of the form $e^{-k^2x^2}$. Similarly Jones' two correction curves (a) and (b) apply only to the cases where the β contour has the respective forms $e^{-k^2x^2}$ and $1/(1+k^2x^2)$. The form of the b contour assumed by Jones was experimentally obtained by microphotometering a Debye-Scherrer line at a Bragg angle large enough to clearly resolve the Kα doublet.

Recently Shull[4] and Stokes[5] have developed Fourier transform procedures for deducing the β contour from observed b and B contours. The method of Stokes is the more generally applicable but it requires a means for the rapid summation of Fourier series. More recently one of the present authors[6] has shown how the convolution, or *Faltung*, theorem can be used to synthesize the form of a b or B contour generated by an x-ray spectrometer starting with a pure diffraction contour of known dimensions. In the light of these developments it seemed that this was a propitious time to examine the problem of crystallite size determination with the x-ray spectrometer with a view to improving the accuracy with which the width of the pure diffraction contour can be deduced free of the various instrumental broadening effects.

Since most of the commercial spectrometers in use today are of the older Norelco design which is limited to the θ range from 0° to 45°, it is felt desirable to concentrate the present analysis on crystallite size determinations which can be carried out in this angular range. Hence, we shall consider size measurements mainly in the range 0 to 500A and particularly those between about 250 and 500A, where the errors due to improper correction of the instrumental contributions may be very large. With the older type of spectrometer, having a wide x-ray source contour and limited to angles below $\theta=45°$, it is futile to attempt size measurements for crystallites much larger than 500A because the mandatory precision of the experimental measurements becomes too great for practical work.

II. COMPUTATION OF A CORRECTION CURVE FOR CRYSTALLITE SIZE DETERMINATION WITH THE X-RAY SPECTROMETER

In reference 6 the broadening effects of the five significant instrumental factors, or weight functions,

50	2.040	2.040	0.103	1.000

upon a pure diffraction contour were investigated. A scheme of convolution analysis was employed to develop generalized broadening curves for each of the factors, and it was shown that by successively employing each of these curves the width of the diffraction contour generated by the spectrometer could be predicted, starting with a pure diffraction contour of any assumed width.

In reference 6 it was pointed out that with a proper choice of the experimental conditions three of the five instrumental factors causing contour broadening become negligible and only the effects of (I) the x-ray source width and (V) the receiving slit width need be considered. The requisite conditions are that the linear absorption coefficient of the powder for the x-ray beam be not too small ($\mu \geqq 40$) and that the diffraction angle 2θ be 20° or greater. The first condition is met in the case of CuKα radiation for nearly all materials except organic and metal-organic compounds, and the second condition can nearly always be satisfied by the proper choice of a diffraction line. It will accordingly be assumed in the development to follow that these simplifying conditions obtain.

The results of the convolution analysis can be easily plotted as a correction curve in the manner given by Jones[3] wherein β/B is plotted as a function of b/B. In order to simplify the terminology the notation of Jones will be used as far as possible. However, as it will prove necessary to refer to the different symbols of reference 6 occasionally, it will be helpful at the outset to compare the two notations:

Function	Jones	Reference 6
Pure diffraction breadth	β	w
Observed breadth for large crystallites (uncorrected for Kα doublet)	b_0	w_6
Same (corrected for Kα doublet)	b	w_5
Observed breadth for small crystallites (uncorrected for Kα doublet)	B_0	w_4
Same (corrected for Kα doublet)	B	w_3

It will be noticed that the contour breadths for small and large crystallites have not been distinguished in the notation of reference 6. This is because the analysis of reference 6 was of a general nature, applicable to contours of any breadth. Unless otherwise indicated the term *width*, or *breadth*, of a contour in the present paper denotes the width at half maximum intensity. Jones' analysis and correction curves apply to the integral breadth, which is defined by $\beta_z=(\int I_z dx)/(I_z)_{max}$.

The present analysis will deal mainly with the case of a relatively wide x-ray source (appropriate for the older Norelco spectrometer). For materials with crystallite size larger than 1000A the observed contour breadth b_0 will be due largely to the x-ray source and to a lesser extent to the receiving slit (unless an abnormally wide slit is employed). For materials smaller than 1000A the observed contour breadth B_0 will also be widened because of the width of the pure diffraction contour, β. If the crystallite size is very small the pure diffraction broadening becomes the dominant factor in determining the breadth of the observed contour. In addition to these effects, if the Kα doublet is not resolved, the observed contour will in all cases be widened as a result of the superposition of the overlapping contours produced by the α_1 and α_2 components of the radiation.

It will be assumed in the present paper that all observed contours have been corrected for Kα doublet broadening before the crystallite size correction curve is to be employed. The curve of Jones[3] for correcting for Kα doublet broadening is satisfactory for use with x-ray spectrometers having wide sources (of the order of 0.20° 2θ).

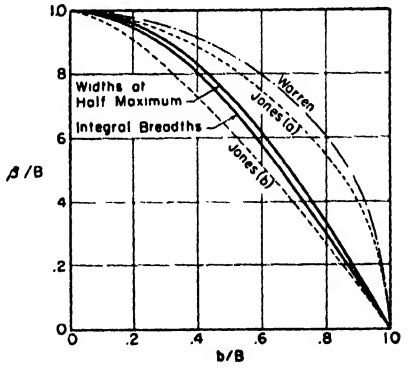

FIG. 1. X-ray spectrometer curves for correcting the breadths of diffraction contours for instrumental broadening. Also shown are the curves of Jones and Warren for Debye-Scherrer photographs.

Our procedure will now be as follows: (a) Using Eq. (1) compute the pure diffraction breadth, β, of the contour produced by a material of crystallite dimension D. (b) Using the convolution method of reference 6 compute the breadth B of the contour generated by the instrument without the added effect of the Kα doublet. (c) Similarly compute the breadth b of the contour generated for materials of large crystallite size (for which $\beta \to 0$). (d) Following the appropriate scheme of Jones, plot β/B as a function of b/B.

The success of this method of arriving at the correction curve will be contingent upon our correct choice of mathematical functions to describe the pure dif-

fraction contour and the x-ray source contour. A careful appraisal of these functions will be found in Parts III and IV of reference 6, so that it is necessary here only to repeat the final results, *viz.*, that a typical crystallite size distribution tends to generate a pure diffraction contour which is closely approximated by $1/(1+k^2\phi^2)$, whereas an x-ray source contour is more nearly described by $e^{-k^2\phi^2}$. Accordingly, the derivation of the correction curve which follows will be based on the premise that these simple mathematical functions accurately describe the pure diffraction and x-ray source contours.

The method of determining the curve of β/B as a function of b/B will be illustrated in detail by the calculation of one selected point, after which the complete data required for locating the entire curve will be tabulated. We shall select the case $\theta=30°$ and a crystallite size of $D=500$A. The spectrometer is assumed to be of the older design with an x-ray source width (w_I) of 0.200°, and a relatively narrow receiving slit width, $w_s=0.088°$, is employed. The radiation is CuKα, for which $\lambda=1.542$A.

Using the standard crystallite size equation with K set equal to unity, we find for the theoretical breadth of the pure diffraction contour

$$\beta=w=\frac{K\lambda}{D\cos\theta}=\frac{1.542\times57.3}{500\times.866}=0.204°.$$

The ratio of the width of the contour to that of the source is $w/w_I=0.204°/0.200°=1.02$. Referring to Fig. 4(I) of reference 6, we find for the broadening ratio $w_1/w=1.62$. Then the width of the resulting contour is

$$w_1=w\times(w_1/w)=0.204°\times1.62=0.330°.$$

This contour will be intermediate between $e^{-k^2\phi^2}$ and $1/(1+k^2\phi^2)$ in form because it is the convolution of two functions which are of these two pure forms and of approximately equal width.

We turn next to the action of the receiving slit in broadening this contour. The ratio of its width to that of the slit is $w_1/w_s=0.330°/0.088°=3.75$. Since we are neglecting the instrumental weight functions II, III, and IV, this ratio becomes the abscissa, w_4/w_s, of Fig. 4(V) of reference 6. The initial contour will be broadened by an amount which is approximately the mean of the values given by curves (a) and (b), hence $w_5/w_4=(1.030+1.036)/2=1.033$. This leads to a resulting contour width of

$$B=w_5=w_4\times(w_5/w_4)=0.330°\times1.033=0.341°.$$

For the reference material of large crystallite size the pure diffraction breadth β is zero. Hence, we start with the source contour and determine the broadening ratio due to the action of the receiving slit upon it. We have then

$$w_I/w_s=0.200°/0.088°=2.27,$$

TABLE II. Calculation of the crystallite sizes of four materials from spectrometer measurements after determining β (A) by Stokes' Fourier method and (B) from the correction curve of Fig. 1 (widths at half maximum).

	CaF_2	MgO	Cristobalite	Basic calcium phosphate
Observed breadths				
B_0	0.500°	0.700°	0.470°	0.468°
b_0 (quartz powder)	0.330°	0.330°	0.320°	0.330°
Breadths after correcting for $K\alpha_1\alpha_2$				
B	0.460°	0.674°	0.462°	0.456°
b	0.276°	0.284°	0.307°	0.314°
Correction ratios				
b/B	0.600	0.421	0.665	0.689
β/B (Fig. 1)	0.620	0.810	0.533	0.500
Pure diffraction breadths				
β (Stokes' method)	0.335°	0.530°	0.260°	0.215°
β (Fig. 1)	0.285°	0.546°	0.246°	0.228°
Calculated crystallite sizes				
D(A.) (Stokes' method)	290	179	346	422
D(A.) (Fig. 1)	342	174	366	398

and from Fig. 4(V), curve (a), of reference (6), $w_5/w_4=1.05$, and consequently

$$b=w_5=w_4\times(w_5/w_4)=0.200°\times1.05=0.210°.$$

From these calculated values of β, b, and B we obtain

$$b/B=0.616 \quad \text{and} \quad \beta/B=0.598.$$

By proceeding in a similar manner for a number of crystallite sizes ranging from 50 to 1000A the remaining data of Table I of the present paper were obtained. When plotted with β/B as a function of b/B, the solid curve marked "Widths at Half Maximum" of Fig. 1 is obtained. Although deduced specifically for the case of $\theta=30°$ and a receiving slit width of 0.088°, this curve is found to be perfectly general for all values of θ in the range 0–45° and for receiving slit widths ranging from 0 to about 0.20°. When the slit width exceeds the angular width of the source by an appreciable amount, the correction curve shifts to the right. The most satisfactory policy in this regard is to always employ the narrowest receiving slit that is compatible with the diffracted energy available.

By a parallel set of calculations it can be shown, or by direct comparison of the geometrical conditions it can be inferred, that this same correction curve applies, within limits, to spectrometers with narrower sources. However, when the source width becomes much smaller than 0.10°, the several minor broadening factors become relatively significant, so that the premises upon which the present curve is based are no longer correct.

III. EXPERIMENTAL SUBSTANTIATION OF THE CORRECTION CURVE

In Part III of reference 6 the pure diffraction contours of six miscellaneous materials were investigated, five of them by the Fourier transform method of Stokes.[5] Four of these materials made excellent subjects

TABLE III. Comparison of the crystallite sizes of four materials as deduced by different correction curves. The figures are calculated crystallite sizes in A.

Method of correction	CaF_2	MgO	Cristobalite	Basic calcium phosphate
Stokes (Fourier)	290	179	346	422
Curve of Fig. 1, widths at half maximum	342	174	366	398
Jones' curve (a)	285	162	284	301
Jones' curve (b)	414	201	448	491
Warren's curve $[\beta/B=(1-b^2/B^2)^{\frac{1}{2}}]$	265	156	260	274

for a test of the spectrometer correction curve of Fig. 1. The widths of the pure contours deduced by the Fourier method can be considered to be the best obtainable and hence to also lead to the most reliable values of the crystallite sizes. In Table II the crystallite sizes are calculated using the curve of Fig. 1 marked "Widths at Half Maximum," and the resulting values are compared with the presumably best values from the Stokes procedure.

In every case an appropriate quartz maximum was measured in order to obtain the required value of b_0 for a material of large crystallite size. The contours were measured with a Norelco Geiger-Counter Spectrometer, Type No. 12021 (with wide x-ray source), the spectrometer arm being set manually at appropriate intervals and the counting rates being recorded directly. In every instance except that of basic calcium phosphate it was possible to reduce the probable statistical counting error in the peak height above background to 1 percent or less. It is seen that in three out of four cases the agreement is highly satisfactory, and, furthermore, that in the single case of less satisfactory agreement (CaF_2) a greater deviation from the presumably best value (by Stokes' method) is to be expected because the pure diffraction contour is intermediate in nature between the forms $1/(1+k^2\phi^2)$ and $e^{-k^2\phi^2}$ rather than resembling more closely the first function (refer to Table I of reference 6).

Table III compares the crystallite sizes of these same materials as calculated using various correction curves with the values arrived at by Stokes' Fourier method. For the sake of ready comparison these correction curves are also plotted in Fig. 1. An examination of Table III shows that on the average the present curve gives much better agreement with the Fourier results than any of the other curves. Only in the case of the somewhat anomalous contour of CaF_2 would somewhat better results have been obtained by using other curves, e.g., by employing either Warren's curve or Jones' curve (a). It is interesting to note from Fig. 1 that the new spectrometer curve agrees more nearly with Jones' curve (b) at large values of b/B (large crystallite sizes), while it approaches both Jones' curve (a) and Warren's curve more closely at small values of b/B (small crystallite sizes). However, as is well-known, the choice of correction curve is unimportant for small crystallite sizes.

IV. DISCUSSION OF THE CORRECTION CURVE

In Part II it was emphasized that the derivation of the present correction curve is based on the premise that the functions $1/(1+k^2\phi^2)$ and $e^{-k^2\phi^2}$ accurately describe the pure diffraction contour and x-ray source contour respectively. These formulas should be regarded realistically as being only limiting functions which are approached only more or less imperfectly in any experimental situation. Consequently the most that should be claimed for the present correction curve is that the probability of its yielding an accurate value of β is good and also much better than that of curves based on other pairs of simple mathematical functions.

In particular, it is suggested that each investigator test the focal spot of the particular x-ray tube employed for agreement with the function $e^{-k^2\phi^2}$. A simple but sufficiently accurate method for accomplishing this is described in Part IV of reference 6. If reasonably good agreement is found he may then use the present correction curve with confidence.

For a spectrometer with a wide source the correction curve of Fig. 1 will have rather general reliability provided that the following experimental requirements are satisfied: (a) The linear absorption coefficient of the powder (including solid and interstices) should be approximately 40 or larger. (b) The diffraction angle, 2θ, should be greater than 20°. (c) The receiving slit width should not exceed the width at half maximum intensity of the x-ray source contour (both expressed in terms of 2θ units). (d) By proper adjustment of the x-ray slit the horizontal and vertical divergence of the x-ray beam should preferably be limited to moderate values, say, 1° and 2° respectively. Under these circumstances, if we disregard the usual remaining uncertainty in K of Eq. (1), satisfactory measurements can be made of crystallite sizes as large as 500A provided that B_0 and b_0 can be measured with an accuracy of ±0.01° or better for the larger sizes. For the new spectrometers with narrower x-ray sources the present curve is fairly reliable for crystallite size measurements below 500A. However, although instruments of this design are theoretically capable of application in the size range 500–1000A, the novel geometrical factors involved are such as to require a special analysis in order that a correction curve may be established for work in this size range.

If it is desired to use integral contour breadths, defined by $\beta_x=(\int I_x dx)/(I_x)_{max}$, rather than widths at half maximum intensity, the curve marked "Integral Breadths" in Fig. 1 should be employed. This curve was derived by substituting the functions $1/(1+k_1^2x^2)$ and $\exp(-k_2^2x^2)$ respectively for $F(kx)$ and $f(x)$ in Jones' Eqs. (4) and (5).[8] The integral breadth is more convenient for mathematical analysis but less readily employed in the experimental measurement of crystallite size.

When measurements of the highest reliability are required, it is recommended that the Fourier transform method of Stokes be employed for determining β. Once the equipment for the rapid summation of Fourier series has been constructed and the technique for performing the operations has been mastered, the time consumption per analysis is not excessive (possibly one or two hours). The Fourier method has completely

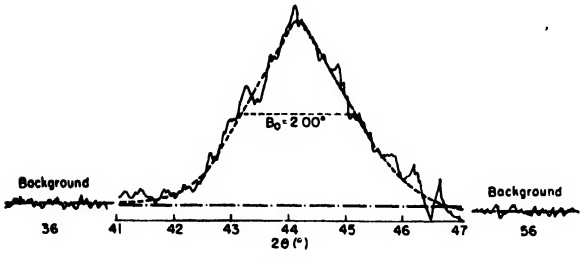

FIG. 2. Determination of the crystallite size of a nickel catalyst from an automatic strip chart record of the (111) maximum. CuKα-radiation; scanning speed 1° per minute; background measured at $2\theta=36°$ and 56°. Neglecting b_0, $D_{111}=48$ A. Using $b_0=0.33°$ for the (220) reflection of NaCl powder, $D_{111}=49$ A.

general applicability regardless of the particular forms of the pure diffraction contour and the various instrumental broadening functions. Furthermore Kα doublet broadening is automatically allowed for.

V. PRACTICAL SUGGESTIONS FOR CRYSTALLITE SIZE DETERMINATION WITH THE X-RAY SPECTROMETER

The following discussion applies to the older spectrometer design incorporating a wide x-ray source and a working range of $2\theta=0$ to 90°. Three crystallite size ranges will be given special consideration, each amenable to a somewhat different experimental approach.

For all except the smallest crystallite sizes it is necessary to measure the contour widths of both the material being studied (B_0) and a reference material which gives no crystallite size broadening (b_0). In order that the geometrical broadening effects may be as nearly identical as possible, the two peaks should be situated at approximately the same diffraction angle. When the linear absorption coefficients for x-rays of the "unknown" and reference powders are both high (say, $\mu=40$ or more when the interstices of the powder are included in the calculation) or when the absorption coefficients are known to be very nearly equal, good results can be obtained when the two materials are mounted and analyzed separately. However, when the coefficients are small, and in particular when they are known to differ considerably, the two materials should be intimately mixed and the measurements made on a single sample. The fact that the calculated absorption coefficients of the two solid materials are nearly equal is in itself no guarantee that the powders will absorb equally because they may not pack to the same density. When this is evidently true, or when there is any doubt in this regard, the materials should always be mixed. Fine quartz powder manifests a fairly typical packing behavior and is found to assume a state in which solid and interstices constitute about 40 and 60 percent respectively of the total sample volume. Hence, the linear absorption coefficient of the powder is only 0.40 as large as that of the solid material [for CuKα radiation μ (quartz powder) $=0.40\times93=37$].

The above suggestions presuppose the use of a sample of sufficient thickness to give maximum absorption (see remarks in reference 6, Part VII). If sufficient intensity can be obtained with the use of a very thin sample, such as a film of powder mounted on a suitable plane substrate, the differences in absorption become much less important and it is usually unnecessary to mix the powders.

Case 1. Size Range < 150A

In this range fairly good results can be had by preparing automatic strip chart records at a sufficiently slow scanning speed to yield a contour of easily measurable width. The background is also measured at selected points on either side of the maximum, after which the best straight horizontal line is drawn through the statistical fluctuations of each background record and a smooth curve is drawn to delineate the peak contour. This method is not successful unless the peaks in question are relatively strong. In favorable cases of this sort β can be determined with a probable error of 5 to 10 percent. Figure 2 illustrates the application of this method to a nickel catalyst of fine crystallite size.

If the peak contours are counted and plotted manually and if sufficient counts are taken to permit the

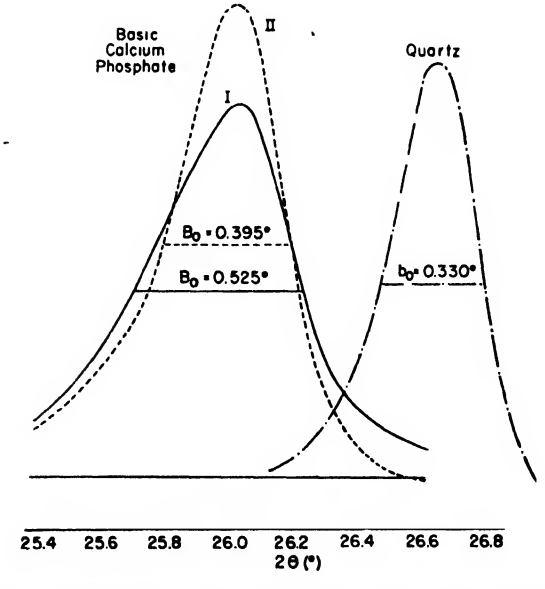

FIG. 3. Diffraction contours of basic calcium phosphate precipitate before (I) and after (II) digestion, and reference contour of quartz powder. The contours were plotted from manually recorded counting rate data. Crystallite sizes (after correcting for Kα doublet broadening): (I) 290 A, (II) approximately 800 A.

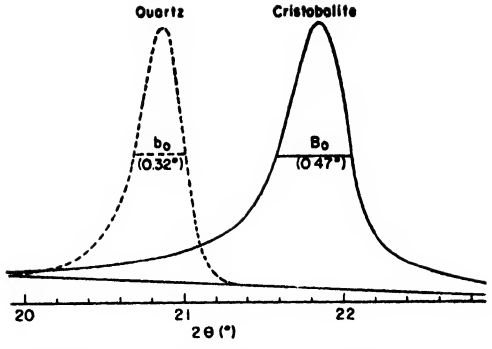

FIG. 4. Diffraction contours used in determining the crystallite size of cristobalite prepared by calcining diatomaceous earth. The contours were plotted from manually recorded counting rate data. Mean crystallite size (after correcting b_0 and B_0 for Kα doublet broadening), 366 A.

determination of the peak height above background with a probable error from counting statistics of 1 percent or less (5000 counts per point for cases with negligibly small backgrounds), the probable error in β can be reduced to 3 percent or less. In this size range it is unnecessary to correct the observed line breadths for Kα doublet broadening. Warren[2] has pointed out that the measured breadth of the "unknown" line, B_0, can be substituted for β directly in the crystallite size formula when $b_0 < B_0/5$, because in such instances the broadening due to the instrumental effects becomes insignificant in comparison with the pure diffraction broadening. Thus, for the nickel catalyst of Fig. 2 the calculated crystallite size was 49A when b_0 was taken into account and 48A when not.

Case 2. Size Range 150–300A

Automatic recording is not satisfactory in this range except for very rough measurements. If the heights of the peaks above background are determined with an accuracy approaching 1 percent (as limited by counting statistics), it is possible to determine β with a probable error of 5 percent. This and succeeding estimates of precision and error take into account a reasonable degree of uncertainty in the position of the spectrometer correction curve (Fig. 1). In this size range it is unnecessary to correct for Kα doublet broadening for $2\theta < 60°$. For higher angles the error involved is sufficient to increase appreciably the 5 percent probable error quoted above.

Case 3. Size Range 300–500A

In this range it is necessary to adopt the best experimental techniques in order to secure good results. A probable error in β of considerably less than 10 percent can be attained by keeping the probable error in counting statistics at points near the tops of the peaks smaller than 1 percent and by correcting for Kα doublet broadening *in all cases*. In addition, for the most accurate work it is recommended that the recorded counting rates be corrected for the nonlinearity of response of the Geiger tube.[7]

Of course, care must also be exercised in defining accurately the sides of the contours at the levels at which the breadths B_0 and b_0 are to be measured. This means measuring the counting rates at two or more points in the immediate vicinities. An analysis of the counting errors involved has shown that it is satisfactory to use a constant time interval for counting all the points defining a given contour, provided only that this time interval furnishes a sufficient number of counts to determine the height of the peak above background with high precision.

The background should preferably be counted with a longer time interval because of the normally much smaller intensities involved, and it is suggested that this interval be made twice as long as that employed in counting the peak contour. When the background is abnormally high and constitutes an appreciable portion of the over-all counting rate measured at the top of the peak, it is necessary to totalize much more than 5000 counts at the top of the peak in order to reduce the probable error in the *net* peak height to less than 1 percent.[8] In any event care should also be taken that the background be measured at points sufficiently far removed from the peak to avoid contributions from the base of the peak itself. For sharp peaks an angular displacement from the peak center of 2.0° is usually satisfactory, but for the very wide maxima generated by a distribution of crystallite sizes in the range below 100A it is necessary to increase this to 5° or even more.

Figures 3 and 4 illustrate crystallite size measurements in the ranges of Cases 2 and 3. In each figure the required reference contour of a material of large crystallite size (fine quartz powder) is also shown. Actually each contour pictured was obtained using a separate sample, but the several contours have been drawn together to facilitate comparison. The growth of the basic calcium phosphate crystallites during digestion is strikingly reflected in the alteration of the diffraction contour shown in Fig. 3. The accuracy of the measurement following digestion is obviously not good (probably not better than 800±150A) because the size involved is outside the satisfactory working range of the spectrometer. Figure 4 portrays the b_0 and B_0 contours which were analyzed in determining the crystallite size of cristobalite, a form of crystalline silica, prepared by calcining diatomaceous earth.

ACKNOWLEDGMENT

The authors are indebted to Elizabeth Kummer and Douglas Pitman for assistance in obtaining the experimental data and performing calculations.

Radiofrequency Mass Spectrometer

WILLARD H. BENNETT
National Bureau of Standards, Washington, D. C.
(Received August 29, 1949)

A mass spectrometer tube using velocity selection is described. The tube has parallel plane grids made with knitted wire nets with a large percentage of open area. The grids are arranged in groups of three, and radiofrequency alternating potential is applied to the middle grid of each group. Stopping potentials are used to turn back all ions except those with the selected mass. The spectrometer has sufficient resolution for ordinary gas analysis requirements and is simpler, more compact, and more rugged than magnetic beam deflection devices.

SEVERAL proposals have appeared in the past for making a mass spectrometer using velocity selection instead of a magnetic deflection of a focused beam of ions.

Smythe and Mattauch[1] used a succession of pairs of condenser plates along a tube, with which radiofrequency alternating fields could be applied to the ions in a collimated beam at right angles to the principal direction of movement of the ions in the beam. The ions in order to arrive at the receiver had to have the velocity necessary to place them opposite each successive pair of condenser plates at successively opposite phase. Because harmonic masses would also be recorded in such an arrangement, Smythe and Mattauch[1] also bent the beam through an arc with an electric field between a curved pair of electrodes in order to eliminate harmonics. From the available publications, this method does not appear to have been successful.

Stephens[2] proposed, and Cameron and Eggers[3] built and tried a pulsed ion source in combination with an oscilloscopic display of the distribution in time of the arrival of ions at a receiver. The resolution obtained, using this attractively simple idea, is disappointingly limited. This limitation is probably inherent in any method which has to use such high speed recording of such small pulses of current.

Weisz[4] has suggested, but apparently not tried, an adaptation of a linear accelerator in which alternately phased radiofrequency alternating potential is applied to a succession of equally spaced coaxial cylindrical electrodes. He proposes to operate the instrument in a manner such that the ions to be selected arrive at the gaps between electrodes at zero phase and that they be selected on the basis that they have neither gained nor lost energy because of the alternating fields between the successive cylindrical electrodes. He fails to make clear how to accomplish such a selection.

Bauer[5] has suggested a method which requires a well-focused beam to travel between parallel plates between which an alternating radiofrequency potential is applied. This method also appears not to have been tried.

Proposals have also appeared[6] for time-of-flight methods which use uniform magnetic fields in obtaining well-focused mass components, and as such have most of the disadvantages of the more familiar magnetic beam deflection methods and can use only as intense an ion beam as can be made to pass through a narrow slit.

The present development grew out of some observations made in 1946 on a pentode with coaxial cylindrical electrodes. A radiofrequency a.c. potential was applied to the intermediate one of the three grids while negative ions were produced at the hot cathode in the central portion of the tube. Although this tube was built for the purpose of separating kinds of negative ions differing in mass by a factor of two or more, it was found that a much better separation was effected than had been anticipated. For this reason, experiments were initiated to explore the possibilities of this kind of velocity selector as a mass spectrometer.

SINGLE-STAGE TUBE

The first tube built using parallel plane grids was a single-stage tube, as shown in Fig. 1, and illustrated schematically in Fig. 2. Electrons from the filament, *a*, are accelerated through a d.c. potential to the first grid, *b*. Positive ions produced by collisions between these electrons and gas molecules in the tube between grids *b* and *c* are accelerated from *b* toward *c* with a potential difference, *V*, between *b* and *c*. The grids *c*, *d*, and *e* are equally spaced at a distance *s*. A radiofrequency field of angular frequency ω is applied to the middle grid *d* giving an electric field between *c* and *d*

$$E_{cd}=E\sin(\omega t+\theta)$$

and between *d* and *e*

$$E_{de}=-E\sin(\omega t+\theta);$$

where t is zero at the instant an ion crosses the plane of grid *c* and $E\sin\theta$ is the value of the field E_{cd} at that instant. We assume a uniform flow of ions up to grid *c* so that there will be equal numbers of ions with each

possible value of θ. Some of these will receive energy from the fields as they pass the grids while others will lose energy to the fields. The collecting plate f has a d.c. stopping potential which turns back all ions except those which have acquired nearly the maximum possible energy from the fields and which originated near the grid b.

An exact solution for the motion of a charged particle in the sinusoidal field is extremely complex and has not been obtained. For purposes of this discussion, a small disturbance approximation will suffice. Experiment has shown that this approximation holds quite well for finite amplitudes. It is assumed that the change in velocity of an ion as it moves through the grids is small compared to its initial velocity so that the effects

FIG. 1.

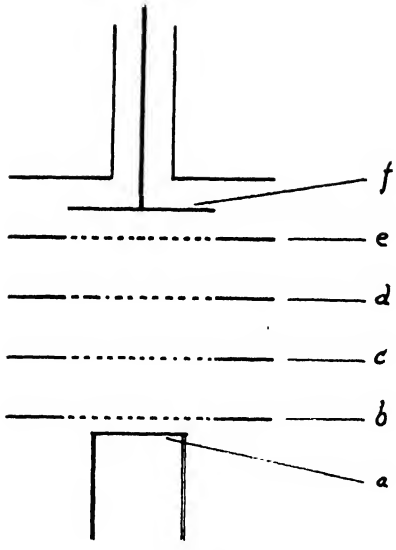

FIG. 2.

of the applied fields on the transit time can be neglected. Space-charge effects are also neglected with negligible error for this system.

The force acting on mass m between grids c and d is

$$F_{cd}=m\ddot{x}=Ee\sin(\omega t+\theta)$$

and between d and e is

$$F_{de}=m\ddot{x}=-Ee\sin(\omega t+\theta),$$

where time t is measured from the time the ion passes the grid c and θ is the phase angle of the alternating potential on d at the instant the ion passes c. Taking for a first approximation, the case when the amplitude of the alternating potential is small compared with the d.c. potential, V, used in accelerating the ion from the source to the grid, c, the variations in the velocity of the ion due to the a.c. fields will be small compared with the average velocity of the ion between grids c and e. The energy acquired from the alternating field is approximately:

$$\Delta W=\Delta(mv^2/2)=v\cdot\Delta(mv)=v\int F dt.$$

The transit time for the ion to travel from one grid to the next is s/v where s is the distance between grids. Then

$$\Delta W=v\left\{\int_0^{s/v}Ee\sin(\omega t+\theta)dt+\int_{s/v}^{2s/v}-Ee\sin(\omega t+\theta)dt\right\}$$

$$\Delta W=\frac{Eev}{\omega}\left[\cos\theta-2\cos\left(\frac{s\omega}{v}+\theta\right)+\cos\left(\frac{2s\omega}{v}+\theta\right)\right].$$

This is a maximum with respect to variations in θ when

$$(s\omega)/v+\theta=\pi=180°,$$

showing that the ions which pass grid d just as the field reverses obtain maximum incremental energy. The expression for ΔW is a maximum with respect to variations in ω when

$$\theta = 46° \text{ (more precisely } 46°26')$$

so the transit angle between grids is

$$(s\omega)/v = 134°.$$

The velocity of the ion receiving maximum incremental energy is obtained from

$$eV = \tfrac{1}{2} M m_0 v^2,$$

where V is the potential difference between the ion source, b, and the grid, c; M is the atomic mass number of the ion; and m_0 is the mass of an ion of unit mass number. Eliminating v between the last two equations gives

$$M = \frac{0.266.10^{12} V}{s^2 f^2},$$

where V is in volts, s is in centimeters, and f is in cycles per second.

Shown in Fig. 3 is the energy, ΔW, acquired by an ion passing the grid d, at 180° phase as a function of the number of cycles, N, executed by the alternating field while the ion travels from grid c to grid e. The principal maximum of this curve is at $N = 0.74$ cycle because the transit angle from the first to the third grid for maximum ΔW is

$$(2s\omega)/v = 267° = 0.74 \text{ cycle}.$$

If the stopping potential applied in the collecting system corresponds to the energy Z, at the horizontal dashed line, the ions can be collected only at frequencies corresponding to positions in the graph between A and B. Ions passing the first grid at phase angles different from the optimum 46° angle acquire a lower energy and can reach the collecting electrode within a narrower range than the range between A and B. The ions collected are those at all phases of entry which can collect enough ΔW to exceed Z so the shape of the line observed for ions of a particular mass is sharper than that portion of the curve above Z.

An example of the line form observed is shown in Fig. 4. This is a plot of the experimentally observed ion currents for mercury positive ions. A smaller stopping potential is used for the upper curve than for the lower curve.

It was found by experiment that the above approximate treatment was adequate if the d.c. potential difference between the source and the first grid was more than 10 times the amplitude of the r-f alternating potential, but that irregular curves for each mass component resulted at larger relative a.c. potentials. However, symmetric mass line forms resulted for a.c. potentials up to about half the d.c. potential on grid d, to which the a.c. potential is added, is reduced by just the amount necessary to reduce the speed of an ion receiving maximum incremental energy, back to the same speed as that with which the ion passed grid c, and if the d.c. potential on grid e were also similarly reduced below that of grid d.

A good example of this can be given in the case where the tube is used for resolving the negative atomic ions produced at the surface of a hot cathode. In this case the potentials applied were:

Ion source, a,	0.0 volt, d.c.
Grid, b,	+10.0 volts d.c.
Grid, c,	+ 4.0 volts d.c. plus 6 volts (r.m.s.) a.c.
Grid, d,	− 2.0 volts d.c.
Grid, e,	−14.1 volts d.c.
Collector, f	+20.0 volts d.c.

It will be noted that in this particular test, the stopping potential was applied to the fourth grid, e, and not to the collector. A simple integration shows that if the grids were ideal grids (very small holes compared with the inter-grid distance), the maximum incremental energy an ion could acquire from the r-f fields would be about the same as would be acquired from a d.c. potential twice the r.m.s. value of the r-f potential on the intermediate grid. Thus the use of an r-f potential of six volts requires stepping back the d.c. potential on each successive grid by about six volts in order to hold approximately constant the velocity of those ions receiving nearly maximum incremental energy. The value of the stopping potential, −14.1 volts, exceeds the value of a little less than −12 expected because the more positive potential of the adjacent electrodes reduces the magnitude of the potential of the middles of the holes in the stopping grid to less than that of the potential applied to that grid.

By appropriately selecting the d.c. potentials, this spectrometer tube serves equally well for separating positive or negative ions. Although no magnetic field is needed with this tube in separating positive ions, it is helpful to use a small magnetic field perpendicular to

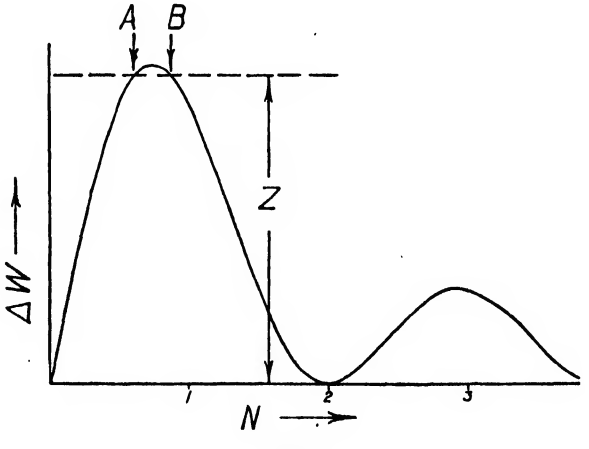

FIG. 3.

the axis of the tube when separating negative ions in order to confine the electrons from the source to the vicinity of the source. This prevents the formation of positive ions throughout the tube by the relatively large electron currents which would otherwise reach the vicinity of the stopping grid.

TWO-STAGE TUBE

The method was extended to a two-stage tube shown schematically in Fig. 5. In this case, the grids *b*, *c*, and *d* serve as the first stage while grids *e*, *f*, and *g* function as the second stage. The same radiofrequency alternating potential is applied to grids *c* and *f* in addition to the two unequal d.c. potentials whose difference provides the compensation described previously in connection with the single-stage tube. As before, the potential *V* accelerates the ions from the source *a* to the first grid *b*, and the d.c. potentials of grids *c*, *d*, *f*, and *g* are similarly adjusted. The grids *d* and *e* are at the same potential so that the region between them is an equipotential drift space. The stopping grid *h* and the collecting plate *p* function as before.

The distance between grids *d* and *e* is such that an ion receiving maximum incremental energy from the first stage will reach the initial grid of the second stage, *e*, at the right phase of the r-f alternating potential to acquire a maximum incremental energy from the second stage also. In order to accomplish this, the r-f potential must execute exactly an integral number of cycles while the ion travels from stage to stage, or more exactly, from *c* to *f*, and so the distance from *d* to *e* must be

$$(2.70n-2)s,$$

where *n* is an integer, and *s* is the distance between the grids in each stage as before. The first two-stage tube was built with $n=6$. This will be referred to as a six-cycle two-stage tube.

The incremental energy which can be acquired by an ion from both stages of a two-stage tube is illustrated in Fig. 6. The envelope of the curve is the same kind of a curve as plotted in Fig. 3 but with twice the ordinate, of course.

In Fig. 7 is shown the current of negative iodine ions from a hot tungsten filament in iodine vapor at 10^{-4}

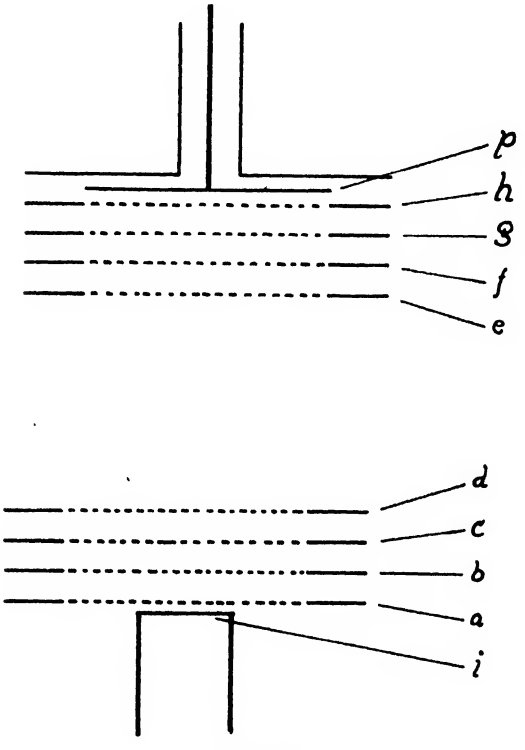

FIG. 5.

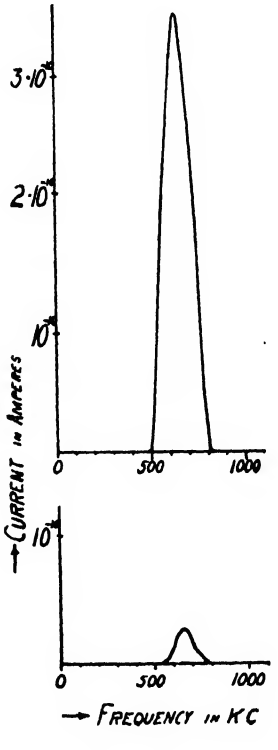

FIG. 4.

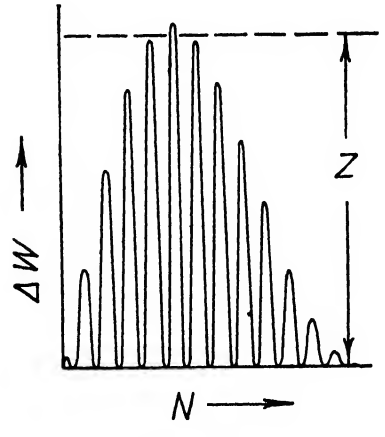

FIG. 6.

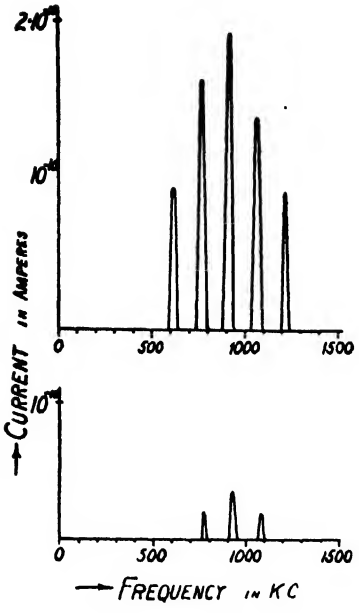

FIG. 7.

mm pressure. The lower curve shows the currents observed using a larger stopping potential, Z, than that used in obtaining the upper curve. It is seen by comparing these curves with those in Fig. 4 that the selection is much sharper than that obtained with a single-stage tube. High peaks occur for frequencies corresponding to other numbers of cycles between stages than the number 6 for the principal peak, and much of the sensitivity of the tube is lost in increasing the stopping potential enough to cut out the adjacent peaks.

THREE-STAGE TUBE

In order to retain much more sensitivity and, at the same time, produce only a single peak for each mass, a third stage is introduced. Such a tube is shown in Fig. 8. The three stages must be spaced so that the r-f alternating potential on the middle grid of each stage executes exactly integral numbers of cycles while the ion acquiring maximum incremental energy travels from stage to stage, i.e., from e to h, and from h to k. These integral numbers between the two successive pairs of stages are so selected as to avoid any appreciable overlap of the harmonic peaks of the two pairs of stages considered as two-stage combinations. This is illustrated in Fig. 9. When the integral numbers are so selected, much more of the principal peak can be left above the blocking potential, Z, than with either the single-stage or two-stage tubes and a corresponding increase in sensitivity is effected.

A 9–7-cycle three-stage tube was built, shown in Fig. 8, and illustrated schematically in Fig. 10. This tube was provided with two different kinds of ion source. One made use of a pencil of electrons, a', which passed at right angles to the axis of the tube. Ions produced along this electron beam were made to drift toward the grid c with a small electric field between b and c. The other source of ions which could alternatively be used made use of electrons from filament a accelerated toward grid b. Ions produced between b and c were similarly made to drift toward c with a small field between b and c.

A d.c. potential, V, accelerates the positive ions emerging through c toward and through d. The grids d, e, and f act as the first stage; g, h, and i the second stage; and j, k, and l the third stage. The only grids receiving the radiofrequency a.c. potential are e, h, and k. The stopping potential difference is applied between the collecting plate p and the grid c. The grid m was

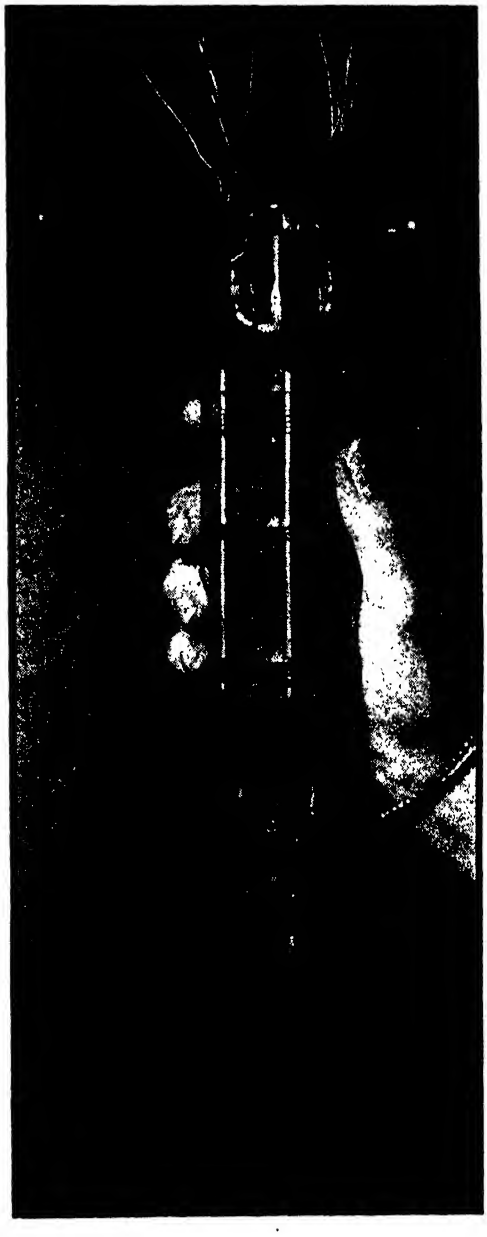

FIG. 8.

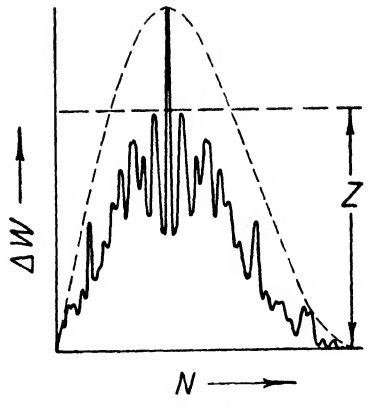

FIG. 9.

held at the same potential as the collector, and grid *n* was held at a more negative potential than any other electrode in the tube in order to turn back all electrons produced in the tube between grids *d* and *n*.

The grids used in this work were made with 0.0005-in. tungsten wire knitted with about 15 loops per centimeter. One of these grids is pictured in Fig. 11. The wire is mounted on the frame in a stretched condition so that the grid does not sag during or after baking. This is quite important in order that the grids remain accurately positioned with respect to each other. The open area of these grids is greater than 95 percent and even though 13 are used in a tube, more than 50 percent of the beam can pass through to the collector. The most open of the woven wire screens available with openings this small have open areas less than 65 percent, and 13 of these in series would pass less than one-half percent and would be quite impractical. Mr. William B. Haliday of this Bureau has assisted considerably in the development of the techniques for making these grids.

In this first of the three-stage tubes built, the grids in the stages were spaced at 2 mm which is of the same order of magnitude as the size of the holes in the grids. For this reason, the grids were far from ideal grids.

Figure 12 shows one of the observations of the spectrum of positive ions of mercury. In this observation, harmonic peaks occur at frequencies above and below the principal peak by about one-eighth the frequency of the principal peak. These harmonic peaks are evidently due to a partial overlap of the first harmonic peaks of the two two-stage combinations whose harmonics occur at frequencies, respectively, at one-ninth and one-seventh of the principal frequency, as illustrated in connection with Fig. 7.

Increasing the stopping potential and correspondingly reducing the intensity of the observed line eliminates these harmonic peaks as shown in Fig. 13. In this figure, the solid vertical lines under the curve are drawn proportional to the relative abundance of the isotopes. The width of this observed line at half the maximum height is 3½ percent while the width, due to the spread in isotope distribution, should be at least 1½ percent. However, the line flares out at the base much more than the lines did in the two-stage cases. This is believed to be due to the fact that this tube used grid

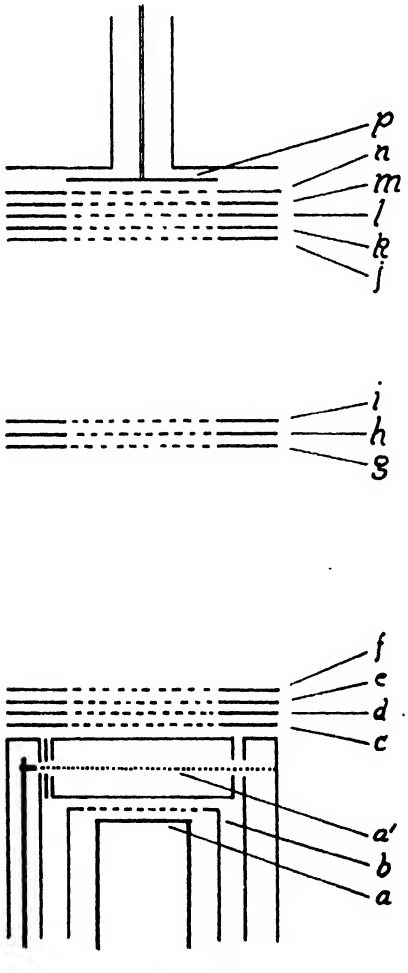

FIG. 10.

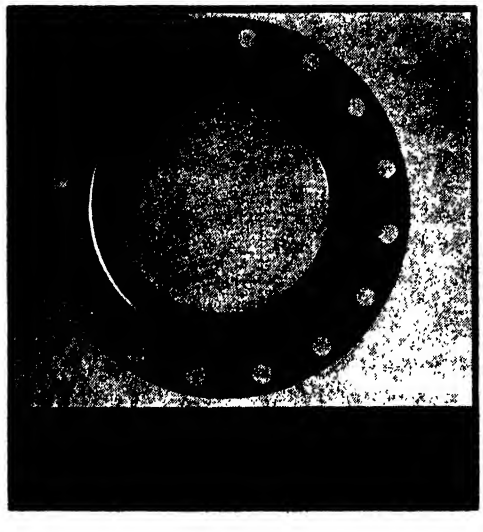

FIG. 11.

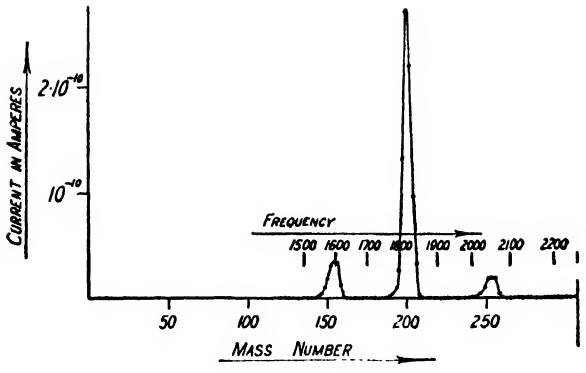

FIG. 12.

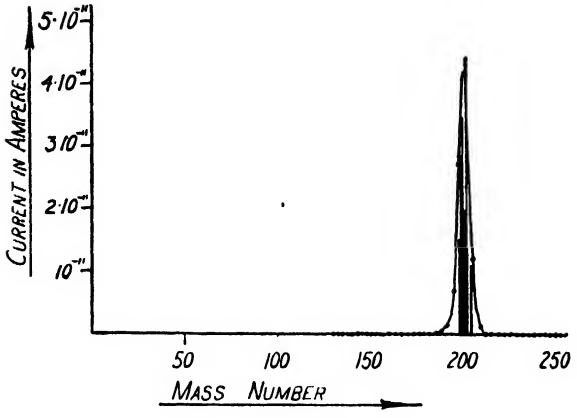

FIG. 13.

distances which were too small compared with the size of the holes in the grids.

From the shape of the line shown in Fig. 13, it is seen that this spectrometer should have sufficient resolution for those gas analyses where the masses to be completely separated differ by more than six percent, as is the case in many ordinary gas analyses of the lighter substances.

It should be noted that after constructing this spectrometer tube with proper care given to the accuracy of the grid spacings, and the accuracy of measurement of the potential, V, the formula

$$M = \frac{0.266.10^{12}V}{s^2f^2}$$

accurately gives the frequencies at which the various mass components appear. The instrument, when built with due attention to grid spacing, does not have to be calibrated with known gases and, in this sense, this is an absolute instrument.

This spectrometer tube has been found to operate well at pressures from 10^{-6} to 10^{-4} mm. It should be built in a form which can be baked because, otherwise, the gases usually found in unbaked tubes can give strong background mass components in the observations. On the other hand, masses can be resolved at pressures up to values of the pressure where the mean free path of the ions is about equal to the length of the tube.

It is important to note that no slits are required. All the ions produced in the ion source are accelerated through the essentially open structure of the tube toward the stopping electrode. The current at the top of the principal peak in Fig. 12 corresponds to about five percent of all the ions produced in the ion source.

Experiments are continuing to determine whether the harmonic peaks shown in Fig. 12 can better be eliminated by some other selection of integer combination for the number of cycles between stages or by increasing the ratio of the grid distances to the hole-sizes in the grids. A number of simplifications of the tube and equipment are now being tested to determine which can be introduced without losing too much resolution for analytical applications.

Mr. Harry Diamond and Dr. Robert D. Huntoon, of this Bureau, have contributed much in encouragement in this development.

Strain Induced Grain Boundary Migration in High Purity Aluminum

PAUL A. BECK AND PHILIP R. SPERRY*
Department of Metallurgy, University of Notre Dame, Notre Dame, Indiana
(Received August 8, 1949)

A method has been developed for the study of grain boundary migration in high purity aluminum, which allows positive determination of the *direction* of grain boundary movements. By means of this method it was confirmed that the migration of grain boundaries resulting from surface energy takes place in the direction toward the centers of curvature of the boundaries. On the other hand, strain induced grain boundary migration, such as occurs in recrystallization, proceeds in a direction away from the centers of curvature of the moving boundaries. It was also found that certain strained grains serve as nuclei for strain-free grains of the same orientation which grow at the expense of neighboring strained grains. Most of the strain-free grains formed during the annealing of high purity aluminum cold rolled up to about 40 percent are produced by this mechanism of strain-induced boundary migration, without the formation of new nuclei.

RECENT investigations of Harker and Parker,[1] C. S. Smith,[2] and J. E. Burke[3] revealed some important aspects of the type of boundary migration connected with gradual grain growth. A distinctive feature of this type of migration is that the boundaries move *in the direction of their centers of curvature.* A typical example is shown in Fig. 1, which represents two successive stages in the migration of grain boundaries in an annealed high purity aluminum specimen. By means of a technique developed at this Laboratory,[4] the two successive stages are shown superimposed on each other. The driving energy of grain growth is the excess free energy associated with the grain boundary surfaces. Grain growth tends to decrease this free energy, thus allowing the structure to approach equilibrium, by decreasing the grain boundary curvatures and the total grain boundary surface per unit volume.

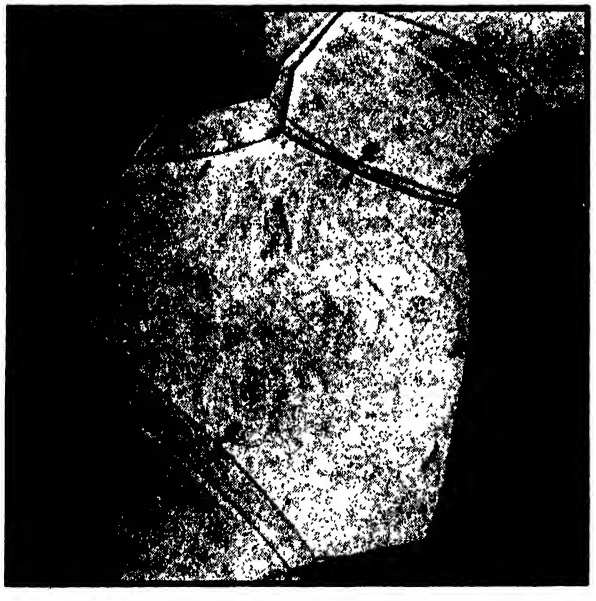

FIG. 1. In grain growth, boundary surfaces migrate toward their centers of curvature. Boundaries in high purity aluminum, after annealing 2 min. at 600°C (1), and after an additional anneal of 30 sec. at 600°C (2). Magnification 75×.

The recrystallization of cold worked metals also proceeds by means of boundary migration. However, in this case the moving boundaries separate strain hardened grains from annealed grains, and the direction of the movement is such that the volume of the annealed material increases with time at the expense of the cold worked material. The familiar concept of recrystallization involves the formation of nuclei of new strain-free grains in the midst of the strain hardened material. Most of the small new grains are at first entirely surrounded by one or two grains of the cold worked structure. During the growth of these new grains, their convex boundaries move in a direction *opposite to their centers of curvature.* Two stages of the growth of such a new grain (*C*) are shown in Fig. 2 by means of the same technique used in Fig. 1. The driving force of recrystallization is the excess free energy stored in the strain hardened material as a result of cold working. Even though the grain boundary movements here, as far as they can be observed under the microscope, take place in a direction opposite to that required by surface energy considerations, the total free energy is decreasing, and equilibrium is approached, as the strain hardened grains of high free energy content are replaced by low energy annealed grains.

Figure 2 also shows four successive stages of the migration of a grain boundary (1) already present in the original strain hardened structure. As revealed by the color effect in polarized light after electrolytic oxidation[4] and by x-ray diffraction, the orientation of the material swept by the moving boundary is very closely the same as that of the adjacent strain hardened grain (*A*). At first glance it might appear as if this boundary migration was related to ordinary grain growth, since one of the grains already present in the structure (*A*), is growing at the expense of another one

(*B*). On closer inspection, however, it becomes obvious that this process is different from grain growth, and that it is in important respects similar to recrystallization. This type of boundary migration takes place only in strain hardened material and it leads to an increase, rather than to a decrease, of grain boundary surface area, as seen in Fig. 2.

The question arises whether or not the observed boundary movements are motivated by the excess free energy of strain hardening, as in recrystallization. Figure 3 shows an example of the type of strain induced grain boundary migration discussed. The material swept by the moving boundary consists of a number of sections with very slightly different orientation. All these orientations are almost identical with the average orientation of the adjacent strain hardened grain (*A*). With the type of specimen preparation used, the surface of strain hardened grains becomes roughened, while the surface of strain free grains remains quite smooth. Figure 4 shows, by means of oblique illumination, that grains (*A*), (*B*) and (*C*), remaining from the original cold worked structure, have rough surfaces. On the other hand, the area swept by the moving boundary while migrating from position 1 to position 2, is quite smooth. As confirmed by means of x-ray diffraction, the material in this area is essentially in the annealed, strain-free, condition. It thus appears that in the strain induced boundary migration considered, as in ordinary recrystallization, the moving boundaries separate annealed material from strain hardened material and the direction of the boundary movement is such as to increase the volume of the annealed material. It is clear that the driving energy of the two processes is the same.

There is one significant difference, however, between the type of strain induced boundary migration shown

FIG. 2. In recrystallization (grains *C*, *D* and *E*) boundary surfaces migrate away from their centers of curvature. Strain induced growth of grain *A* at the expense of grain *B*. High purity aluminum annealed 90 min. at 600°C, rolled 7.5 percent (heavily outlined straight boundaries (1)), annealed successively 5 sec. (2), 5 sec. (3), 15 sec. (4), and 7 sec. (5) at 500°C. Magnification 75×.

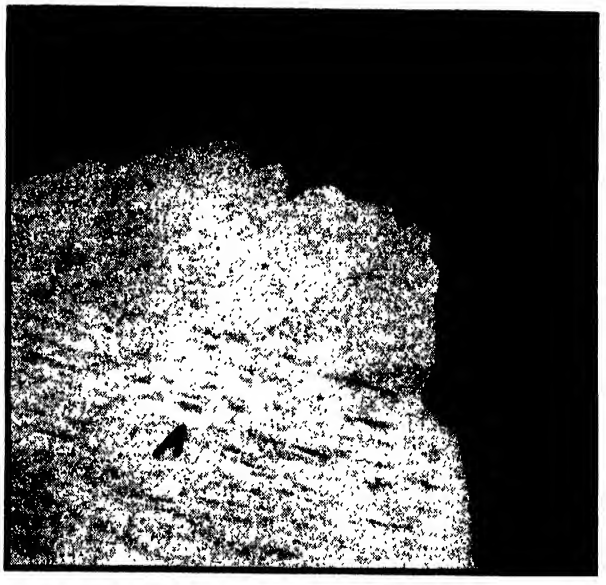

FIG. 3. Strain induced boundary migration in high purity aluminum. Orientation in area swept by migrating boundary is almost identical with that of strain hardened parent grain (A). Penultimate anneal: 5 min. at 650°C. 14 percent reduction by rolling. Last anneal 5 min. at 400°C. Magnification 75×.

in Fig. 3 and ordinary recrystallization. In the former, the annealed material swept by the migrating boundary has the same orientation as its strain hardened parent (*A* in Fig. 4), while in recrystallization a nucleus of different orientation is formed. As seen in Fig. 4, strain induced boundary migration without strain induced nucleation results in annealed areas bounded by an ordinary grain boundary on one side, and bordering on a strain hardened grain of the same orientation, without any intervening grain boundary, on the other side. That this is not so in ordinary recrystallization is shown in Fig. 5, where recrystallized grains *A* and *B* are located between strain hardened grains *C* and *D* and are separated from both of them by ordinary grain boundaries.

In summary, it may be stated that the processes of strain induced boundary migration found in aluminum is very much akin to recrystallization but that it differs from the latter by the fact that it is apparently nucleated by a strain hardened grain already present in the structure. Thus, *strain induced boundary migration may be considered as recrystallization without the formation of new nuclei.* Correspondingly, it was observed in many instances that, at the boundaries where it does occur, strain induced boundary migration starts promptly at the beginning of the annealing treatment. On the other hand, it is well known that a definite period of incubation is required for the formation of recrystallization nuclei and for their growth to microscopic sizes. This point is illustrated by Fig. 2, where each successive period of annealing has brought about a clearly observable migration of the boundary initially

FIG. 4. Strain induced boundary migration in high purity aluminum, as in Fig. 3. Strain hardened grains (*A*), (*B*), and (*C*) are roughened by etching, strain-free area, swept by migrating boundary, is smooth, and has no grain boundary toward grain (*A*). Oblique illumination.

FIG. 5. Recrystallized grains (*A*) and (*B*) are smooth and have grain boundaries toward both grains (*C*) and (*D*). The latter are strain hardened and consequently roughened by etching. Magnification 75×.

situated at (1). However, a recrystallized grain (*C*) came into existence only during the third period of annealing, and its two boundary positions, seen in the picture, correspond to the end of the last two annealing periods. Similarly, another recrystallized grain (*E*) was born during the fourth period of annealing and, therefore, the figure shows only one boundary position (5) for this grain. It was found that the ordinary recrystallization process, involving nucleation, plays a relatively minor role during the annealing of high purity aluminum deformed by rolling up to about 40 percent reduction of area. In such instances the type of strain induced boundary migration not involving the formation of new nuclei appears to predominate in the transformation to the strain-free condition.

The External Field Produced by a Slot in an Infinite Circular Cylinder*

SAMUEL SILVER AND WILLIAM K. SAUNDERS
Division of Electrical Engineering and the Antenna Laboratory, University of California, Berkeley, California
(Received August 10, 1949)

Expressions are derived for the external field produced by a slot of arbitrary shape in the wall of a circular wave guide (of infinite extent and infinite conductivity), the tangential components of the electric field in the slot being assumed to have been prescribed. This is accomplished by matching a Fourier representation of the external field, built up by superposition of basic sets of cylindrical waves, to a Fourier expansion of the prescribed field over the surface of the cylindrical wave guide. The far-zone field is obtained by applying the method of steepest descent to the Fourier integrals that constitute the coefficients in the expansion for the external field. The results satisfy the radiation conditions for far-zone fields.

I. INTRODUCTION

THIS paper, the first of a series of studies of the radiative properties of slots in conducting surfaces, is concerned with the field set up in space by a slot of arbitrary shape in the wall of a circular cylindrical wave guide. A complete analysis of the properties of a slot in the wall of a wave guide must make proper connection between the interior and exterior fields, thus determining the field distribution in the slot itself. Such a unified treatment is difficult to carry out and as yet has not been achieved for even the simplest slot configurations. Instead, the procedure has been to treat the interior and exterior problems separately in terms of assumed field distributions in the slot,[1] a procedure that we follow here. Under certain conditions, as for example in the case of an elongated narrow slot, reasonable assumptions can be made concerning the field distribution in the slot and results can be obtained that are of considerable usefulness in the design of radiating systems.

The subject of the slot in a circular wave guide has been treated previously under various restrictive conditions on its geometry and field distribution. G. Sinclair[2] and C. H. Papas and R. W. P. King[3] have discussed the field of a narrow slot of infinite length running parallel to the axis of the cylinder, excited uniformly along its length in the transverse direction. More recently C. H. Papas,[4] by means of a Green's function technique, has solved the problem of a finite slot in which the electric field has but a single tangential component that is parallel to the axis of the cylinder. This essentially restricts the configuration of the slot to be developable into a rectangle oriented with its boundaries respectively parallel to and perpendicular to the axis of the cylinder. As we shall show in Section V, the several previous results can be obtained directly from our general expressions.

II. GENERAL CONSIDERATIONS

The analysis presented here is free from the restrictive conditions on the slot geometry and fields that characterize the earlier work but is based also on the assumptions that the wave guide is infinite in extent and has infinite conductivity. The time dependence of the fields is taken to be harmonic and the complex exponential $e^{+i\omega t}$ is chosen as its representation.

The axis of the cylinder, which has a radius a, serves as the z axis of our coordinate system. Cylindrical coordinates ρ, ϕ, z are most suited for developing the general solution. Later, for purposes of describing the far-zone field, spherical coordinates R, θ, ϕ will be more appropriate; the cylinder axis will then form the polar axis of the spherical coordinate system. On the surface of the cylinder we have a slot of arbitrary shape, bounded in the axial direction by the planes $z=z_1$ and $z=z_2$ and defined circumferentially by the curves $\phi_1(z)$ and $\phi_2(z)$; the various quantities are shown in Fig. 1.

The tangential electric field in the slot will in general have both ϕ and z components which we consider to be prescribed functions $f_1(\phi, z)$ and $f_2(\phi, z)$, respectively. In view of the infinite conductivity of the wall

[3] C. H. Papas and R. W. P. King, Cruft Laboratory Technical Report No. 32, ONR Contract N5-ori-76 (March, 1948); Quart. App. Math. 7, No. 2 (July, 1949).

[4] C. H. Papas, Cruft Laboratory Technical Report No. 58, ONR Contract N5-ori-76 (September, 1948); J. App. Phys. 20, 437 (1949); Cruft Laboratory Technical Report No. 61, ONR Contract N5-ori-76 (October, 1948) to be published in J. Math. and Phys. 28, No. 4 (January, 1950).

this represents a complete knowledge of the tangential electric field over the entire surface of the cylinder, namely,

$$E_\phi = f_1(\phi, z) \quad \phi_1 \le \phi \le \phi_2;\ z_1 \le z \le z_2;$$
$$= 0 \qquad \text{outside the slot;} \tag{1a}$$

$$E_z = f_2(\phi, z) \quad \phi_1 \le \phi \le \phi_2;\ z_1 \le z \le z_2;$$
$$= 0 \qquad \text{outside the slot.} \tag{1b}$$

A solution of Maxwell's equations must be constructed that assumes the prescribed value of the tangential electric field over the cylinder and that satisfies certain radiation conditions at infinity. For a time-periodic field the latter take the form:[5]

$$\lim_{R\to\infty} R\mathbf{E} \text{ is finite,} \tag{2a}$$

$$\lim_{R\to\infty} R[\mathbf{R}_1 \times \mathbf{H} + (\epsilon/\mu)^{\frac{1}{2}}\mathbf{E}] = 0, \tag{2b}$$

$$\lim_{R\to\infty} R\mathbf{H} \text{ is finite,} \tag{2c}$$

$$\lim_{R\to\infty} R[(\mathbf{R}_1 \times \mathbf{E}) - (\mu/\epsilon)^{\frac{1}{2}}\mathbf{H}] = 0, \tag{2d}$$

where $\mathbf{R}_1$ is a radial unit vector in the spherical coordinate system (see Fig. 1). Equations (2b) and (2d) are the radiation conditions proper and express the fact that we have only outgoing waves at infinity. A time-periodic solution that meets the above requirements is unique.

The procedure is to construct Fourier representations for the tangential electric field over the cylinder and for the field in space. The latter is synthesized by superposition of basic sets of cylindrical waves that satisfy the requisite conditions at infinity. The coefficients of the expansion for the surface field are known; the coefficients of the representation for the space field are determined by the requirement that its tangential components at the surface of the cylinder shall reduce to the Fourier representation of the field prescribed over the latter. The resulting expressions are in the form of a Fourier series whose coefficients are Fourier integrals.

III. DEVELOPMENT OF THE FIELDS

The Tangential Field over the Cylinder

We shall first develop the Fourier expansion for the tangential components of the electric field over the surface of the cylinder. Let f_α denote either $f_1(\phi, z)$ or $f_2(\phi, z)$ and let E_α be the corresponding field component. In the ϕ-direction E_α is a periodic function and is therefore to be represented by a Fourier series

$$E_\alpha(\phi, z) = \sum_{n=-\infty}^{\infty} A_n{}^\alpha(z) e^{-jn\phi}, \tag{3}$$

the coefficients $A_n{}^\alpha$ being functions of z. It is readily evident that

$$A_n{}^\alpha = \frac{1}{2\pi}\int_{\phi_1(z)}^{\phi_2(z)} f_\alpha(\beta, z) e^{jn\beta} d\beta, \quad z_1 \le z \le z_2; \tag{4a}$$

$$= 0. \qquad z < z_1, \quad z > z_2. \tag{4b}$$

$A_n{}^\alpha(z)$ is thus a piecewise continuous function and its Fourier representation is the Fourier integral

$$A_n{}^\alpha = \frac{1}{2\pi}\int_{-\infty}^{\infty} dh \int_{z_1}^{z_2} A_n{}^\alpha(\xi) e^{-jh(z-\xi)} d\xi; \tag{5}$$

or,

$$A_n{}^\alpha(z) = \frac{1}{4\pi^2}\int_{-\infty}^{\infty} dh \int_{z_1}^{z_2} d\xi \times \int_{\phi_1(\xi)}^{\phi_2(\xi)} f_\alpha(\beta, \xi) e^{jn\beta} e^{-jh(z-\xi)} d\beta. \tag{6}$$

The tangential electric field over the cylinder is thus expressed in the form of a Fourier expansion:

$$E_\alpha(\phi, z) = \frac{1}{4\pi^2}\sum_{n=-\infty}^{\infty} e^{-jn\phi} \int_{-\infty}^{\infty} dh \int_{z_1}^{z_2} d\xi \times \int_{\phi_1(\xi)}^{\phi_2(\xi)} f_\alpha(\beta, \xi) e^{jn\beta} e^{-jh(z-\xi)} d\beta. \tag{7}$$

The External Field Expansion

We construct the external field by superposition of basic sets of cylindrical waves. The reader is referred to Stratton[6] for an exposition of the general theory of the latter. The basic sets fall into two groups: the transverse magnetic (TM) type having no H_z component and the transverse electric (TE) type having no E_z component. Appropriate combinations of these can be made to form a basic set of field components from which a general field that is periodic in ϕ can be synthesized. Each member of the latter set is a Fourier series as follows:

$$\mathcal{E}_\rho = \left\{ \sum_{n=-\infty}^{\infty} \left[-jha_n \frac{\partial H_n{}^{(2)}(\Lambda\rho)}{\partial\rho} - \frac{n\omega\mu}{\rho} b_n H_n{}^{(2)}(\Lambda\rho) \right] e^{-jn\phi} \right\} e^{-jhz}, \tag{8a}$$

$$\mathcal{E}_\phi = \left\{ \sum_{n=-\infty}^{\infty} \left[-\frac{nh}{\rho} a_n H_n{}^{(2)}(\Lambda\rho) + j\omega\mu b_n \frac{\partial H_n{}^{(2)}(\Lambda\rho)}{\partial\rho} \right] e^{-jn\phi} \right\} e^{-jhz}, \tag{8b}$$

[5] S. Silver, *Microwave Antenna Theory and Design* (McGraw-Hill Book Company, Inc., New York, 1949), Radiation Laboratory Series, Vol. 12, Chapter 3.

[6] J. A. Stratton, *Electromagnetic Theory* (McGraw-Hill Book Company, Inc., New York, 1941), Chapter 6. Note that our expressions differ from those of Stratton in signs because of our choice of $e^{+j\omega t}$ rather than $e^{-j\omega t}$ to represent the time dependence. This also leads to the use of the Hankel function of the second kind to represent an outward traveling wave.

$$\mathcal{E}_z=\left\{\sum_{n=-\infty}^{\infty}[(k^2-h^2)a_nH_n^{(2)}(\Lambda\rho)]e^{-jn\phi}\right\}e^{-jhz}, \quad (8c)$$

$$\mathcal{H}_\rho=\left\{\sum_{n=-\infty}^{\infty}\left[\frac{nk^2}{\mu\omega\rho}a_nH_n^{(2)}(\Lambda\rho)-jhb_n\frac{\partial H_n^{(2)}(\Lambda\rho)}{\partial\rho}\right]e^{-jn\phi}\right\}e^{-jhz}, \quad (8d)$$

$$\mathcal{H}_\phi=\left\{\sum_{n=-\infty}^{\infty}\left[-j\frac{k^2}{\mu\omega}a_n\frac{\partial H_n^{(2)}(\Lambda\rho)}{\partial\rho}-\frac{nh}{\rho}b_nH_n^{(2)}(\Lambda\rho)\right]e^{-jn\phi}\right\}e^{-jhz}, \quad (8e)$$

$$\mathcal{H}_z=\left\{\sum_{n=-\infty}^{\infty}[(k^2-h^2)b_nH_n^{(2)}(\Lambda\rho)]e^{-jn\phi}\right\}e^{-jhz}, \quad (8f)$$

with

$$\Lambda=[k^2-h^2]^{\frac{1}{2}}. \quad (9)$$

In the case of harmonic time dependence k is a constant that is given in terms of the constitutive parameters—magnetic permeability μ, electric permittivity ϵ, conductivity σ—of the medium under consideration and the angular frequency by

$$k=[\omega^2\mu\epsilon-j\mu\sigma\omega]^{\frac{1}{2}}; \quad -\pi/2<ph\,k\leq 0. \quad (10)$$

The parameter h with respect to which the set is ordered is in general complex; its values are to be taken to suit the required boundary conditions. The Hankel function of the second kind enters into the wave functions to represent outgoing waves. However, this property of the Hankel functions depends on the definition of the phase of Λ for the various values of h. We shall return to this matter shortly.

The terms in Eqs. (8) having the common coefficients a_n belong to the set of TM waves; those having common coefficients b_n are of the TE type. It will be observed that there are only two sets of independent coefficients and hence, a knowledge of any two field components is sufficient to establish the complete field. The coefficients a_n and b_n are independent of ρ and z but in general are functions of h.

We can now build up an arbitrary z dependence by superposition of components of various values of h. Regarding h as a complex quantity, different representations can be obtained according to the path in the h plane along which h is allowed to vary. In the present case where we are to fit the field at $\rho=a$ to a Fourier integral along the surface of the cylinder the path along the real-h axis is indicated. Thus for any field component $E_\alpha(\rho, \phi, z)$ we shall write

$$E_\alpha(\rho, \phi, z)=\int_{-\infty}^{\infty}\mathcal{E}_\alpha(\rho, \phi, h)dh. \quad (11)$$

Similar expressions hold for the magnetic field components.

We have noted before that the phase of $\Lambda=(k^2-h^2)^{\frac{1}{2}}$ must be defined along the path of integration in such a way as to produce proper behavior of the field at infinity. The locations of the branch points $h=\pm k$ are shown in Figs. 2(a) and 2(b), the latter applying to the case when the external medium has neither an ohmic nor a dielectric dissipation factor. To define the phase of Λ let us consider the behavior of $H_n^{(2)}(\Lambda\rho)$ for very large values of ρ, making use of the asymptotic form of the Hankel function,

$$H_n^{(2)}(\Lambda\rho)\approx[2/\pi\Lambda\rho]^{\frac{1}{2}}e^{-j\Lambda\rho}e^{j(2n+1)\pi/4}. \quad (12)$$

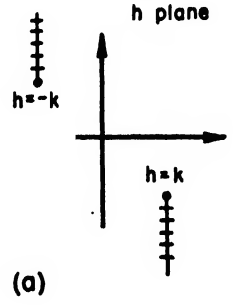

FIG. 2. Path of integration in the h Plane: (a) k complex; (b) k real.

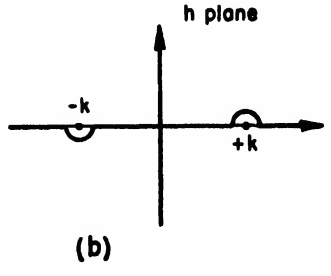

For the general case, when k is complex, it is seen that it is necessary to require

$$Re\Lambda\geq 0, \quad Im\Lambda\leq 0 \quad (13)$$

in order to have outward radial propagation and to keep the field components bounded at infinity. If k is real, the conditions (13) reduce to

$$ph\Lambda=0 \qquad |h|<k, \quad (14a)$$

$$ph\Lambda=-\pi/2 \qquad |h|>k, \quad (14b)$$

and it is seen that the contour must be indented around the branch points in the manner shown in Fig. 2(b).

Evaluation of the Coefficients

With the sense of Λ properly defined the components of the external field are given by Eq. (11). To evaluate

the coefficients a_n and b_n we match the components E_ϕ and E_z to the assigned values over the cylinder. From Eqs. (8) and (11), on interchanging summation and integration, we obtain

$$E_\phi = \sum_{n=-\infty}^{\infty} e^{-jn\phi} \int_{-\infty}^{\infty} \left[-\frac{nh}{\rho} a_n H_n^{(2)}(\Lambda\rho) + j\omega\mu b_n \frac{\partial H_n^{(2)}(\Lambda\rho)}{\partial\rho} \right] e^{-jhz} dh, \quad (15a)$$

$$E_z = \sum_{n=-\infty}^{\infty} e^{-jn\phi} \int_{-\infty}^{\infty} (k^2 - h^2) a_n H_n^{(2)}(\Lambda\rho) e^{-jhz} dh. \quad (15b)$$

At $\rho = a$ these must reduce to the expansions of Eq. (7); hence,

$$\left[-\frac{nh}{a} H_n^{(2)}(\Lambda a) \right] a_n + \left[j\omega\mu \frac{\partial H_n^{(2)}(\Lambda a)}{\partial a} \right] b_n = \frac{1}{4\pi^2} \int_{z_1}^{z_2} d\xi \int_{\phi_1(\xi)}^{\phi_2(\xi)} f_1(\beta, \xi) e^{jn\beta} e^{jh\xi} d\beta, \quad (16a)$$

$$[(k^2 - h^2) H_n^{(2)}(\Lambda a)] a_n = \frac{1}{4\pi^2} \int_{z_1}^{z_2} d\xi \times \int_{\phi_1(\xi)}^{\phi_2(\xi)} f_2(\beta, \xi) e^{jn\beta} e^{jh\xi} d\beta; \quad (16b)$$

or,

$$a_n = \frac{1}{4\pi^2 (k^2 - h^2) H_n^{(2)}(\Lambda a)} \int_{z_1}^{z_2} d\xi \times \int_{\phi_1(\xi)}^{\phi_2(\xi)} f_2(\beta, \xi) e^{jn\beta} e^{jh\xi} d\beta, \quad (17a)$$

$$b_n = \frac{-jnh}{4\pi^2 \omega\mu a (k^2 - h^2) (\partial H_n^{(2)}(\Lambda a)/\partial a)} \int_{z_1}^{z_2} d\xi \times \int_{\phi_1(\xi)}^{\phi_2(\xi)} f_2(\beta, \xi) e^{jn\beta} e^{jh\xi} d\beta - \frac{j}{4\pi^2 \omega\mu (\partial H_n^{(2)}(\Lambda a)/\partial a)} \int_{z_1}^{z_2} d\xi \times \int_{\phi_1(\xi)}^{\phi_2(\xi)} f_1(\beta, \xi) e^{jn\beta} e^{jh\xi} d\beta. \quad (17b)$$

These taken together with Eqs. (8) and (11) give the formal solution to the problem. The surface current distribution **K** over the cylinder is given directly by the tangential magnetic field at the surface:

$$K_\phi = -H_z(a, \phi, z); \quad K_z = H_\phi(a, \phi, z). \quad (18)$$

Whereas the process of obtaining the formal solution is a relatively simple one, the numerical evaluation of the fields is a task of considerable magnitude, particularly for points in the neighborhood of the slot. However, for the far-zone field the expressions simplify to a large extent and numerical work becomes more tractable. We shall discuss this region of the field in the following section.

IV. THE FAR-ZONE FIELD

The reduction of the general expressions for this region is effected by making use of the asymptotic forms of the Hankel functions and subsequently carrying out certain integrations by the saddle-point method.[8] We shall restrict the treatment to the case when k is real.

It is convenient to describe the far-zone field in terms of spherical coordinates R, θ, ϕ (see Fig. 1), and, accordingly we make the substitutions

$$\rho = R\sin\theta, \quad z = R\cos\theta \quad (19)$$

in the expressions for the components of the field. We are interested in the dominant characteristics of the field at large distances R; that is, we wish to obtain the leading terms in a development of the field components in inverse powers of R. Except for small values of θ we may, for large values of R, replace $H_n^{(2)}(\Lambda\rho) = H_n^{(2)}(\Lambda R\sin\theta)$ by the asymptotic form given in Eq. (12).† When this is done and the order of integration is suitably rearranged, it is found that the expressions for the field components take the general form

$$\frac{1}{4\pi^2} \sum_{n=-\infty}^{\infty}{}' e^{-jn\phi} \left\{ \int_{z_1}^{z_2} d\xi \int_{\phi_1(\xi)}^{\phi_2(\xi)} f_1(\beta, \xi) e^{jn\beta} d\beta \times \int_{-\infty}^{\infty} u(h, R, \theta; n) e^{jh\xi} e^{-jR[\Lambda \sin\theta + h\cos\theta]} dh + \int_{z_1}^{z_2} d\xi \int_{\phi_1(\xi)}^{\phi_2(\xi)} f_2(\beta, \xi) e^{jn\beta} d\beta \times \int_{-\infty}^{\infty} v(h, R, \theta; n) e^{jh\xi} e^{-jR[\Lambda \sin\theta + h\cos\theta]} dh \right\}. \quad (20)$$

The functions u and v can readily be evaluated for each particular component. It will be observed that they vary slowly over the range of h as compared with the exponential functions. The integrals over h in (20) are, therefore, of the general type to which the saddle-point method is applicable. We are here primarily concerned with the region of the field where R is very

[8] See, for example, G. N. Watson, *Bessel Functions* (Cambridge University Press, London, 1944), pp. 235 ff.

† We shall not enter here into a consideration of the different asymptotic representations that must be used according as to whether the order of the Hankel function is small, nearly equal to, or large compared with the magnitude of $\Lambda\rho$. From a practical standpoint these details are not too important inasmuch as the terms of the series are found to diminish rapidly with increasing values of n.

much larger than both the wave-length and the axial extent of the slot ($R \gg \xi$). The variation of the phase factor involving R thus dominates that involving ξ and we have the simplest form of saddle-point problem. It will be well to note in passing that in the case of a slot whose axial extent is large compared with the wave-length there is an intermediate zone, at distances about equal to or possibly less than the total axial dimension, for which (20) also gives the dominant terms. In the latter case, however, we have two rapidly varying phase factors to consider in the integration over h and consequently a saddle-point problem involving two large parameters.‡ Inasmuch as the intermediate zone

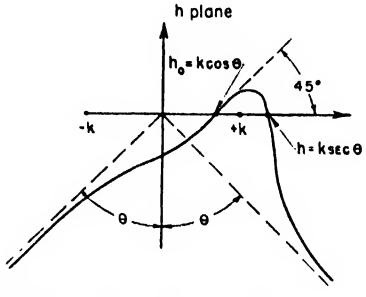

FIG. 3. Modified path through the saddle-point.

is of limited interest it will not be discussed further in this paper. Practical interest usually centers about the far-zone field pattern which is one of the primary specifications that are laid down for the design of a given antenna system.

With the restriction $R \gg \xi$ we may formulate our problem as that of evaluating an integral of the form

$$\int_{-\infty}^{\infty} F(h)e^{-jR[\Lambda \sin\theta + h\cos\theta]}dh = \int_{-\infty}^{\infty} F(h)e^{R\Phi(h)}dh \quad (21)$$

for large values of R, with

$$F(h) = \left.\begin{matrix} u(h, R, \theta; n) \\ v(h, R, \theta; n) \end{matrix}\right\} e^{jh\xi}. \quad (21a)$$

The saddle-point technique consists of deforming the path of integration into one that passes through the point h_0 for which $\Phi'(h_0) = 0$ and is such that over its entirety

$$Im\Phi(h) = Im\Phi(h_0).$$

If the integral converges along this path, the major contribution to the integral arises from a small segment about the saddle-point $h = h_0$. In our case the new path is a function of θ; its general form is shown in Fig. 3. The deformation from the real axis to this path is possible by virtue of the analytic properties of $F(h)$ and by the extension of conditions such as were imposed on Λ in Eq. (13) to the entire exponent, namely $Im\Phi(h) < 0$. This makes the integral over the arc connecting the real axis and the new path at infinity vanish, and also ensures the convergence of the integral along the modified path. Considering the small segment of the latter in the neighborhood of h_0 having the modulus $u < \epsilon$, we have

$$\begin{aligned}
&\int_{-\infty}^{\infty} F(h)e^{R\Phi(h)}dh \\
&\quad \approx F(h_0)e^{[R\Phi(h_0)+j\pi/4]} \int_{-\epsilon}^{\epsilon} e^{j\Phi''(h_0)u^2/2}du \\
&\quad = F(k\cos\theta)e^{-j(kR-\pi/4)} \int_{-\epsilon}^{\epsilon} e^{-Ru^2/2k\sin^2\theta}du \\
&\quad \approx F(k\cos\theta)e^{-j(kR-\pi/4)}\left[\frac{2k\sin^2\theta}{R}\right]^{\frac{1}{2}} \int_{-\infty}^{\infty} e^{-\tau^2}d\tau;
\end{aligned}$$

or,

$$\int_{-\infty}^{\infty} F(h)e^{R\Phi(h)}dh \approx \left[\frac{2\pi k}{R}\right]^{\frac{1}{2}} \sin\theta F(k\cos\theta)e^{-jkR}e^{j\pi/4}. \quad (22)$$

The leading terms are found to be of order R^{-1}. These form the radiation field. The components of E_ρ and E_z in the R-direction that are of this order of magnitude cancel one another; the same occurs in the magnetic field. The radiation field is thus transverse to the R-direction and, in general, has non-zero components:

$$E_\theta = -\frac{1}{2\pi^2}\frac{e^{-jkR}}{R}\sum_{n=-\infty}^{\infty}\frac{j^{n+1}e^{-jn\phi}}{\sin\theta H_n^{(2)}(ka\sin\theta)} \times \int_{z_1}^{z_2} d\xi e^{jk\xi\cos\theta}\int_{\phi_1(\xi)}^{\phi_2(\xi)} f_2(\beta, \xi)e^{jn\beta}d\beta; \quad (23a)$$

$$\begin{aligned}
E_\phi = \frac{1}{2\pi^2}\frac{e^{-jkR}}{R}\sum_{n=-\infty}^{\infty}\frac{j^n e^{-jn\phi}}{H_n^{(2)\prime}(ka\sin\theta)} \\
\times\left[\int_{z_1}^{z_2} d\xi e^{jk\xi\cos\theta}\int_{\phi_1(\xi)}^{\phi_2(\xi)} f_1(\beta, \xi)e^{jn\beta}d\beta\right. \\
\left. + \frac{n\cot\theta}{ka\sin\theta}\int_{z_1}^{z_2} d\xi e^{jk\xi\cos\theta} \times\int_{\phi_1(\xi)}^{\phi_2(\xi)} f_2(\beta, \xi)e^{jn\beta}d\beta\right]; \quad (23b)
\end{aligned}$$

$$H_\theta = -(\epsilon/\mu)^{\frac{1}{2}}E_\phi; \quad H_\phi = (\epsilon/\mu)^{\frac{1}{2}}E_\theta. \quad (23c)$$

These show explicitly that the solutions satisfy the required conditions at infinity that are formulated in Eqs. (2).

‡ The problem is very similar to that of obtaining various asymptotic forms of the cylinder functions according to the relative magnitudes of the order and the argument of the functions; see reference (8), Chapter 8.

V. ILLUSTRATIVE EXAMPLES

To illustrate the applicability of the results we shall touch briefly upon two cases reported previously in the literature to show how the earlier results are readily obtained from our general expressions:

1. The Uniformly Excited Circumferential Slot[4]

The slot runs completely around the cylinder and has a height $2w$ that is very much smaller than the circumference. For convenience we shall take $z_1=-w$, $z_2=w$. Note also that $\phi_1(z)=0$, $\phi_2(z)=2\pi$. The tangential electric field in the slot has only a z component and that independent of ϕ; thus

$$f_1(\phi, z)=0; \quad f_2(\phi, z)=E_0. \tag{24}$$

The integrals over β in Eqs. (17) vanish except for $n=0$. Consequently, the only non-zero coefficient is

$$a_0=\frac{2E_0w(\sin hw/hw)}{2\pi(k^2-h^2)H_0^{(2)}(\Lambda a)}. \tag{25}$$

Defining the voltage across the slot to be $V=2E_0w$, we get for the general expression for the z component of the field in space

$$E_z(\rho, \phi, z)=\frac{V}{2\pi}\int_{-\infty}^{\infty}\frac{H_0^{(2)}[(k^2-h^2)^{\frac{1}{2}}\rho]}{H_0^{(2)}[(k^2-h^2)^{\frac{1}{2}}a]}\frac{\sin hw}{hw}e^{-jhz}dh. \tag{26}$$

If the slot is a δ-slot, that is, $w\to 0$ while V is constant, $\sin hw/hw$ reduces to unity. The far-zone field is also readily obtained by evaluating the $n=0$ term of Eq. (23a) for the given $f_2(\phi, z)$.

2. The Infinite Axial Slot[2,3]

Another case that has been dealt with in the literature is that of a narrow rectangular slot, parallel to the axis of the cylinder, over which the field has only an E_ϕ component. The width of the slot will be taken to be $2a\phi_0$. The assumed field distribution in the slot is

$$f_1(\phi, z)=E_0, \quad f_2(\phi, z)=0. \tag{27}$$

All the coefficients a_n are now equal to zero, while for b_n we get

$$b_n=\lim_{l\to\infty}\frac{E_0}{j4\pi^2\omega\mu(\partial H_n^{(2)}(\Lambda a)/\partial a)}\times\int_{-l}e^{jh\xi}d\xi\int_{-\phi_0}e^{jn\beta}d\beta. \tag{28}$$

Defining a voltage $V=2E_0a\phi_0$ and making use of the Fourier integral definition of the δ-function,

$$\delta(h-0)=\frac{1}{2\pi}\int_{-\infty}^{\infty}e^{jh\xi}d\xi \tag{29}$$

we obtain finally for the E_ϕ component of the field

$$E_\phi=\frac{V}{2\pi a}\sum_{n=-\infty}^{\infty}\frac{\sin n\phi_0}{n\phi_0}\frac{H_n'^{(2)}(k\rho)}{H_n'^{(2)}(ka)}e^{-jn\phi}. \tag{30}$$

If the slot is regarded as a δ-slot in the ϕ-direction, $\sin n\phi_0/n\phi_0\to 1$ for all n.

Further application of the theory will be presented in a forthcoming paper in which we discuss the transverse rectangular slot in detail and give experimental data in conjunction with the theoretical results.

The Reversal Theorem of Linearized Supersonic Airfoil Theory*

M. M. Munk
Naval Ordnance Laboratory, White Oak, Silver Spring, Maryland
(Received May 27, 1949)

It is demonstrated on simple dynamic principles that a supersonic airfoil under certain conditions exhibits the same drag and the same lift slope regardless of whether it flies forward or backward.

THE thin airfoil theory in the supersonic regime is ordinarily referred to as the linearized theory. The boundary condition is simplified exactly as in the case of the incompressible fluid. In addition, the partial differential equation is also simplified, and it reduces to the wave equation:

$$\frac{\partial^2 F}{\partial x^2}+\frac{\partial^2 F}{\partial y^2}-\frac{\partial^2 F}{\partial z^2}=0. \tag{1}$$

Herein, F denotes either the velocity potential, any one Cartesian velocity component, or the pressure. The variables x, y, and z denote Cartesian coordinates in spanwise, liftwise, and fore-aft-wise direction of an airfoil, respectively. The corresponding components of the increment velocity are u, v, and w. The increment velocity is small when compared with the velocity of advance W_0.

In the computations of this theory, the density ρ_0 occurs as if it were constant. Absence of divergence of velocity is not assumed, not even approximately, in conjunction with such constant density. The increment pressure Δp is

$$\Delta p=-\rho_0 w W_0. \tag{2}$$

The rate at which energy is left behind the airfoil advancing with the velocity W_0 in air otherwise at rest is equal to DW_0, the product of the drag and of the velocity of advance. We assume specifically that the drag as defined from this relation is consistent with what follows, especially with the absence of a finite chordwise, leading-edge force. Since Eq. (1) is linear, the superposition of any number of individual solutions will again be a solution.

The vortex theorems hold. All vortices within the air are parallel to the Z direction. No finite force acting on an infinitely thin leading edge in the chordwise direction is supposed to exist. The opposite would be inconsistent with finite bounds for the pressure or suction. The resultant airfoil force is, therefore, merely the sum total of the ordinary pressure effects. With a constant local angle of attack of a plane, infinitely thin airfoil, the resultant airforce is at right angles to the airfoil. The constant angle of attack is equal to the drag-lift ratio. Both the leading edge and the trailing edge are points or lines of separation or rejoining of the flow. It is assumed that this double-edge condition is not inconsistent with the existence of a solution of Eq. (1). The solution is not made unique by selecting the trailing edge as a rejoining line. Rather, the solution is made unique by stipulating that all free vortices be trailing behind the airfoil and that all pressure waves proceed in the rear of the airfoil. In other words, all perturbations are restricted to the region downstream of the leading edge of the airfoil. With a large sweepback angle such as occurs with arrow wings, there may not exist any solution of (1) if both the leading separation line and the trailing separations line are arbitrarily specified. This is the case of the "subsonic" leading edge, where the downstream Mach cones, having their apices at the trailing edge, intersect with or enclose the leading edge. In that case it is necessary that the leading separation line be compatible with the other geometric conditions including the position of the trailing separation line, that is the trailing edge and with Eq. (1).

There exists an infinity of solutions that do not comply with this last stipulation. All of these solutions are acceptable on physical grounds and occasionally represent what happens or what may happen.

Reversing all velocities or all increment velocities leads again to a solution of (1).

Equation (1) is the basic equation in acoustics. Therefore, it has been stated that acoustical problems are analogous to the airfoil problems now considered. That is an extreme understatement: the linearized airfoil problem is itself an acoustical problem. The solutions exhibit all ordinary features of acoustical phenomena, wave effects, focusing effects, and that pronounced absence of harmony and of the continuity of analytic functions peculiar to acoustics. The solutions are disharmonic and non-unitary—a patchwork of heterogeneous pressure distributions of contrasting character. The computation has to be adapted to this state of things. One region after another region has to be computed in piecemeal fashion. No individual solution obtained may be applied to a slightly modified airfoil or Mach number by the application of the intuitive faculty along without careful scrutiny.

Notwithstanding their erratic character, the solutions are subordinated to simple, broad, and universal principles, transcending the irregularity in detail. Consider for instance a plane strip of constant width b extending streamwise into infinity. Its lift is finite, not even depending on the Mach number, such that the angle of

* Sponsored by the Office of Naval Research.

attack is equal to

$$\alpha = \frac{2L}{\rho_0 W_0^2 b^2 \pi}. \tag{3}$$

The spanwise lift distribution approaches (summed up streamwise) the elliptic lift distribution. The lift density asymptotically approaches zero in downstream direction, but it approaches it in a kind of periodic fashion and by no means monotonically.

If the strip is cambered with straight parallel span lines, the angle of attack at the leading edge is zero, the streamwise curvature also approaches zero and the angle of attack approaches asymptotically the above value (3). Then the drag will assume the minimum induced drag of the incompressible fluid theory. This is a very academic point, indeed, for the large airfoil area required would lead to excessive and dominating surface friction drag forces. Still, this illuminates the conditions and exemplifies the simple relations transcending the erratic details.

Many individual solutions of (1) relating to airfoils of various planviews and of wind sections have been determined. Those working in this field observed that all solutions are consistent with a remarkable symmetry principle. [See Bibliography.] Any airfoil moved under otherwise equal conditions forward and backward yields equal drag in these linearized computations. Turning the airfoil by 180° about a spanwise direction changes in general the lift distribution and the drag distributions, and sometimes very radically too. But the computed sum total of the drag remain always the same. With a plane, infinitely thin airfoil the computed lift also remains the same, so that for any airfoil the computed lift slope remains the same.

We proceed now to present a general proof of this reversal theorem based on very simple grounds. Picture the airfoil in place and expose it to the undisturbed flow (A). An increment flow (a) in rear of the airfoil is then produced. Leave the airfoil in place, but expose it now to an undisturbed airflow (B) having equal but opposite velocity as (A). This time an increment flow (b) will be created downstream of the airfoil in relation to (B), but upstream of the airfoil in relation to (A). The two increment flows (a) and (b) are ordinarily quite different, but not wholly uncorrelated. Combine or superpose now the flows (A), (a), and (b). This combination flow is now associated with free vortices and with pressure waves upstream of the airfoil as well as with free vortices and with pressure waves downstream of the airfoil. Right at the airfoil surface, all liftwise increment velocities at right angles to the airfoil cancel out. The airfoil consistent with the superposition flow is, therefore, plane, infinitely thin, and has zero incidence. The airfoil still has a lift distribution, but it cannot have any drag. The rate of energy transport upstream of the airfoil is equal to that of the flow (B)–(b). The rate of energy transport downstream of the airfoil is that of the flow (A)–(a). Both are alike, because the drag of the combination airfoil is zero. Hence the drag of the reversed airfoil must be equal to the drag of the airfoil in its initial direction.

Since, furthermore, the angle of attack of the plane infinitely thin airfoil does not change by the reversal, and since this angle is equal to the drag-lift ratio, it follows that for such special airfoils having a drag the total lift in both cases must also be the same. Hence, the lift slope must remain unchanged by the reversal for any airfoil.

Two airfoils may, of course, be associated with equal drag and with equal lift slope without being the reversal of each other. If the airfoils are the reversal of each other, no further proof is needed for equal drag and lift slope. The airfoils are not truly reversals of each other if the leading edge of the profile remains the leading edge unless the profiles are symmetric fore and aft. A full bodily reversal of the airfoil is necessary to make the preceding proof applicable. It is, on the other hand, apparent that the proof does not call for a single airfoil. Any assembly or combination of several airfoils in multiplane or in tandem relations or both, is permitted without invalidating the preceding proof. The airfoils must then not be reversed individually, but in the whole formation.

The proof does not lead to any information about the center of pressure of the reversed airfoil to its lift, unless the airfoil has zero camber. The symmetric relation holds only for the lift slope of an airfoil with arbitrary camber.

The argument of paragraph 10 implies the requirement that both the leading edge and the trailing edge be defined and serve as the separation line and as the rejoining line of the flow, respectively. Otherwise, very large streamwise increment velocity components would be generated, in contradiction with the assumptions made leading to the adoption of the linearized flow. The streamwise increment velocity component would not then be small throughout when compared with the velocity of advance. Hence the cancellation of the liftwise increment-velocity components of (a) and (b) in paragraph 9 would not be assured. Also the basic laws of mechanics would not be approximated by a solution obtained from the linearized differential equation. It is also implicit that the existence of a solution is not inconsistent with one double-edge condition. The requirement regarding the leading edge and the trailing edge is inconsistent with the existence of a solution of Laplace's equation in the theory of airfoils moving through an incompressible fluid. The requirement may be inconsistent with the existence of a solution of Eq. (1). It is by no means always inconsistent. It is not if the leading and the trailing edge are both "supersonic" throughout, that is, if the edges form an angle with the direction of advance larger than the

Mach angle. It is also not inconsistent if the local mean angle of attack of the airfoil is zero at all points. Supersonic edges throughout are not a necessary condition for the existence of a solution. There is some indication that nonexistence of a solution may require that portions of the leading edge be downstream and in the Mach direction relative to portions of the trailing edge. It seems that it has not yet been determined rigorously or finally under what conditions the two edges may be prescribed to serve as separate line and rejoining line, respectively, without excluding a solution of Eq. (1), and under what conditions they may not.

The Impact of a Body on a Water Surface at an Arbitrary Angle

LEON TRILLING*

Hydrodynamics Laboratory, California Insitute of Technology, Pasadena, California

(Received August 18, 1949)

This paper presents an approximate method of determining the pressure distribution during impact on the surface of a body which strikes a horizontal water surface at an arbitrary angle.

The effect of the splash is neglected and the pressure on the free boundary is assumed proportional to the potential, as if the process were an impulse. The shape of the submerged portion of the striking body is approximated by a semi-ellipse (two dimensions), by a hemisphere, half an ellipsoid of revolution and half a general ellipsoid. Under those conditions, explicit results for the pressure distribution are found. As a special example, the impact pressures on a sphere striking at 45° angle are computed in detail.

AN estimate of the pressure forces on a body which strikes a water surface at an arbitrary angle is important in many problems, such as the design of seaplane hulls or naval ballistics.

The present work discusses the earliest stage of the water entry phenomenon which precedes the appearance of a cavity and displays the highest pressures. It is usually called the impact stage.

The problem of water impact has been discussed by numerous writers interested in the landing characteristics of seaplanes and the underwater trajectory of projectiles. Because of the difficulty of the problem, they were forced to various simplifying assumptions. Thus, von Karman[1] approximated the shape of the striking body by a growing flat plate in the plane of the water surface. H. Wagner[2,3] refined Karman's analysis by making some allowance for the water splash, and M. S. Plesset[4] by replacing the flat plate by an elliptic disk. To take into account the penetration of the body into the water, Schiffman and Spencer[5,6] approximated its shape by a spherical lens; P. Y. Chou[7] approximated it by a spherical bowl, whose potential was calculated by A. B. Basset.[8] Those latter investigations give accurate results in the case of normal impact, but they are too complicated to be generalized to impact at an arbitrary angle. Some simple two-dimensional problems were solved in all generality by L. I. Sedoff[9] who used the powerful methods of conformal transformation.

In the following pages, the problem is linearized and the classical methods of potential theory are applied to determine the pressure on two-dimensional bodies whose submerged portion may be approximated by a semi-ellipse, and on three-dimensional bodies which may be approximated by a hemisphere, half an ellipsoid of revolution, and half a general ellipsoid. Because of the linear nature of the simplified problem the effect of the vertical and horizontal components of impact velocity may be discussed separately and superimposed, so that one obtains results valid for any angle of impact.

1. STATEMENT OF THE PROBLEM

A three-dimensional half-space filled with incompressible fluid of density ρ at rest with a horizontal free

surface, is struck by a body S which travels at a velocity $\bar{V}$, at an angle α from the horizontal plane. The fluid in the vicinity of the impact is set into motion; a small amount rises above the horizontal plane and forms a splash; a larger quantity is disturbed below the free surface, which is no longer horizontal, to make room for the body. The force of gravity, the hydrostatic force, viscous drag forces, surface tension forces, and the hydrodynamic forces all act on the body. But if the velocity $\bar{V}$ is large, during the impact stage, the hydrodynamic forces alone are significant, and the other forces are neglected in all that follows.

The hydrodynamic force is equal to the rate of change of momentum of the fluid set into motion by the impact. Since the fluid is assumed to be non-viscous and the motion is started from rest, the flow is irrotational and the velocity field may be derived from a potential Φ. The force is therefore:

$$\bar{F}=\frac{\rho}{\bar{V}}\frac{d}{dt}\int_{S+S'+S''}\Phi\frac{\partial\Phi}{\partial n}dS. \tag{1.1}$$

The integration is carried out over the boundaries of the fluid.** The forces acting on the body are therefore computed by a quadrature if the flow potential is known. Since the impact occurs in a very short time interval, $\bar{V}$ is assumed constant.

The velocity potential Φ of an incompressible perfect fluid satisfies the Laplace equation:

$$\Delta\Phi=0 \tag{1.2}$$

and certain conditions along the boundary of the fluid. The disturbance due to the impact must disappear far from the point of impact. Thus, if r denotes the distance from the point of impact, one has

$$\lim_{r\to\infty}\nabla\Phi=\lim_{r\to\infty}(\partial\Phi/\partial t)=0 \tag{1.3}$$

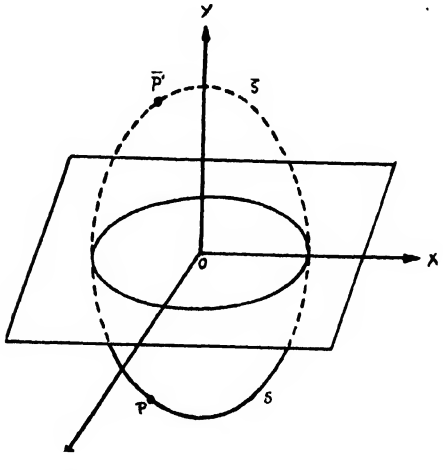

FIG. 1. General boundary conditions.

** S represents the surface of the submerged portion of the body, S' the free water surface, and S'' is a hemisphere of infinitely large radius with center at the body.

or the equivalent condition

$$\lim_{r\to\infty}\Phi=0. \tag{1.3a}$$

The velocity component normal to the surface of the impinging body must vanish:

$$\left(\frac{\partial\Phi}{\partial n}\right)_S=-V\cos\lambda, \tag{1.4}$$

where n is the direction normal to the wetted surface S, and λ is the angle between that normal and the direction of $\bar{V}$. Finally, along the free surface, the pressure in the fluid must equal atmospheric pressure, which may be taken equal to zero. This gives a condition on Φ, when Euler's equation is used:

$$(\partial\bar{u}/\partial t)+\bar{u}\cdot\nabla\bar{u}=(-1/\rho)\nabla p, \tag{1.5}$$

where $\bar{u}$ is the velocity vector in the fluid and p the pressure. An integration brings this equation into the form

$$-\partial\Phi/\partial t+\tfrac{1}{2}(\nabla\Phi)^2=-(p/\rho)+F(t). \tag{1.5a}$$

Boundary condition (1.3) applied on the free surface where p vanishes, gives $F(t)\equiv 0$, so that the boundary condition valid on the free surface is:

$$\tfrac{1}{2}(\nabla\Phi)^2-(\partial\Phi/\partial t)=0. \tag{1.5b}$$

One is thus led to investigate solutions of (1.2) subject to boundary conditions (1.3a, 1.4, 1.5b). Since (1.5b) is not linear, and the surface where it holds must be determined from the solution, this problem is extremely difficult; indeed, it has not been solved.

In linearizing boundary condition (1.5b), one argues that the impact occurs during a very short time interval, and may therefore be considered as an impulse. But it is known[10] that in the case of impulsive motion, the dynamic pressure is proportional to the velocity potential. Since the pressure vanishes on the free surface, one replaces condition (1.5b) by the more restrictive condition

$$\Phi(S')=0, \tag{1.5c}$$

where S' denotes the free surface. It is further assumed that the effect of the deformation of the free surface due to the splash is small, so that (1.5c) is applied along the original free surface:

$$\Phi(x,0,z,t)=0 \tag{1.5d}$$

in a cartesian system with origin at the center of impact, where the y axis is normal to the undisturbed free surface and the vector $\bar{V}$ lies in the plane $z=0$.

The problem of finding the potential Φ which satisfies Eq. (1.2) with boundary conditions (1.3a, 1.4, 1.5d) is a linear harmonic problem. It is convenient to investigate the potentials due to the various components

[10] H. Lamb, *Hydrodynamics* (Dover Publications, New York, 1944), sixth edition, London, (1932).

of $\bar{V}$ separately and to superimpose the results. Thus:

$$\Phi = V_x\varphi_1 + V_y\varphi_2 + V_z\varphi_3 + \Omega_{yz}\varphi_4 + \Omega_{zx}\varphi_5 + \Omega_{xy}\varphi_6 \quad (1.6)$$

where $V_{x,y,z}$ represent the x, y, z components of the velocity vector $\bar{V}$ and Ω_{ij} represent rotation velocities about the axes. In the problems to follow, V_z, Ω_{ij} vanish identically, so that

$$\Phi = V(\varphi_1 \cos\alpha + \varphi_2 \sin\alpha). \quad (1.6a)$$

If the symmetric image $\bar{S}$ of the wetted surface S with respect to the plane $y=0$ is constructed, (Fig. 1) and the field of flow is continued into the upper half-space, it follows from condition (1.5d) and the harmonic character of Φ that:

$$\Phi(x, y, z, t) = -\Phi(x, -y, z, t). \quad (1.5e)$$

The velocity components u, v, w, parallel to the x, y, z, axes, therefore have the following symmetry properties:

$$u(x, y, z) = -u(x, -y, z) \quad (1.7a)$$

$$v(x, y, z) = v(x, -y, z) \quad (1.7b)$$

$$w(x, y, z) = -w(x, -y, z) \quad (1.7c)$$

or, if the velocities normal to the surface $S+\bar{S}$ at two symmetric points $P, \bar{P}$ are compared,

$$(\partial\varphi/\partial n)_P = -(\partial\varphi/\partial n)_{\bar{P}}. \quad (1.7d)$$

If λ_1, λ_2 denote the angle between the normal to the surface $S+\bar{S}$ and the x, y axes, it follows from (1.7d) that boundary conditions (1.5, 1.4) become, for the potentials φ_1, φ_2

$$-\partial\varphi_1/\partial n = \cos\lambda_1 (|y|/y) \quad (1.8a)$$

$$-\partial\varphi_2/\partial n = \cos\lambda_2 \quad (1.8b)$$

these conditions being valid in the entire space.

The problem is thus split into two parts. The velocity component normal to the horizontal free surface induces the same potential as that of a fully submerged body in translation. The velocity component parallel to the horizontal free surface induces the potential which would obtain if the fluid above the plane of symmetry were flowing with a velocity equal and opposite that of the fluid below, causing a vortex sheet along the plane of symmetry.

One is now ready to express the momentum integral in terms of φ_1 and φ_2:

$$\frac{\rho}{V}\int_S \Phi \frac{\partial\Phi}{\partial n} dS' = \rho V \Big[\mathbf{i} \cos^2\alpha \int_S \varphi_1 \frac{\partial\varphi_1}{\partial n} dS + \sin\alpha\cos\alpha \Big(\mathbf{i}\int_S \varphi_2 \frac{\partial\varphi_1}{\partial n} dS + \mathbf{j}\int_S \varphi_1 \frac{\partial\varphi_2}{\partial n} dS \Big) + \mathbf{j}\sin^2\alpha \int_S \varphi_2 \frac{\partial\varphi_2}{\partial n} dS \Big] = \mathbf{i}M_x + (\mathbf{i}+\mathbf{j})M_{xy} + \mathbf{j}M_y, \quad (1.9)$$

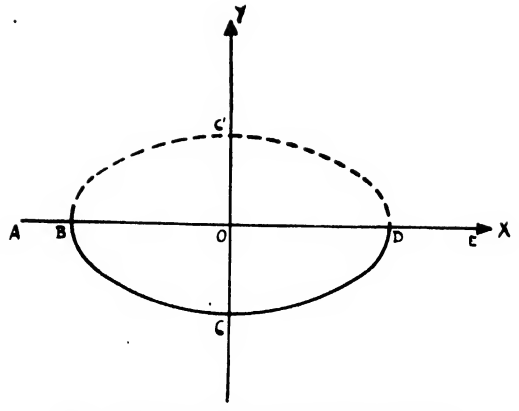

FIG. 2. Water impact of an elliptic cylinder.

where $\mathbf{i}$ and $\mathbf{j}$ are unit vectors parallel to the x, y axes. Note that φ_2 is positive over the entire surface S. On the other hand, φ_1 may be negative over part of the rear-half of the surface. If S is symmetric with respect to the plane $x=0$, φ_1 is antisymmetric and negative over the entire rear-half. But the dynamic pressure $p=\rho\Phi$ cannot become negative, since this would imply that the fluid is in tension and therefore separates from the body surface to form a cavity. Actually, because of the action of viscous forces and surface tension forces, separation is not instantaneous, and during the short period of time in which the impact occurs, the streamline pattern is not changed appreciably. But the integration in (1.9) must be carried out only over regions where $\varphi = \varphi_1\cos\alpha + \varphi_2\sin\alpha$ is positive.

The simplified problem formulated above does not depend on the time parameter directly since the equation of motion (1.2) and its boundary condition (1.3, 1.8) do not involve time variations. But as time passes, an increasing volume of the striking body is immersed in the fluid. Passage of time is, therefore, marked by a change in the dimensions and shape of the immersed body. Translation of the body in a horizontal direction does not change the shape of the immersed body and induces no force, but translation perpendicular to the free surface does.

In order to compute the time rate of change of momentum, therefore, it is necessary to determine how the immersed portion of the body changes with time. Most bodies whose impact may be of interest (projectiles, seaplane floats, etc.) have immersed portions of shapes so complicated that an analytic determination of φ_1, φ_2 is not possible. Following the scheme of previous calculations, one is led to approximate the immersed portion of the striking body at any time by some geometrically simple body (hemisphere, half-ellipsoid, etc.). The simple shape is defined by a certain number of parameters: the sphere by its radius, the ellipsoid of revolution by two axes, the general ellipsoid by three axes, etc. The approximating process consists in selecting certain properties of the actual body and defining the parameters of the approximating body so

that those properties are preserved. One can generally preserve as many properties as there are independent parameters defining the approximating body. For instance, if at any time t, the immersed portion of the striking body is approximated by a half-ellipsoid, the three axes of the ellipsoid are chosen so that the depth of penetration, the length and the immersed volume of the half-ellipsoid equal those of the actual body. As time passes, the depth of penetration, length and immersed volume of the actual body change, and the three axes of the approximating half-ellipsoid change correspondingly. The three axes of the ellipsoid are, therefore, known functions of time, when the motion of the actual body is known, either from measurements or from calculations. The momentum integral M (1.9a) of the approximating body depends only on its geometrical parameters $\alpha_1, \alpha_2, \alpha_3 \cdots \alpha_i$, which are known functions of time, since V and ρ are constant. The drag force is therefore given by:

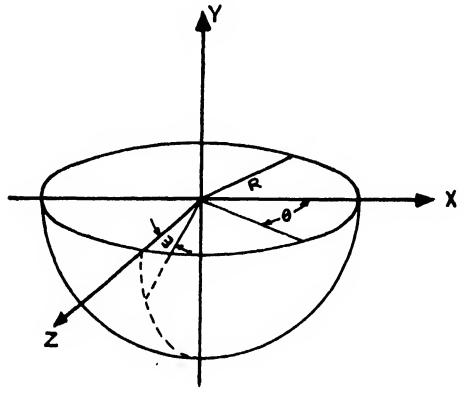

FIG. 3. Water impact of a sphere.

$$F_x=\rho V\cos\alpha\sum(d\alpha_i/dt)\times[(\partial M_x/\partial\alpha_i)\cos\alpha+(\partial M_{xy}/\partial\alpha_i)\sin\alpha] \quad (1.10a)$$

$$F_y=\rho V\sin\alpha\sum(d\alpha_i/dt)\times[(\partial M_{xy}/\partial\alpha_i)\cos\alpha+(\partial M_y/\partial\alpha_i)\sin\alpha]. \quad (1.10b)$$

The problem of finding approximately the forces acting on a given body when it strikes a horizontal surface is, therefore, investigated as follows:

An approximating body is selected and its parameters α_i are computed as functions of time from the known behavior of the actual body.

The potential problem for the approximating body is solved and the momentum integral is computed in terms of α_i.

The force function is found by application of Eqs. (1.10).

The second step of this procedure is the most important and difficult. It can be carried out once and for all for several approximating body shapes. Then the results can be applied to a wide variety of problems by the proper fitting procedure.

In the following, the potential problem is solved for an infinitely wide semi-elliptic cylinder (two-dimensional problem solved by Sedoff's methods) and for a sphere, an ellipsoid of revolution and a general ellipsoid (solved by harmonic analysis methods). As an example of the fitting process, the water entry forces on a sphere striking at 45° are computed by using a general ellipsoid as the approximating body.

2. INFINITE SEMI-ELLIPTIC CYLINDER

The first potential problem discussed in detail concerns an infinitely wide semi-elliptic cylinder of major axis $2a$ and minor axis $2b$, the free surface $y=0$ coinciding with the major axis (Fig. 2). The boundary conditions to be satisfied by the potentials φ_1, φ_2 in the entire x, y plane are obtained from (1.8). If a stream function ψ is introduced, then, on the body surface,

$$\partial\varphi/\partial n=\partial\psi/\partial s=\cos\alpha(\partial y/\partial s)(|y|/y)-\sin\alpha(\partial x/\partial s), \quad (2.1)$$

where ds is a length element along the surface of the ellipse. This is integrated to give:

$$\psi=|y|\cos\alpha-x\sin\alpha. \quad (2.1a)$$

One is now required to find an analytic complex potential function $F(z)=F(x+iy)$ whose imaginary part satisfies (2.1a) on the boundary of the ellipse.

The conformal transformation

$$-2z=(a-b)\zeta+(a+b)1/\zeta \quad (2.2)$$

transforms the ellipse in the z plane into the unit circle in the ζ-plane. Therefore, in the ζ-plane the complex potential $F(\zeta)$ must satisfy the conditions below on the unit circle $\zeta=e^{i\theta}$:

$$\psi=b|\sin\theta|\cos\alpha+a\cos\theta\sin\alpha=\frac{2b\cos\alpha}{\pi}\left[1-2\sum_1^\infty\frac{\cos 2n\theta}{4n^2-1}\right]+a\sin\alpha\cos\theta. \quad (2.3)$$

It follows that:

$$F(\zeta)=\frac{2bi\cos\alpha}{\pi}\left[1+2\sum_1^\infty\frac{\zeta^{2n}}{4n^2-1}\right]+ai\sin\alpha\zeta. \quad (2.4)$$

To sum the power series inside and on the unit circle, note that

$$2\sum_1^\infty\frac{\zeta^{2n}}{4n^2-1}=\zeta\sum_1^\infty\frac{\zeta^{2n-1}}{2n-1}-\frac{1}{\zeta}\sum_1^\infty\frac{\zeta^{2n+1}}{2n+1} \quad (2.5a)$$

and since

$$\sum_1^\infty\zeta^{2n}=\zeta^2/1-\zeta^2 \quad (2.5b)$$

one has

$$\sum_1^\infty\frac{\zeta^{2n-1}}{2n-1}=\int_0^\zeta\frac{d\zeta}{1-\zeta^2}=\tfrac{1}{2}\log\frac{1+\zeta}{1-\zeta} \quad (2.5c)$$

$$\sum_1^\infty\frac{\zeta^{2n+1}}{2n+1}=\int_0^\zeta\frac{\zeta^2d\zeta}{1-\zeta^2}=-\zeta+\tfrac{1}{2}\log\frac{1+\zeta}{1-\zeta} \quad (2.5d)$$

so that

$$F(\zeta)=\frac{ib\cos\alpha}{\pi}\left(\frac{1}{\zeta}-\zeta\right)\log\frac{1+\zeta}{1-\zeta}+ia\zeta\sin\alpha. \quad (2.6)$$

All the manipulations carried out above are valid in the annulus $0<|\zeta|<1$ because all series and integrals converge uniformly there. It is easily verified that $F(\zeta)$ is an analytic function regular everywhere in and on the unit circle. Separating real and imaginary parts, on the circle, one finds

$$\psi=b\cos\alpha|\sin\theta|+a\cos\theta\sin\alpha \quad (2.7a)$$

$$\varphi=-\sin\theta[(2b/\pi)\cos\alpha\log|\tan(\theta/2)|+a\sin\alpha]. \quad (2.7b)$$

The boundary condition (2.3) is therefore satisfied and the pressure distribution is given by (2.7b). The separation point occurs at θ_s defined by

$$(2b/\pi)\cos\alpha\log|\tan(\theta_s/2)|+a\sin\alpha=0 \quad (2.8a)$$

or

$$\theta_s=2\tan^{-1}\exp[-(a\pi/2b)\tan\alpha]. \quad (2.8b)$$

In most cases $a\gg b$ and $\tan\alpha=0(1)$; then θ_s is small: $\theta_s=0(10^{-3})$ and the separation phenomenon may be neglected. Under those circumstances, the momentum integrals are:

$$M_x=2b^2/\pi \quad (2.9a)$$

$$M_{xy}=M_{yz}=0 \quad (2.9b)$$

$$M_y=\pi a^2/2. \quad (2.9c)$$

3. THE SPHERE

Consider a sphere of radius R half-submerged in a fluid (Fig. 3). The potential $\varphi=\varphi_1\cos\alpha+\varphi_2\sin\alpha$ must satisfy the equation

$$\Delta\varphi_1=\Delta\varphi_2=0 \quad (3.1)$$

with the boundary conditions:

$$\lim_{r\to\infty}\varphi_1=\lim_{r\to\infty}\varphi_2=0 \quad (3.2)$$

$$(\partial\varphi_2/\partial r)(R,\theta,\omega)=-\cos\omega \quad (3.3a)$$

$$(\partial\varphi_1/\partial r)(R,\theta,\omega)=-(|\cos\omega|/\cos\omega)\cos\theta. \quad (3.3b)$$

The potential φ_2 is immediately found:

$$\varphi_2=(R^3/2r^2)\cos\omega. \quad (3.4)$$

The potential φ_1 is determined by fitting the general harmonic function convergent for large r

$$\varphi_2=\sum_0^\infty\sum_0^{n+1}\frac{1}{r^{n+1}}P_n^s(\cos\omega)[a_n^s\cos s\theta+b_n^s\sin s\theta] \quad (3.5)$$

to satisfy boundary condition (3.3b). It is clear by inspection that $b_n^s=0$ and $a_n^{s>1}=0$, while the non-vanishing coefficients a_n^1 must satisfy the relation:

$$\sum_0^\infty\frac{n+1}{R^{n+2}}a_n^1P_n^1(\cos\omega)=\sum_0^\infty\alpha_nP_n^1$$

$$=-1 \quad [0<|\omega|<(\pi/2)]$$

$$=1 \quad [(\pi/2)<|\omega|<\pi]. \quad (3.6)$$

If Eq. (3.6) is multiplied by $P_k^1(\cos\omega)\sin\omega$ and integrated from 0 to π, all terms in the series except the k

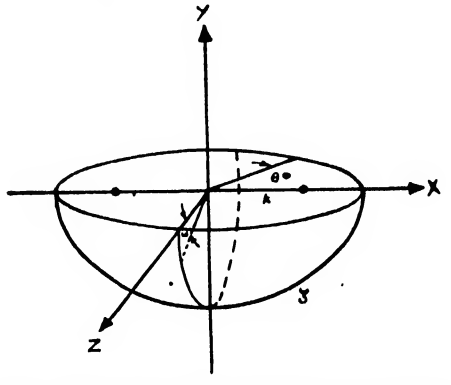

FIG. 4. Water impact of an ellipsoid of revolution.

term vanish because of the orthogonality of Legendre polynomials. One, therefore, obtains:

$$\alpha_k=\frac{2k+1}{2k(k+1)}\left[\int_0^{\pi/2}P_k^1(\cos\omega)\sin\omega d\omega-\int_{A/2}^{\pi}P_k^1(\cos\omega)\sin\omega d\omega\right]. \quad (3.7a)$$

Since $P_k^1(\cos\omega)=\sin\omega[dP_k(\cos\omega)/d(\cos\omega)]$, this is rewritten, with due regard to symmetry properties:

$$\alpha_{2k}=\frac{4k+1}{2k(2k+1)}\int_0^{\pi/2}\sin^2\omega P_{2k}'(\cos\omega)d\omega. \quad (3.7b)$$

$$\alpha_{2k+1}=0$$

By use of Rodrigues's Formula[11] the Legendre polynomial $P_{2k}(z)$ can be written as:

$$P_{2k}(z)=\frac{1}{2^kk!}\sum_{r=0}^{k}\binom{k-r}{r}\frac{(2k+2r-1)!!}{(2r-1)!!}(-)^{k-r}z^{2r}. \quad (3.8a)$$

It is also known[12] that

$$\int_0^{\pi/2}\sin^2\omega\cos^{2r-1}\omega d\omega=\frac{(2r-2)!!}{(2r+1)!!}. \quad (3.8b)$$

[11] Whittaker and Watson, *Modern Analysis* (Cambridge University Press, London, 1940), fourth edition.

[12] H. B. Dwight, *Tables of Integrals and Other Mathematical Data* (MacMillan Company, Ltd., London, 1934).

Combining formulas (3.8a) and (3.8b), one obtains:

$$\alpha_{2k}=\frac{4k+1}{2^k k!(2k+1)}\sum_{r=1}^{k}(-)^{k-r+1}\times\binom{k-r}{k}\frac{r(2r-2)!!(2k+2r-1)!!}{(2r-1)!!(2r+1)!!}. \quad (3.9)$$

Thus, for instance:

$$\begin{aligned}&\alpha_2=5/6=0.833 && \alpha_8=-0.041\\ &\alpha_4=-(3/40)=-0.075 && \alpha_{10}=0.0658.\\ &\alpha_6=0.147 && \alpha_{12}=-0.0094\cdots\end{aligned} \quad (3.9a)$$

The convergence of the series (3.6) is established by noting that the integral in (3.7b) can be determined asymptotically as $k\to\infty$ as follows:

$$\begin{aligned}\lim_{k\to\infty}\int_0^{\pi/2} P_{2k}'(\cos\omega)\sin^2\omega d\omega &= \int_0^{\pi/2}\sin^2\omega\lim_{k\to\infty}P_{2k}'(\cos\omega)d\omega\\ &= \int_0^{\pi/2}\sin^2\omega(k/\pi)^{\frac{1}{2}}\sin 2k\omega d\omega\\ &= \tfrac{1}{4}(k/\pi)^{\frac{1}{2}}\int_0^{\pi}(1-\cos\theta)\sin k\theta d\theta\sim 1/(k)^{\frac{1}{2}}. \end{aligned} \quad (3.10)$$

The general coefficient α_k therefore behaves as $k^{-\frac{1}{2}}$. Since[13]

$$\lim_{k\to\infty}P_{2k}^{1}(\cos\theta) = -2(k/\pi\sin\theta)^{\frac{1}{2}}\sin[(2k+\tfrac{1}{2})\theta+3\pi/4] \quad (3.10')$$

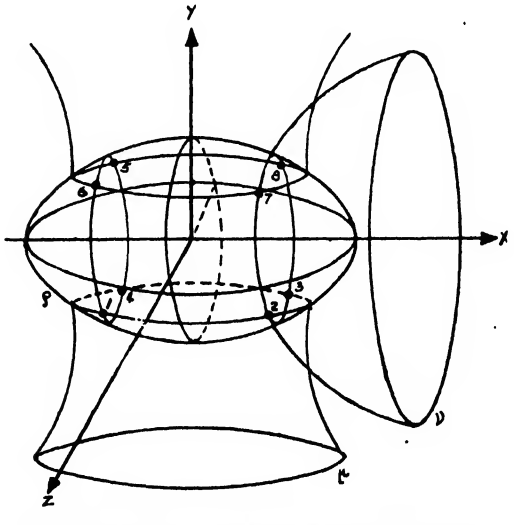

Fig. 5. Coordinate system for a general ellipsoid.

[13] E. W. Hobson, *The Theory of Spherical and Ellipsoidal Harmonics* (Cambridge University Press, London, 1931), Chapter 11.

the series (3.6) behaves as $\sum(e^{ik\theta}/k)$ which is known to converge.

The potential of the horizontal flow past a sphere of radius R is, therefore,

$$\varphi_1=R\cos\theta\sum_1^{\infty}(R/r)^{n+1}(\alpha_n/n+1)P_n^1(\cos\omega). \quad (3.11)$$

The separation point is reached along the curve $\theta(\omega)$ where the following relation holds:

$$\theta=\sec^{-1}[-2\cot\alpha\sec\omega\sum_1^{\infty}(\alpha_n/n+1)P_n^1(\cos\omega)]. \quad (3.12)$$

If separation effects are neglected, one finds the following momentum integrals:

$$M_x=(\pi/2)\rho R^3\sum_0^{\infty}(\alpha_n)^2 \quad (3.13a)$$

$$M_{xy}=M_{yx}=0 \quad (3.13b)$$

$$M_y=(\pi/3)\rho R^3. \quad (3.13c)$$

4. HALF AN ELLIPSOID OF REVOLUTION

A slight generalization is obtained if the hemisphere considered above is replaced by an ellipsoid of revolution whose axis is parallel to the horizontal velocity component (Fig. 4). The potential problem is most simply discussed in terms of elliptic coordinates. If x, y, z, are cartesian coordinates as before, and the distance between the foci of the ellipsoid is $2k$, the new coordinates μ, ζ, ω are defined by

$$x=k\mu\zeta \quad (4.1a)$$

$$y=k[(1-\mu^2)(\zeta^2-1)]^{\frac{1}{2}}\sin\omega \quad (4.1b)$$

$$z=k[(1-\mu^2)(\zeta^2-1)]^{\frac{1}{2}}\cos\omega. \quad (4.1c)$$

The ellipsoid under study is defined by a value ζ_0 of the parameter ζ, and solutions are sought in the domain $\zeta>\zeta_0$ which corresponds to the space outside the ellipsoid.

The boundary conditions corresponding to (1.8a, b) are here:

$$\left(\frac{\partial\varphi_1}{\partial\zeta}\right)_{\zeta_0}=-k\mu\frac{|\cos\omega|}{\cos\omega} \quad (4.2a)$$

$$\left(\frac{\partial\varphi_2}{\partial\zeta}\right)_{\zeta_0}=-k\zeta_0\left(\frac{1-\mu^2}{\zeta_0^2-1}\right)^{\frac{1}{2}}\sin\omega. \quad (4.2b)$$

The potential φ_2 is known to be[11]

$$\varphi_2=\frac{k}{\tfrac{1}{2}\log(\zeta_0+1/\zeta_0-1)-[\zeta_0^2-2/\zeta_0(\zeta_0^2-1)]}\times\left\{\tfrac{1}{2}\log\frac{\zeta+1}{\zeta-1}-\frac{\zeta}{\zeta^2-1}\right\}[(1-\mu^2)(\zeta^2-1)]^{\frac{1}{2}}\cos\omega. \quad (4.3)$$

The general potential convergent for $\zeta > \zeta_0$ is

$$\varphi_1 = \sum_0^\infty \sum_1^{n+1} Q_n^s(\zeta) P_n^s(\mu)[a_n^s \sin s\omega + b_n^s \cos s\omega] \quad (4.4)$$

so that boundary condition (4.2a) gives:

$$\sum_0^\infty \sum_1^{n+1} Q_n'^s(\zeta_0) P_n^s(\mu) a_n^s \sin s\omega$$

$$= \sum_0^\infty \sum_1^{n+1} \alpha_n^s P_n^s(\mu) \sin s\omega = -\mu(-\pi < \omega < 0) \quad (4.5a)$$

$$= \mu(0 < \omega < \pi)$$

from which the coefficients α_n^s are determined. Multiplication of (4.5a) by $\sin(r\omega)$ and integration between $-\pi$ and π leads to:

$$\sum_0^\infty \alpha_n^{2r-1} P_n^{2r-1}(\mu) = -\frac{4}{\pi} \frac{(-)^r \mu}{2r+1} \quad (4.5b)$$

$$\alpha_n^{2r} = 0.$$

Multiplication of (4.5b) by $P_k^{2r+1}(\mu)$ and integration between -1 and 1 leads to:

$$\alpha_{2k}^{2r-1} = \frac{(-)^r 8(4k+1)(2k-2r-1)!}{\pi(2r+1)(2k+2r+1)!} \times \int_0^1 \mu P_{2k}^{2r+1}(\mu) d\mu \quad (4.5c)$$

$$\alpha_{2k+1}^{2r+1} = 0.$$

After two integrations by parts, the integral in (4.5c) becomes:

$$\int_0^1 \mu P_{2k}^{2r+1}(\mu) d\mu = \int_0^1 \mu(1-\mu^2)^{\frac{1}{2}} \frac{d}{d\mu} P_{2k}^{2r}(\mu) d\mu$$

$$= \int_0^1 \frac{2\mu^2 - 1}{(1-\mu^2)^{\frac{1}{2}}} P_{2k}^{2r}(\mu) d\mu$$

$$= \int_0^1 (2k^2 - 1) \frac{d}{d\mu} P_{2k}^{2r-1}(\mu) d\mu$$

$$= -4 \int_0^1 \mu P_{2k}^{2r-1}(\mu) d\mu \quad (4.6a)$$

since

$$P_{2k}^{2r+1}(0) = P_{2k}^{2r+1}(1) = 0.$$

The recursion formula (4.6a) gives at once:

$$\int_0^1 \mu P_{2k}^{2r+1}(\mu) d\mu = (-4)^r \int_0^1 \mu P_{2k}^1(\mu) d\mu$$

$$= (-4)^r \int_0^{\pi/2} \sin^2\theta P_{2k}'(\cos\theta) d\theta, \quad (4.6b)$$

By using the representation (3.8a) for $P_{2k}(z)$ and the relation:

$$\int_0^{\pi/2} \sin^2\theta \cos^{2p}\theta d\theta = \frac{\pi}{2} \frac{(2p-1)!!}{(2p+2)!!} \quad (4.6c)$$

one finds the coefficient α_{2k}^{2r+1}

$$\alpha_{2k}^{2r+1} = \frac{4^{r+1}}{2^{k-1}k!} \frac{4k+1}{2r+1} \frac{(2k-2r-1)!}{(2k+2r+1)!} \times \sum_{p=1}^k (-)^{k-p+1} \binom{k-p}{p} \frac{p(2k+2p-1)!!}{(2p+2)!!} \quad (4.7)$$

Thus for instance:

$$\begin{array}{lll} \alpha_2^1 = 1.250 & & \\ \alpha_4^1 = 0.281 & & \\ \alpha_6^1 = 0.127 & \alpha_4^3 = 0.00161 & \alpha_6^5 = 0.00001. \\ \alpha_8^1 = 0.0726 & \alpha_6^3 = 0.00002 & \\ \alpha_{10}^1 = 0.0471 & & \\ \alpha_{12}^1 = 0.0328 & & \end{array} \quad (4.7a)$$

The uniform convergence of the doubly infinite series (4.5a) is established by the Weierstrass M test if $\sum\sum \alpha_k^r$ converges: The integral in (4.5c) converges:

$$\lim_{k \to \infty} \left| \int_0^1 \mu P_{2k}^1 d\mu \right| < \frac{A}{(k)^{\frac{1}{2}}} \quad (4.8a)$$

as can be shown by an argument similar to that of (3.10). For any value of r, therefore, the series

$$\sum_{k=0}^\infty \alpha_k^r = S'(r)$$

converges absolutely. For any given value of k,

$$\lim_{r \to \infty} \sum_0^k \alpha_k^r < A(k) \sum \frac{4^r}{(2r+1)(4r)!} \quad (4.8b)$$

so that the sum of rows as well as the sum of columns converges absolutely. Then, one has

$$|\sum\sum \alpha_k^r| < \sum\sum (1/(k+r)!) \quad (4.8c)$$

which establishes the convergence of the series. The potential φ_1 for the horizontal flow past the half-ellipsoid of revolution is, therefore:

$$\varphi_1 = \sum_{n=1}^\infty \sum_{s=0}^{n-1} \frac{Q_{2n}^{2s+1}(\zeta)}{Q_{2n}'^{2s+1}(\zeta_0)} \times \alpha_{2n}^{2s+1} P_{2n}^{2s+1}(\mu) \sin(2s+1)\omega. \quad (4.9)$$

The momentum integrals are:

$$M_x = -\frac{\pi}{4} k^3(\zeta_0^2 - 1) \sum_{n=1}^\infty \sum_{s=1}^{n-1} \frac{Q_{2n}^{2s+1}(\zeta_0)}{Q_{2n}'^{2s+1}(\zeta_0)} \times \frac{(2n+2s+1)!}{(2n-2s-1)!} \frac{(\alpha_{2n}^{2s+1})^2}{4n+1} \quad (4.10a)$$

$$M_{xy}=M_{yz}=0 \tag{4.10b}$$

$$M_y=\frac{\pi k^3}{2}\zeta_0(\zeta_0^2-1)$$

$$\times\frac{\log(\zeta_0+1/\zeta_0-1)-(2\zeta_0/\zeta_0^2-1)}{\log(\zeta_0+1/\zeta_0-1)-[2(\zeta_0^2-2)/\zeta_0(\zeta_0^2-1)]}. \tag{4.10c}$$

Note that the entire argument was carried through for a prolate ellipsoid ($\zeta>1$). If the ellipsoid is oblate ($\zeta<1$), ζ is replaced by $i\zeta$ and the function $q(\zeta)$ replaces $Q(\zeta)$, where

$$g_n^s(\zeta)=Q_n^s(i\zeta) \tag{4.11}$$

everything else remaining unchanged.

5. HALF A GENERAL ELLIPSOID

A further generalization is obtained by considering an ellipsoid with focal length $2k$ parallel to the horizontal velocity component, and focal length $2h$ horizontal and normal to it. The problem is now formulated in terms of ellipsoidal coordinates defined by E. W. Hobson:[13]

$$x=\rho\mu\nu/hk \tag{5.1a}$$

$$y=\frac{[(\rho^2-h^2)(\mu^2-h^2)(h^2-\nu^2)]^{\frac{1}{2}}}{h(k^2-h^2)^{\frac{1}{2}}} \tag{5.1b}$$

$$z=\frac{[(\rho^2-k^2)(k^2-\mu^2)(k^2-\nu^2)]^{\frac{1}{2}}}{k(k^2-h^2)^{\frac{1}{2}}}. \tag{5.1c}$$

The surfaces $\rho=$const. represent confocal ellipsoids; ρ_0 in particular represents the ellipsoid under investigation; $\mu=$const. are hyperboloids of one sheet and $\nu=$const. are hyperboloids of two sheets. The coordinate system is shown on Fig. 5. Any point is defined uniquely if the signs of the radicals in (5.1) are defined. Boundary conditions (1.8a, b) become in this system:

$$\left(\frac{\partial\varphi_1}{\partial\rho}\right)_{\rho_0}=-\frac{\mu\nu}{hk}\frac{|y|}{y} \tag{5.2a}$$

$$\left(\frac{\partial\varphi_2}{\partial\rho}\right)_{\rho_0}=-\frac{\rho_0}{h}\left\{\frac{[(\mu^2-h^2)(h^2-\nu^2)]}{[(\rho_0^2-h^2)(k^2-h^2)]}\right\}^{\frac{1}{2}}. \tag{5.2b}$$

The potential φ_2 is given explicitly in the standard literature[11] by the formula:

$$\varphi_2=\frac{\rho_0}{2h}\left[\frac{(\rho_0^2-h^2)(\rho_0^2-k^2)}{k^2-h^2}\right]^{\frac{1}{2}}$$

$$\times\frac{1}{1-\rho_0[(\rho_0^2-h^2)(\rho_0^2-k^2)]^{\frac{1}{2}}\int_{\rho_0}^{\infty}\frac{d\rho}{(\rho^2-h^2)^{\frac{1}{2}}(\rho^2-k^2)^{\frac{1}{2}}}}$$

$$\times[(\rho^2-h^2)(\mu^2-h^2)(h^2-\nu^2)]^{\frac{1}{2}}$$

$$\times\int_{\rho}^{\infty}\frac{d\rho}{(\rho^2-h^2)^{\frac{1}{2}}(\rho^2-k^2)^{\frac{1}{2}}}. \tag{5.3}$$

The general potential convergent for $\rho>\rho_0$ is

$$\varphi_1=\sum_0^\infty\sum_1^{2n+1}a_n^sF_n^s(\rho)E_n^s(\mu)E_n^s(\nu), \tag{5.4a}$$

where F_n^s, E_n^s are general Lamé functions, convergent as $\rho\to\infty$ and μ, $\nu\to0$, and satisfying Lamé's differential equation:

$$(\lambda^2-h^2)(\lambda^2-k^2)(d^2E_n/d\lambda^2)$$
$$+\lambda(2\lambda^2-h^2-k^2)(dE_n/d\lambda)$$
$$+[(h^2+k^2)p-n(n+1)\lambda^2]E_n=0 \tag{5.4b}$$
$$\lambda=\rho,\ \mu,\ \nu$$

the parameter n is an integer, while $p(h, k, n)$ is chosen so that E_n^s is a polynomial. The theory of Lamé functions is discussed in detail in.[13]

Boundary condition (5.2a) gives here:

$$hk\sum_0^\infty\sum_1^{2n+1}F_n'^s(\rho_0)a_n^sE_n^s(\mu)E_n^s(\nu)$$

$$=\sum_0^\infty\sum_1^{2n+1}\alpha_n^sE_n^s(\mu)E_n^s(\nu)=\mu\nu[(\mu^2-h^2)^{\frac{1}{2}}>0]$$

$$=-\mu\nu[(\mu^2-h^2)^{\frac{1}{2}}<0]. \tag{5.5}$$

From the form of the function to be expanded, it is clear that only odd Lamé functions K_{2n+1}^s of the form

$$K_{2n+1}^s(\lambda)=\beta_1^s\lambda+\beta_3^s\lambda^3+\cdots\beta_{2n+1}^s\lambda^{2n+1} \tag{5.6a}$$

will appear in φ_1. The coefficients β_n^s are defined by recurrence formulas and depend on (h, k, p). They have been tabulated by Guerritore.[14] It is then known[15] that the coefficients α_n^s are given by:

$$\alpha_{2n+1}^s=\frac{\int_0^h\int_h^k(\mu^2-\nu^2)\mu\nu K_{2n+1}^s(\mu)K_{2n+1}^s(\nu)\frac{d\mu}{[(h^2-\mu^2)(\mu^2-k^2)]^{\frac{1}{2}}}\frac{d\nu}{[(h^2-\nu^2)(k^2-\nu^2)]^{\frac{1}{2}}}}{\int_0^h\int_h^k(\mu^2-\nu^2)[K_{2n+1}^s(\mu)K_{2n+1}^s(\nu)]^2\frac{d\mu}{[(h^2-\mu^2)(\mu^2-k^2)]^{\frac{1}{2}}}\frac{d\nu}{[(h^2-\nu^2)(k^2-\nu^2)]^{\frac{1}{2}}}}. \tag{5.7}$$

[14] M. Guerritore, Table of Lamé functions, Giornale de Matematica (2) XVI, 164–172 (1909).

[15] O. Volk, "Uber die entwicklung von functionen zweier complexen veranderlichen nach lameschen functionen," Math. Zeitsch 23, 224 (1925).

If the expansion (5.6) for $K_{2n+1}{}^{s}(\lambda)$ is substituted into the integrals (5.7), it is found that one must investigate integrals of the form:

$$A_{2r}(\lambda)=\int_0^h \frac{\lambda^{2r}d\lambda}{[(h^2-\lambda^2)(k^2-\lambda^2)]^{\frac{1}{2}}} \tag{5.8a}$$

$$B_{2r}(\lambda)=\int_h^k \frac{\lambda^{2r}d\lambda}{[(\lambda^2-h^2)(k^2-\lambda^2)]^{\frac{1}{2}}}. \tag{5.8b}$$

It is easily verified that:

$$A_0=(1/k)F(h/k) \qquad B_0=(1/k)F\left[\frac{(k^2-h^2)^{\frac{1}{2}}}{k}\right] \tag{5.9a,b}$$

$$A_2=k(F(h/k)-E(h/k)) \quad B_2=kE\left[\frac{(k^2-h^2)^{\frac{1}{2}}}{k}\right]. \tag{5.9c,d}$$

Repeated integrations by parts then lead to the recurrence formulas:

$$(2n-1)A_{2n}=(2n-4)(h^2+k^2)A_{2n-2} -(2n-3)h^2k^2A_{2n+4} \tag{5.10}$$

and an identical result for B_{2n}. The integrals A_{2n}, B_{2n} are, therefore, expressed as functions of the parameters h, k in terms of elliptic integrals.

The numerator and denominator of (5.7) are now simply expressed in terms of the known coefficients $\beta_n{}^{s}$ and the integrals A_{2n}, B_{2n}.

$$N_{2n+1}{}^{s}=(\beta_1{}^{s})^2(B_4A_2-B_2A_4) +\beta_1{}^{s}\beta_3{}^{s}(B_6A_2-A_6B_2) +(\beta_3{}^{s})^2(B_6A_4-B_4A_6)\cdots \tag{5.11a}$$

$$D_{2n+1}{}^{s}=(\beta_1{}^{s})^4(B_4A_2-B_2A_4) +2\beta_3{}^{s}(\beta_1{}^{s})^3(B_6A_2-A_6B_2)\cdots \tag{5.11b}$$

$$\alpha_{2n+1}{}^{s}=N_{2n+1}{}^{s}/D_{2n+1}{}^{s}. \tag{5.11c}$$

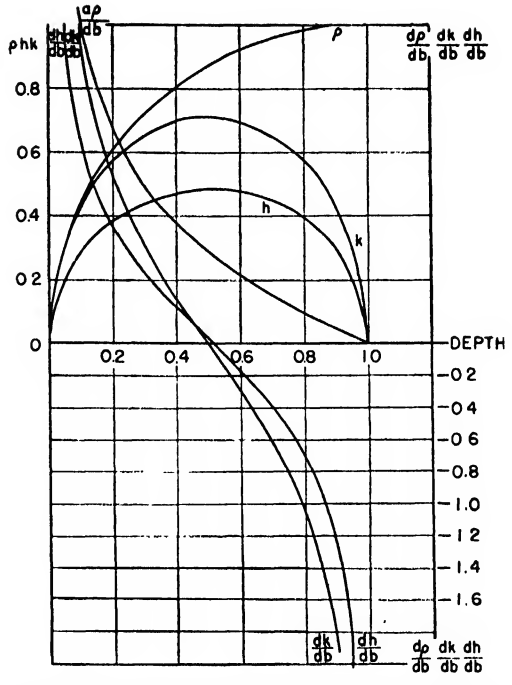

FIG. 6. The approximating functions for a partially submerged sphere and their derivatives.

The potential function φ_1 is then given by:

$$\varphi_1=\frac{1}{hk}\sum_0^{\infty}\sum_1^{n+1/2}\frac{F_{2n+1}{}^{s}(\rho)}{F_{2n+1}{}'^{s}(\rho_0)} \times\alpha_{2n+1}{}^{s}K_{2n+1}{}^{s}(\mu)K_{2n+1}{}^{s}(\nu). \tag{5.12}$$

The momentum integrals are:

$$M_x=\frac{[(\rho_0^2-h^2)(\rho_0^2-k^2)]^{\frac{1}{2}}}{h^2k^2}\sum_0^{\infty}\sum_1^{n+1/2}\frac{F_{2n+1}{}^{s}(\rho_0)}{F_{2n+1}{}'^{s}(\rho_0)}(\alpha_{2n+1}{}^{s})^2D_{2n+1}{}^{s} \tag{5.13a}$$

$$M_{xy}=M_{yz}=0 \tag{5.13b}$$

$$M_y=(\pi\rho_0/12)[(\rho_0^2-h^2)(\rho_0^2-k^2)]^{\frac{1}{2}}\frac{\rho_0[(\rho_0^2-h^2)(\rho_0^2-k^2)]^{\frac{1}{2}}\int_{\rho_0}^{\infty}\frac{d\rho}{\rho_0(\rho^2-h^2)^{\frac{1}{2}}(\rho^2-k^2)^{\frac{1}{2}}}}{1-\rho_0[(\rho_0^2-h^2)(\rho_0^2-k^2)]^{\frac{1}{2}}\int_{\rho_0}^{\infty}\frac{d\rho}{\rho_0(\rho^2-h^2)^{\frac{1}{2}}(\rho^2-k^2)^{\frac{1}{2}}}}. \tag{5.13c}$$

The first three terms of this expansion were computed numerically and used in Section 6.

6. WATER IMPACT OF A SPHERE AT AN ENTRY ANGLE OF 45°

The results of the previous pages are now applied to a specific problem. The drag on a sphere of radius R which strikes the water surface at 45° is computed as a function of time. The submerged portion of the sphere is approximated by a half-ellipsoid in such a manner that the depth of penetration d of the sphere equals the minor axis, the diameter of the circle of intersection between the sphere and the free surface equals the major axis and the submerged volume of the sphere, V, equal the volume of the semi-ellipsoid. If the dimensionless length ξ is introduced, one has:

$$\xi=tV\sin\alpha/R \tag{6.1a}$$

$$\rho_0(t)/R=[\xi(2-\xi)]^{\frac{1}{2}} \tag{6.1b}$$

$$k(t)/R=[2\xi(1-\xi)]^{\frac{1}{2}} \tag{6.1c}$$

$$h(t)/R=\tfrac{1}{2}\left[\frac{\xi(1-\xi)(7-3\xi)}{2-\xi}\right]^{\frac{1}{2}} \tag{6.1d}$$

$$d\alpha_i/dt=(V\sin\alpha/R)(d\alpha_i/d\xi). \tag{6.1e}$$

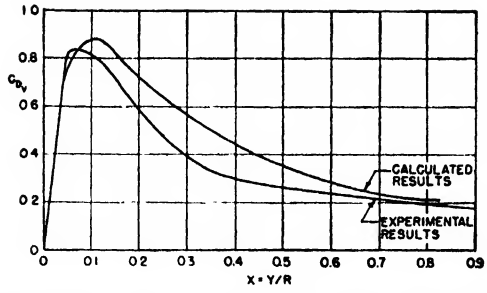

FIG. 7. Vertical component of drag of a sphere of unit radius in water impact $C_D = F_Y/\pi R^2\rho(V^2/2)$.

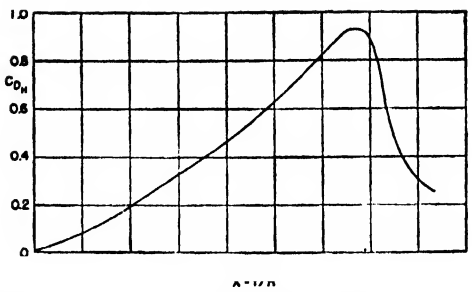

FIG. 8. Horizontal component of drag of a sphere in water impact.

The force functions are given by formulas (1.10a, b) and the derivatives are given explicitly as:

$$d\rho_0/dt = V\sin\alpha\frac{1-\xi}{2[\xi(2-\xi)]^{\frac{1}{2}}} \tag{6.2a}$$

$$dk/dt = V\sin\alpha\frac{1-2\xi}{[2\xi(1-\xi)]^{\frac{1}{2}}} \tag{6.2b}$$

$$dh/dt = V\sin\alpha\frac{7-20\xi+14\xi^2-3\xi^3}{2[\xi(1-\xi)(7-3\xi)(2-\xi)^2]^{\frac{1}{2}}} \tag{6.2c}$$

while the derivatives $\partial M/\partial\alpha_i$ are obtained by differentiating (5.13) with respect to ρ_0, h, k. This formulation is valid only while $\xi<1$, or up to the time when the sphere is half-submerged. After that instant, flow past an ellipsoid does not give a good approximation to the streamline pattern, and a cavity is beginning to develop.

The results of the calculation for the sphere are shown on Figs. 6, 7, 8. It is found that the value of the vertical drag component agrees fairly well with the value obtained in unpublished experiments carried out at the Morris Dam Hydrodynamics Station; it also gives the same type of result as that obtained by Schiffman and Spencer. The horizontal component of drag reaches its greatest value at a later point.

CONCLUSION

The impact of a body of arbitrary shape at an arbitrary angle was investigated by approximate methods. The two main approximations consisted in linearizing the boundary condition at the free surface by neglecting the splash and in replacing the submerged portion of the body at any time by an ellipsoid of identical depth of penetration, length, and submerged volume. As an illustration of the method, the impact of a sphere at a 45° angle was studied in some detail. The vertical force component turned out to be in good agreement with experimental results. The behavior of the horizontal component, which has not been measured, was also computed and shown.

Depolymerization by Ultrasonic Irradiation: The Role of Cavitation

ALFRED WEISSLER
Naval Research Laboratory, Washington, D. C.
(Received July 7, 1949)

Contrary to current belief, cavitation has been found responsible for the depolymerizing effect of intense ultrasonic waves. This was demonstrated by irradiating two portions of a 1 percent polystyrene solution in toluene under conditions identical except for the following. The first portion was given no special prior treatment, showed many cavitation bubbles during irradiation, and decreased in molecular weight (as measured by the intrinsic viscosity) to about one-tenth of the initial value. The second portion was given a preliminary treatment of degassing by boiling under vacuum, showed no cavitation bubbles during the irradiation, and underwent no appreciable change in molecular weight.

Similar experiments with solutions of hydroxyethyl cellulose in water showed that, in this case also, cavitation is necessary for depolymerization. The opposite conclusion of earlier investigators is attributed to their inadequate method for eliminating cavitation.

Oxidants known to be produced by ultrasonic waves in solutions containing dissolved oxygen or nitrogen cannot be responsible for the degradation, because substantially the same amount of depolymerization occurs even when helium is the only gas present.

INTRODUCTION

SOLUTIONS of high polymers may be affected by ultrasonic irradiation in two different ways.[1,2] First, Freundlich and Gillings found[3] that weak irradiation of fresh solutions of gelatin in water causes a considerable reduction in the structural or non-Newtonian viscosity. But on standing for several days, the solution regains almost as high a viscosity as it had before irradiation. This effect is believed due to the temporary breaking of the loose gel network of van der Waals bonds between adjacent polymer molecules. It does not take place to an appreciable extent in the absence of cavitation.[4]

The second way in which ultrasonic waves may affect high polymers is to cause depolymerization—the actual breaking of chemical bonds in the chain, to give molecules of smaller size than originally, and therefore a *permanent* decrease in viscosity. This was studied in detail by Schmid and Rommel[5] in order to determine whether cavitation is responsible for this effect also. In a typical experiment, they found that a solution of nitrocellulose in butyl acetate underwent considerable degradation when irradiated in a steel bomb for an hour under atmospheric pressure, but less degradation under 5 atmos. of nitrogen, and none at all under 8 atmos. of oxygen. Similarly, a solution of polystyrene in toluene suffered much depolymerization when irradiated under atmospheric pressure, less under 8 atmos. of O_2, and still less under 15 atmos. of O_2. Schmid concluded that depolymerization occurs in the complete absence of cavitation, because as little as 5 atmos. excess pressure would have suppressed cavitation caused by the moderate-intensity ultrasonic waves used.

However, this conclusion appears questionable, for the following reason. Although 5 atmos. excess hydraulic pressure applied in the body of the liquid by a piston will eliminate cavitation under the given conditions, applying 5 atmos. of oxygen above the surface will force 5 times as much oxygen into solution (Henry's Law). Then when the instantaneous pressure is reduced 1 or 2 atmos. in the negative part of the sound wave cycle, oxygen will come out of solution and bubbles will be formed in the liquid. Therefore, it seemed desirable to investigate this question further, using a more positive means for eliminating cavitation: degassing the solution by boiling under vacuum for at least 15 minutes, prior to irradiation.

EXPERIMENTAL

A sample of high molecular-weight polystyrene,[6] obtained through the courtesy of Dr. S. G. Weissberg of

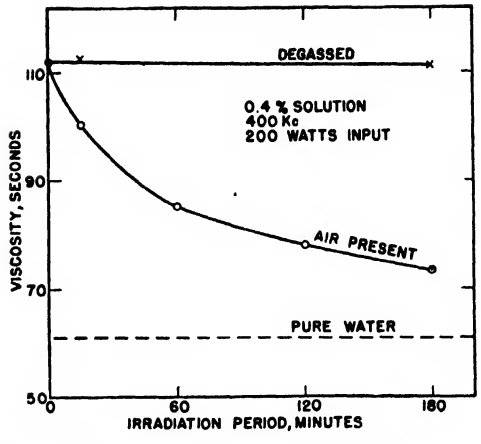

FIG. 3. Ultrasonic depolymerization of hydroxyethyl cellulose in water.

the National Bureau of Standards, was dissolved in toluene to give a 1 percent solution. A 50 ml sample of this solution, containing dissolved air, was irradiated[7] for 10 minutes (at a power level of 50 watts d.c. in the plate circuit of the output tube of the ultrasonorator) and then diluted to 100 ml. After this treatment the viscosity (measured at 30°C with an Ostwald-Fenske viscometer) was 665.7 seconds, compared to 929.3 seconds for an unirradiated diluted solution and 163.6 seconds for the pure solvent toluene. But when a similar sample was degassed first by boiling under vacuum, then cooled in the absence of air, irradiated, and diluted to 100 ml, no viscosity change was found (Fig. 1). Also, there were no cavitation bubbles in the degassed solution, although many were visible in the solution containing air.

Similarly, 3 hours irradiation gave only a very slight change (to 925.7 seconds) in a degassed solution, but a large viscosity decrease (to 270.9 seconds) in the solution containing air. Several intermediate points are also shown on Fig. 1. These viscosity decreases were permanent; no change could be detected after the solutions had stood for 20 hours.

The extent of depolymerization corresponding to the observed viscosity decrease was calculated from the equation

$$[\eta]=KM^a,$$

where M is the molecular weight, and $K=1.6\times10^{-4}$ and $a=0.66$ are two constants (obtained by extrapolation from data in the literature[8]) characteristic of toluene solutions of polystyrene which has been prepared by polymerization at 30°C, as was the present sample. The intrinsic viscosity $[\eta]$ is defined in terms of the viscosity of pure solvent η_0 and the viscosity η_c of a solution of concentration c:

$$\eta=\lim_{c\to0}\frac{\eta_c-\eta_0}{c\eta_0}=\lim_{c\to0}\frac{\eta_{sp}}{c}.$$

By means of successive dilutions, η_{sp} was evaluated for each irradiated solution at concentrations of 0.50, 0.20, and 0.10 gram/100 ml, and the results extrapolated to infinite dilution to give $[\eta]$. Figure 2 shows that the viscosity-average molecular weight decreases from about 6,000,000 to 600,000 in the ordinary solution, but in the degassed solution the decrease is negligible—of the same order of magnitude as the experimental error.

This result indicates that cavitation is responsible for the depolymerization. In order to determine whether the same is true in water solutions, analogous experiments were performed on a 0.80 percent aqueous solution of hydroxyethyl cellulose WS-1000 (obtained through the courtesy of the Carbide and Carbon Chemicals Corporation). Here again, ultrasonic irradiation

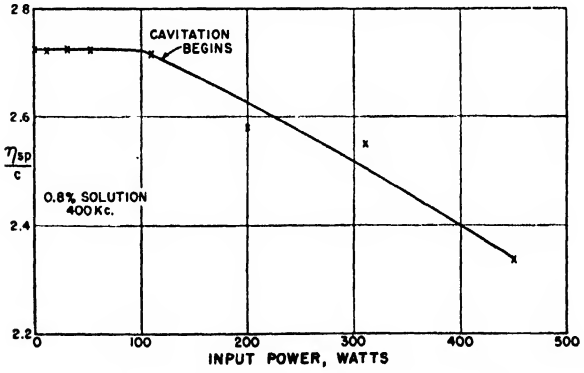

FIG. 4. Effect of input power on hydroxyethyl cellulose depolymerization.

[7] The container was a 50×400 mm test tube, closed at the top with a ground joint through which were sealed two gas-delivery tubes, one extending almost to the bottom of the container. This made it possible to change the nature of the dissolved gas in the solution. The ultrasonic waves used in these experiments had a frequency of 400 kilocycles.

[8] H. Mark in *Physical Methods of Organic Chemistry*, edited by A. Weissberger (Interscience Publishers, Inc., New York, 1945), p. 146; certain errors in this table were corrected for us by Dr. S. G. Weissberg.

for 3 hours at 200 watts input—followed by dilution to 0.4 percent—gave a very slight viscosity change (from 112.2 to 111.3 seconds) in degassed solutions, but a large decrease (to 73.6 seconds) in ordinary solutions; distilled water had a viscosity of 61.1 seconds in this viscometer. This is represented graphically in Fig. 3, together with several intermediate points.

An even more direct relation between cavitation and depolymerization is demonstrated in Fig. 4. It was previously observed that no cavitation bubbles could be detected in water irradiated at the lowest power levels, even with intense transverse illumination. However, bubbles could always be found at input powers above a given threshold, the value of which depended on the experimental conditions; in viscous solutions the threshold was higher and less sharp. In the present work, by subjecting successive portions of hydroxyethyl cellulose solutions to 5-minute irradiations at increasing power levels, it was found that no depolymerization occurred at the low levels where cavitation was absent. But just about at the power where cavitation began, depolymerization also began, and became greater as the power was increased.

It might be supposed that the observed degradation is due to oxidants which are known to be produced by irradiation of solutions containing nitrogen or oxygen.

TABLE I. Effect of dissolved gas on ultrasonic depolymerization.

Dissolved gas	Viscosity of 0.20% solution of polystyrene in toluene, after 30-minute irradiation	Viscosity of 0.40% solution of hydroxyethyl cellulose in water, after 15-minute irradiation
None	256.6 seconds	112.7 seconds
Air	177.6	100.3
Helium	175.0	100.0
Carbon dioxide	184.4	112.3

This view is invalidated, however, by the data in Table I; substantially the same amount of depolymerization occurs even when purified helium is the only gas present. Carbon dioxide also serves just as well in toluene, but not in water solution.

CONCLUSION

It is known that cavitation does not occur at moderate negative pressures in solutions which have been freed of dissolved gas. All concomitants of the ultrasonic wave, other than cavitation, are present in degassed solutions, but no depolymerization takes place. Therefore, it is cavitation which is responsible for the depolymerization caused by ultrasonic irradiation, in the polystyrene-toluene and hydroxyethyl cellulose-water systems.

A Three-Stage Electron Microscope with Stereographic Dark Field, and Electron Diffraction Capabilities

M. E. HAINE,* R. S. PAGE, AND R. G. GARFITT
Metropolitan Vickers Electrical Company, Ltd., Manchester, England
(Received August 2, 1949)

An electron microscope is described in which a range of magnifications between 1000 and 100,000 times can be covered continuously. This is achieved through the use of an intermediate projector lens.

The principles of design are briefly discussed and the construction of the microscope and the high frequency-operated 100-kv power unit is dealt with in some detail. The instrument is provided with objective apertures to enhance image contrast and to permit operation with dark field illumination.

Data is given relating to the electron optical system and it is shown how the instrument can be used to obtain electron diffraction patterns characteristic of small areas of a specimen under microscopic observation. The alignment procedure is briefly described and some typical micrographs are shown.

I. INTRODUCTION

FOLLOWING the work on the design and construction of a two-stage electron microscope Type E.M.2,[1] it was decided to undertake the development of a new instrument, the design of which would aim at obtaining the greatest possible simplicity and economy compatible with the best performance.

This paper describes the design principles evolved for the new instrument (Fig. 1) and explains the versatility in operation and also the mechanical, electrical, and electron optical details.

Previous electron microscopes have used a two-lens system, except that built by Marton[2] which used a three-lens system. The relative advantages of the two systems were considered and it soon became apparent that a three-lens system offered many advantages in providing a more compact design and a much greater versatility. Three-stage instruments have been de-

* Now with the Associated Electrical Industries Research Laboratory, Aldermaston, Berks, England.

[2] L. Marton, "A 100-kv electron microscope," J. App. Phys. 16, 131 (1945).

veloped also coincidently with our own by le Poole[3] and Liebmann.[4]

A two-stage instrument consists of lenses separated by distances of three to four times the length of a lens. This means a long and hence not very rigid column. Ideally a column consisting of lenses, and space enough to allow for the necessary aligning mechanisms, would suffice. If we fix the ideal length per stage at a value l_0 and assume the lenses all have focal lengths f_0, then with n stages the magnification is given approximately by

$$M=(l_0/f_0)^n.$$

Thus,

$$n=\log M/\log(l_0/f_0).$$

For a maximum magnification of 100,000 times, $l_0=20$ cm, and $f=0.4$ cm, n becomes 3 to the nearest integer. The resulting three-stage column is 60 cm long compared with 250 cm for the corresponding two-stage instrument.

Further consideration shows that a much wider range of magnification for a given specimen setting is possible. For instance, whereas in a two-stage instrument the magnification can only be varied over a range of about five to one without changing the specimen position, in the three-stage instrument a range of nearly one hundred to one is possible. This further simplifies design as it obviates the necessity for an intermediate viewing screen for aligning purposes.

A further advantage results by virtue of the ease with which diffraction photographs can be obtained by imaging the diffraction pattern at the back focal plane of the objective lens on to the object plane of the second projector lens, using the first projector lens at unity magnification. The detailed mechanism involved is described in later paragraphs.

In addition to using a three-lens magnifying system, it was thought possible to reduce the over-all volume of the apparatus sufficiently to keep the "pump-down time" low enough to allow complete evacuation in two or three minutes and thus obviate air locks for specimen and photographic plate. This was considered particularly important in view of the difficulties already present in the mechanical stage design which are much aggravated if an air lock is necessary.

Our own past experience and that reported to us from other workers in this field made us decide to use an electron accelerating voltage of 100 kv. There seems little doubt that this represents an appreciable improvement on the 50 kv previously used, and yet it is evident that to increase the voltage to much over 100 kv involves considerable complication and expense.

II. DESCRIPTION OF MICROSCOPE COLUMN

The microscope column (Fig. 2) is built up in eight sections: The electron gun, condenser lens, specimen chamber, objective lens, intermediate alignment section, twin projector lenses, viewing chamber, and camera. Each unit is supported directly by the section underneath and vacuum sealed by rubber gaskets. Mechanical rigidity, a first consideration in electron microscope design, is maintained by the use of the type of rubber gasket seal used on the Type E.M.2 instrument which allows the opposing flanges to be clamped together in metal to metal contact.

A. The Electron Gun and Condenser Lens

The electron gun is totally enclosed, utilizing a screened cable entry bushing insulator (103) to conduct the high voltage lead (101) to the cathode. Thus no high voltage is exposed at the electron gun and the necessity for a cumbersome screening compartment is obviated.

The three-core high voltage cable is terminated in a three-contact plug assembly which fits into the central bore of the conical porcelain insulator and makes contact with the cathode assembly of the gun. A conical screen surrounds the whole insulator and serves to connect the cable screening direct to the main body of the microscope. The cathode assembly (111) is of more

or less conventional design, consisting of a tungsten hairpin filament surrounded by a biased cathode shield. The anode (117) has a central aperture to allow the beam to pass out of the gun and also a concentric ring of holes for pumping. The gun is surrounded by a lead-lined x-ray shield (118).

The electron gun is mounted directly on top of the condenser lens; no transverse alignment of the lens with respect to the gun axis has been found necessary.

The electron gun and condenser lens assembly is mounted on an aligning mechanism which allows it to be translated laterally or tilted about a point in the object plane for electron optical alignment. The mechanism employed is similar to that used in the Type E.M.2 instrument, but it has been reduced in size and made more rigid. The lateral movement is obtained by sliding two flat surfaces over one another with the adjusting screws (211) while the tilt is obtained by sliding two spherical surfaces centered at the specimen by means of adjusting the screws (212). Vacuum sealing is effected by a flexible metal bellows. The complete unit is mounted on top of the object chamber and sealed by a rubber gasket.

B. The Specimen Chamber and Mechanical Stage

The specimen chamber (Fig. 3) consists of a brass cylinder brazed to upper and lower sealing plates (302, 303). To provide access to the mechanical stage the front section of the cylinder is cut away to accommodate the door (304), which is sealed with a flat rubber gasket held to the door by an internal retaining plate. A swing catch pivoted at the center of the door engages in slots in the upper and lower flanges. Atmospheric pressure is sufficient to seal the door without addition of any auxiliary pressure, and the catch is provided merely to hold the door closed before evacuation commences. A pumping manifold connection is made at the back of the object chamber.

The object chamber is fixed directly on top of the objective lens by flange bolts, and sealed with a rubber cord gasket.

The object stage itself consists of a cup-shaped carriage (306) which slides directly on the upper face of the objective lens. These sliding surfaces are polished to reduce the friction so that a smooth movement is obtained, while two spring-loaded plungers hold the surfaces in close contact.

The specimen holder (309) is locked into the stereo block (310) by means of the finger-controlled screw (311), and is shown in detail in Fig. 4. The holder can be extracted from the stage through the chamber door with the aid of the special tweezers (Fig. 4) which engage with an internal groove in the holder.

The stereo block into which the specimen holder fits is mounted on two pointed pegs which rest in grooves in the base of the carriage, lying approximately in the plane of the object. The upper face of the block is cylindrically machined about an axis containing the

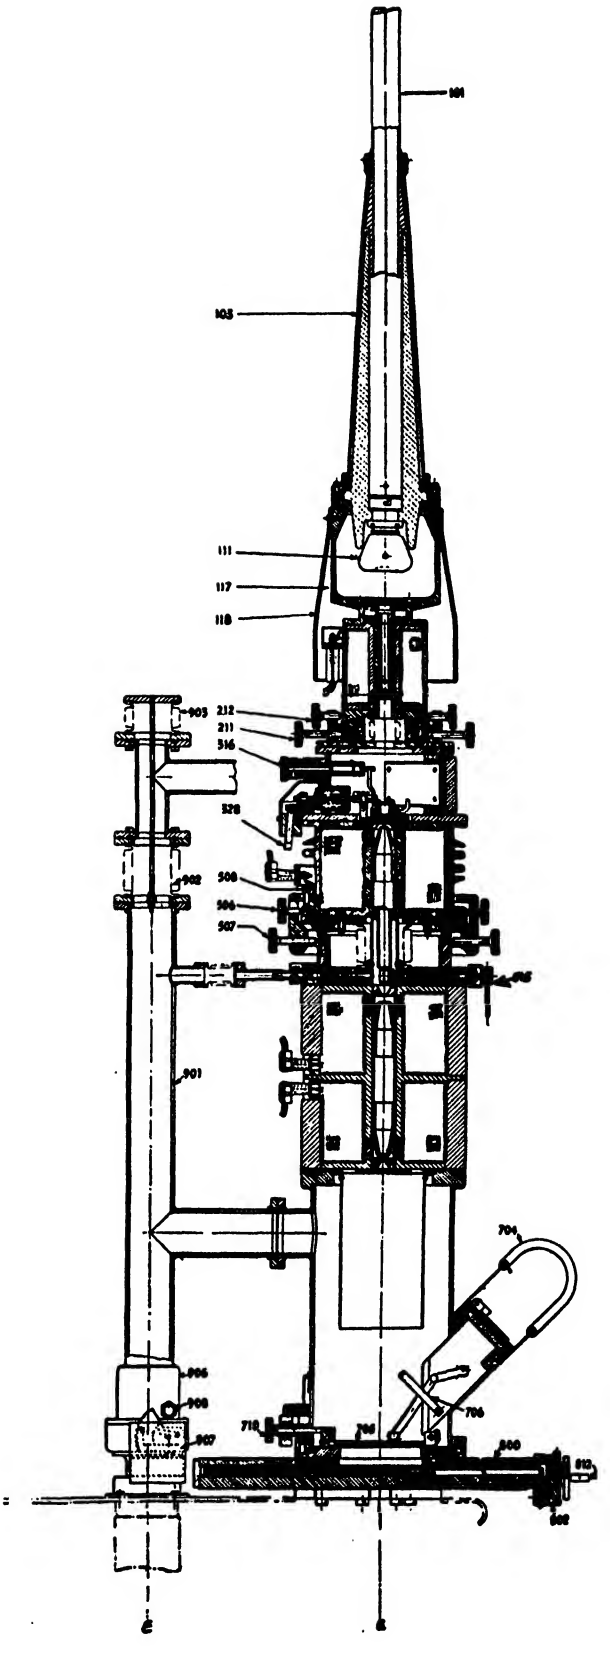

FIG. 2. Cross-sectional drawing of the microscope column.

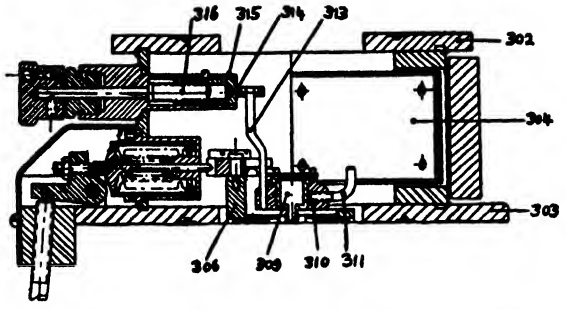

FIG. 3. Cross-sectional drawing of the specimen chamber.

points of the pegs. Leaf springs fastened to the carriage bear on this cylindrical surface, allowing the block to be tilted through a total angle of 10° about the axis in the object plane. Tilting is effected by a vertical lever (313) attached to the stereo block and engaging the tilting mechanism at the top of the specimen chamber. The tilting control consists of a lead screw (316), entering the vacuum through a rubber gland seal, which moves the block (314), keyed to the fixed tube (315), laterally. A rectangular opening in the block allows clearance around the lever so as not to interfere with the mechanical stage movement.

Motion in two directions at right angles is transmitted to the object stage through a lead screw and bell crank system from two knobs at hand level. Careful attention to the friction, controlling springs and rigidity of the operating mechanism gives smooth control to 0.1μ or better. The relatively small mass of the stage and close contact with the objective lens ensures thermal equilibrium between these being reached in a short time.

C. The Objective Lens and Intermediate Aligning Mechanism

The objective lens is of conventional design; the bore is made vacuum tight by a brazed copper spacer in the gap and is ground to give accurate cylindricity.

The pole pieces are asymmetric about the lens center, in order to bring the object focal plane to a position just above the top of the lens. A special grinding technique has been developed to ensure a minimum degree of eccentricity and ellipticity of the pole piece bores to minimize astigmatism. Further improvement in this direction is achieved by making the bore diameter as large as practicable with no increase in focal length, as by so doing the effect of residual mechanical and magnetic defects as well as the primary spherical aberration is reduced.

A focal length of 4 mm is obtained at 100 kv with the specimen plane slightly above the level of the upper lens face and a pole piece diameter of 2.5 mm. The pole pieces are finished by precision grinding to be an accurate push fit in the bore of the lens and can be removed for cleaning relatively easily.

The alignment section immediately below the objective lens provides two movements, one for translating (506) and one for tilting (507) the objective lens and illuminating system with respect to the projector lenses. The tilt takes place about a point in the object plane of the second projector lens. Each movement is controlled by a set of four self-locking screws.

D. Objective Apertures

The microscope has been fitted with two types of objective aperture; one being a relatively large aperture intended to give an increase in image contrast and to be easily inserted and removed. It takes the form of a hollow phosphor bronze cylinder closed at one end by a thin wall into which is drilled the aperture hole 100μ in diameter. The cylinder fits closely into the bore of the objective lens and can be inserted and removed by means of a special tool through the specimen chamber door. The operation takes slightly longer than that of changing the specimen. The plane of the aperture is located approximately at the back focus of the lens so that electron diffraction patterns cannot be obtained with the aperture in position.

The alternative type of aperture takes the form of an assembly which fits into the lower pole piece of the objective lens from the underside. The aperture, again located at the back focus of the objective lens, can be preset in lateral position by four grub screws and is centered before assembly of the objective lens by means of a low power microscope and "V"-block. This precentering allows the use of a smaller aperture. The assembly is thus semipermanent and precludes the use of electron diffraction or low magnification dark field imaging. Normal dark field images can be obtained, however, by tilting the illuminating system sufficiently for the direct beam to be intercepted by the aperture.

In addition, a special intermediate section has been developed for the instrument which carries an adjustable objective aperture assembly, details of which can be seen in the cross section of Fig. 5. The aperture is carried on the detachable end of a tube (551) which slides vertically inside a carrier tube (552) supported in a spherical seating (553) about 3 cm below the center of the objective lens. Thus, transverse movement of the lower end of the carrier tube will translate the aperture in the lens field. A main supporting tube (554) carries the spherical seating at the upper end and a cylindrical block at the lower end. Two fine-threaded

FIG. 4. The mechanical stage, specimen holder, and insertion tweezers.

screws through this cylinder allow adjustment of the position of the carrier tube. These screws extend to knobs outside the walls of the alignment section.

Vertical movement of the aperture tube is controlled by the fork (556) engaging with two pins in the lower end of the tube. The fork is fastened to a shaft projecting through the walls, and a knob on the end engages with stops suitably placed on the external wall.

The normal operating position for the aperture is about 4 mm below the lens center. When it is not required it can be raised to just below the level of the specimen plane so that the cone of electrons leaving the object area is unrestricted. When the specimen is removed, the aperture can be lifted even further so that it projects above the level of the lens face. This enables the cap containing the aperture disk itself to be removed or exchanged without having to dismantle the whole lens assembly.

The aperture used is a thin copper disk produced by Kodak. The hole sizes so far used are 30 and 60μ in diameter.

The lower plate of the aligning section carries a pumping port connected to the vacuum manifold, also another movable aperture system (515) inserted at the level of the first intermediate image. This is used in obtaining electron diffraction patterns as described in Section III. It consists of a cylindrical cap on the end of a shaft controlled by a knob. Two clearance holes in the cap allow the beam to pass unrestricted for normal operation while rotation of the knob through 60° or 120° brings two small apertures of 50μ or 250μ diameter, respectively, in line with the axis of the beam. A screw backstop is provided for initial alignment of these apertures.

E. The Double Projector Lens, Viewing Chamber, and Camera

The construction of the double projector lens is clearly shown in Fig. 2.

The yoke, copper spacers, and end plates are brazed together, giving a vacuum-tight bore. The lens winding is wound directly on the double bobbin so formed and the two halves of the outer iron shroud slide over the whole assembly. The bore is precision ground and sufficient accuracy is obtained to render individual alignment of the two lenses unnecessary.

The viewing chamber is provided with a single wide viewing port with a lead glass window and eyeshield (704). On the sides of the viewing port are fitted the controls for raising the fluorescent screen (705) and for positioning a magnifying lens (706) to aid correct focusing.

A pumping port connects the viewing chamber to the vacuum manifold and the top flange supports a cylindrical μ-metal screen. The viewing chamber is fastened on blocks mounted directly on the main cross members of the desk frame and the camera is strapped underneath

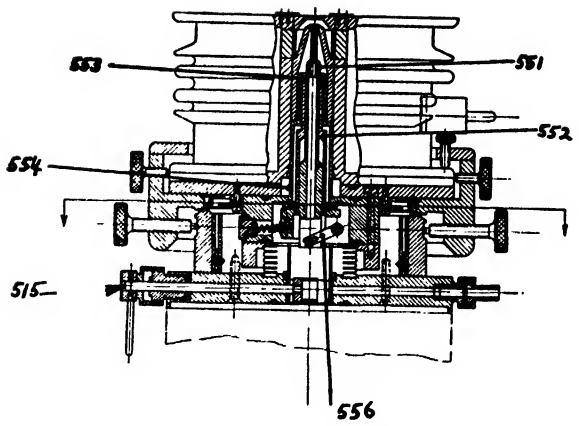

FIG. 5. Cross-sectional drawing of the intermediate alignment section with the adjustable objective aperture.

the lower flange, so that it can be removed without disturbing the rest of the microscope.

The camera consists of a shallow rectangular box with a transverse shaft operating the cassette tray through a pinion and rack. The door (802) is sealed by a flat rubber gasket and held in place by a spring clip. The drive for the racking pinion is brought out through a gland seal and bevel gears to knob (812) at the front right-hand side of the camera and a simple position indicating mechanism is incorporated.

The camera will take two $3\frac{1}{4}\times3\frac{1}{4}$-in. plates end to end, on which two, four, or eight micrographs can be taken. The frame size is selected by masks attached to the fluorescent screen; the appropriate mask is selected by the knob (710) at the rear of the viewing chamber.

F. Vacuum Equipment and Desk

The pumping equipment consists of a Metro-Vick Type D.R.I. two-stage rotary pump backing a Type 02 oil diffusion pump. The pumping system is manually controlled and provided with simple interlocks to prevent damage due to incorrect operation. The backing pump can be connected direct to the microscope column for rough pumping or to the diffusion pump for normal operation.

A simple fine side vacuum valve is incorporated between the diffusion pump and pumping manifold so that the microscope can be open to the atmosphere without shutting down the pumps. The over-all pumping time from atmospheric pressure is about two minutes.

The pumping manifold leading from the diffusion pump via the fine side valve has three connections to the microscope column (Fig. 2) as previously described; one at the viewing chamber, a second at the intermediate section, and a third at the object chamber. Flexible connections are made in the latter two to allow for the necessary alignment of the microscope column. The bending moment exerted on the column by air pressure on the top flexible connection (902) is com-

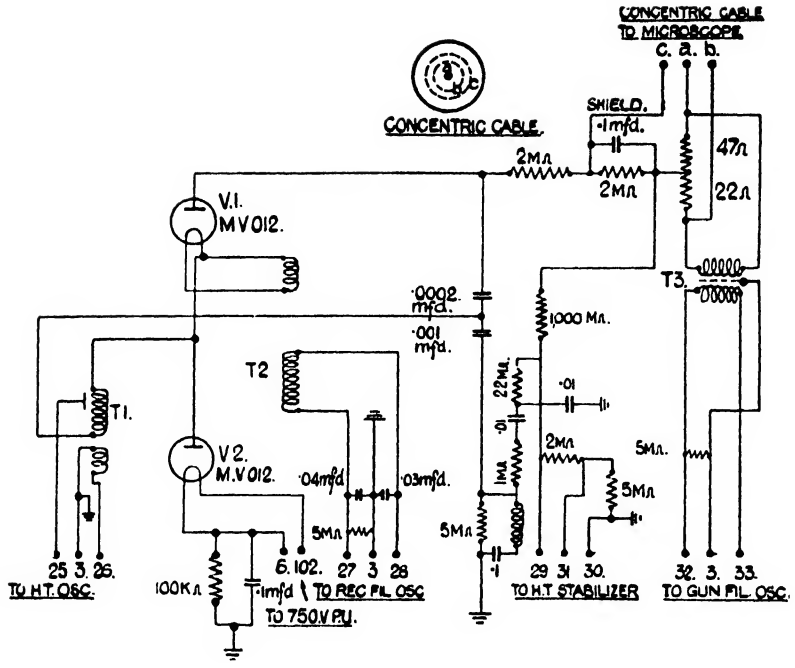

FIG. 6. Circuit diagram of the oil tank assembly.

pensated by a further flexible bellows (903) on the top of the manifold. The top plate sealing this bellows is mechanically connected to a spider in the lower end of the connecting bellows by a stay rod. Thus no resultant moment acts on the column.

The microscope desk (Fig. 1) is constructed from an angle iron framework with sheet metal paneling, and is mounted on rubber-bonded feet to insulate against vibration. A sloping panel at the rear of the desk displays beam current, lens current, and vacuum gauge meters, indicating lights and the a.c. mains circuit switches and fuses. The microscope controls are all grouped on a hinged panel just to the left of the column, while the lens current stabilizers are built on subpanels fastened to the control panel, providing easy access for maintenance.

All internal wiring takes the form of multiple cables or looms interconnecting each unit, terminated with multiple terminal blocks and spade end-coded leads.

G. The High Voltage Power Unit

This follows what may now be regarded as conventional practice for this type of instrument, the high voltage being obtained by rectification of the output of a resonant high frequency transformer fed from a valve oscillator.[5] Stabilization is obtained through negative feedback from a high resistance potential divider connected across the output circuit, via a d.c. amplifier, to the screen circuit of the oscillator valves, four 45-volt batteries providing the stable comparison voltage.

The complete unit contains three separate oscillators supplying power to the high voltage circuit, the high potential rectifier valve filament, and the electron gun filament. The operating frequencies are, respectively, 30, 50, and 50 kc/sec. All the oscillator and stabilizer components are grouped on a single rack-mounted chassis, while a second chassis contains the low voltage power supplies to the oscillators. The high voltage unit, which employs a Greinacher voltage doubler circuit, is housed in a brass oil-filled tank, and the electron gun supply is fed out through a shielded concentric cable. The voltage output of the set is varied by selection of the number of reference batteries in circuit, four 25-kv steps being provided. On the 25-, 50-, and 75-kv ranges, maximum output current is about 1 ma. and 0.4 ma. on the 100-kv range.

The electron gun filament power is remotely controlled from the microscope desk by variation of the anode supply voltage to the appropriate oscillator. Switching of the high voltage supply is accomplished by means of push buttons and relays, which also afford automatic overload protection. Figures 6 and 7 are circuit diagrams, respectively, of the high voltage and oscillator-stabilizer units.

III. ELECTRON OPTICAL PERFORMANCE

A. Illuminating System

The triode electron gun operates with an automatic bias derived from a variable resistor connected between the cathode and the cathode shield. For a given setting of the bias resistor there is thus a value of filament heating current which gives the correct lens action at the cathode shield aperture and produces an intensity maximum at the beam cross-over situated near the anode aperture.

[5] O. H. Schade, "Radiofrequency-operated high voltage supplies for cathode-ray tubes," Proc. I.R.E. 31, No. 4 (April, 1943).

Operating a triode gun under these conditions minimizes the effect of bad alignment of the filament in the shield aperture and also gives maximum brightness conditions. An image of the beam cross-over at approximately unit magnification can be formed in the object plane of the objective lens by the magnetic condenser lens, so that by operating the microscope at low power an image of the crossover can be projected on to the viewing screen. The cross-sectional diameter of the crossover determined in this way has a minimum value of about 0.005 cm, the actual value depending on bias setting and on the height of the filament in the shield. Under optimum conditions, the beam divergence from the crossover is approximately 0.03 radian. With a total beam current of 200 μa, the current passing through the condenser aperture, which subtends an angle at the cathode of 4×10^{-3} radian, is

$$200\times10^{-6}\times\left(\frac{4\times10^{-3}}{3\times10^{-2}}\right)^2=3.56\ \mu\text{a}.$$

The mean current density at the object is therefore

$$\frac{3.56\times10^{-6}}{\pi(2.5\times10^{-3})^2}=0.18\ \text{amp./cm}^2.$$

For adequate brightness on the final screen, a current density of 10^{-11} amp./cm^2 is required; hence the gun gives a sufficient intensity for operation at a magnification of $(0.18/10^{-11})^{\frac{1}{2}}=135{,}000$ times at critical illumination, or at an angular aperture of 5×10^{-4} radian, the visibly usable magnification is

$$1.35\times10^5\times\left(\frac{5\times10^{-4}}{4\times10^{-3}}\right)^2=2100\ \text{times}.$$

B. Lens System

Consideration of minimum aberration in the objective lens calls for the use of the shortest possible value of focal length. For a given pole piece design the minimum focal length is determined by magnetic saturation of the iron. Scaling up the dimensions of the pole pieces while maintaining constant field strength in the gap again shortens the focal length. Limitations here arise due to excessive increase in the excitation ampere turns required and also due to the fact that the lens field becomes so extensive that the back focus comes within the field, after which rays are deflected back toward the axis, and hence the focal length no longer decreases. A further advantage in scaling up the pole pieces results from the relative reduction in the astigmatism resulting from mechanical inaccuracies.

A further limitation in the focal length arises because of the difficulty of accommodating the object holder in

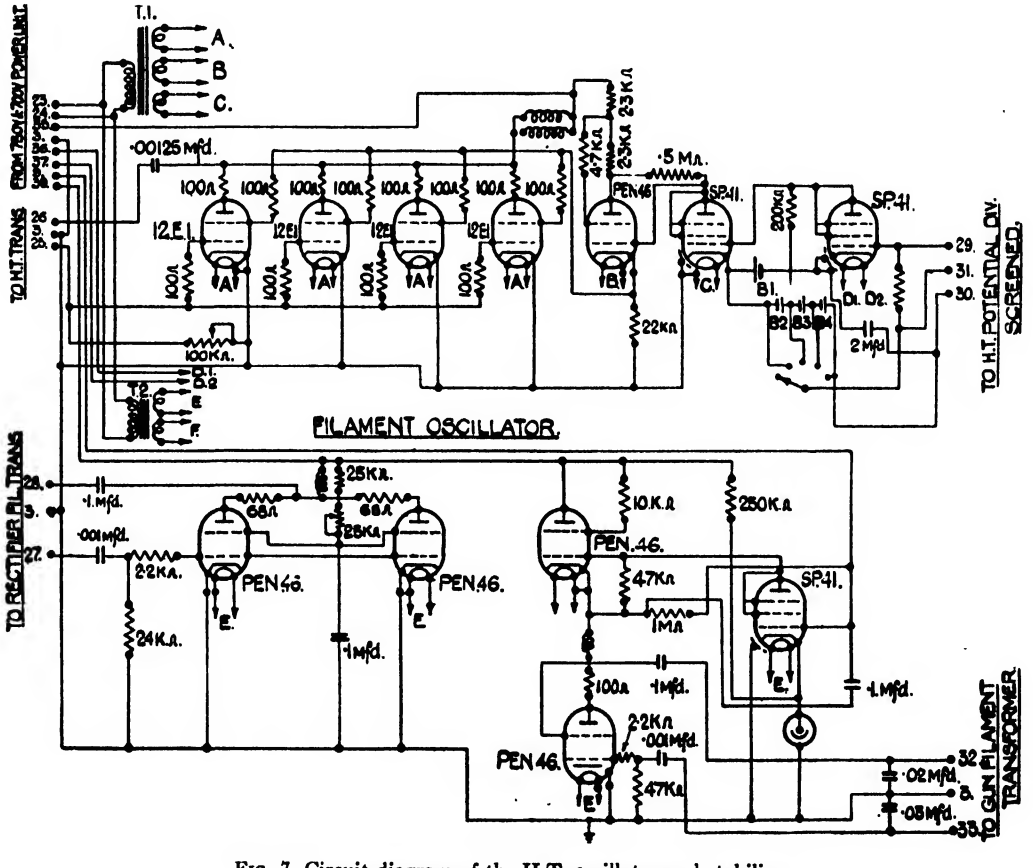

FIG. 7. Circuit diagram of the H.T. oscillator and stabilizer.

TABLE I. Magnification ranges.

ccelerating voltage	Low magnification undistorted	High magnification
100 kv	600–2000	2000– 60,000
75 kv	1000–3000	3000–100,000
50 kv	1500–5000	5000–100,000+

osition very close to the lens without severely tricting its movement. For this reason a focal length 4 mm is used, and the pole piece aperture chosen to as large as possible for saturation at the maximum itation. The maximum objective magnification is n about 35 times.

The three-lens system with the adjustable aperture vides a very flexible imaging system which can oper- under three distinct combinations of focal lengths. ese combinations provide for (1) high range magnifi- ion, (2) low range magnification, and (3) electron raction.

C. Magnification Range

The ranges of magnifications obtainable are shown Table I. On the high magnification range the two jector lenses are used in the normal way, that is, h producing inverted magnified images. The ray h for this condition is shown in Fig. 8(A). To avoid essive pincushion distortion† at the lower magnifica- ns, the second projector is operated at high power l gives most of the magnification (about 50× at) kv). For an 8-cm diameter image, the second pro- tor object field is then 0.16 cm in diameter, so that the bore of this lens can be made small without introducing distortion. Thus, for an over-all magnification of 2000 and first-stage gain of 35, the second lens must give unity magnification. The higher magnification can be obtained now by increasing the first projector power up to a maximum when it works at a focal length of about 4 mm, giving a stage magnification of 35× at 100 kv. This corresponds to an over-all magnification of 60,000×.

To obtain the low magnification condition, the first projector is used to form a reduced erect image by operating at low power. The ray path is shown in Fig. 8(B). The extent of the imaging beams at the projector lens aperture is now of the order of 0.3 cm so that the bore of the lens must be double that required by the high magnification condition in order to avoid barrel distortion. The wider bore is adopted though it slightly reduces the highest magnification obtainable.

D. Electron Diffraction

In this instrument an electron diffraction pattern corresponding to a small selected area of the specimen under examination can be formed immediately and without disturbing the specimen. This is achieved by using the first projector lens to form an image of the diffraction pattern existing in the back focal plane of the objective lens at approximately unit magnification in the object plane of the second projector lens. This image is then enlarged on to the final screen, or photographic plate. This method of obtaining diffraction patterns was originally used by Boersch.‡[6]

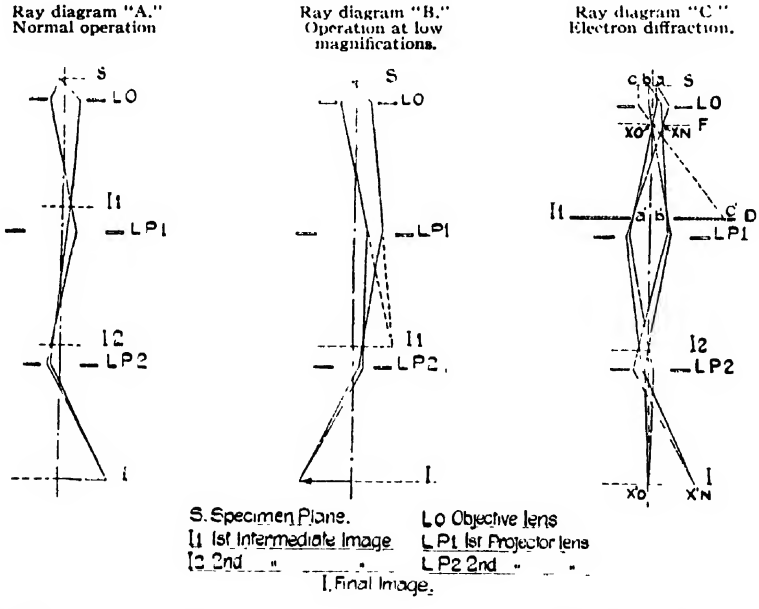

FIG. 8. Diagram of the ray paths.

† To insure negligible pincushion distortion, the area utilized in the object plane of the projector should be one-fourth of the e piece bore diameter.

‡ A similar result has been obtained by le Poole using a slightly modified arrangement incorporating an additional weak lens ference 3).

[6] H. Boersch, "On the primary and secondary image in the electron microscope II. Structure investigation by means of tron diffraction," Ann. d. Physik. 27, 75 (1936).

Under these conditions, the objective lens is used in the normal manner and therefore produces an intermediate magnified image of the object just in front of the first projector lens. A stop placed here will limit the field of the object observed in normal microscopic observation and will also, therefore, in the diffraction usage, limit the area of the object from which diffracted electrons are transmitted. The stop can be relatively large in diameter since the effective diameter is reduced by the magnification of the objective lens (35×). Thus, in practice, two stops 50 and 250μ in diameter are used, corresponding to fields of 1.5 and 7μ at the object. The ray path is shown at Fig. 8(C).

The maximum angle of diffraction allowed for is 0.1 radian. If the whole of the beam contributes to the intermediate image, the confusion disk diameter, given by $C_S\alpha^3M\cdot(C_S=0.5$ cm) becomes 175μ which is larger than the smaller stop. The effect of this when using the stop depends on whether the paraxial or marginal electron rays are focused at the aperture. Most of the intensity will normally be in the paraxial beam and if this is focused, then some of the energy from the outer rings will be lost and some energy from the outer rings of any crystals outside but near the defined area will appear. A better condition is for the intermediate image to be underfocused by such an amount as to allow all the outer ring electrons to pass through the aperture.

The diffraction pattern rings in the back focal plane of the objective will have a diameter given by

$$D=2\alpha_D f,$$

where α_D is the angle of diffraction and f the focal length of the objective lens. Toward the outside of the pattern some distortion is introduced by spherical aberration. This has the effect of reducing the diameter of the outer rings by an amount $C_S\alpha_D^3$. For a maximum angle of diffraction of 0.1 radian and a focal length of 0.4 cm, the ring diameter becomes $D=2\times0.1\times0.4$ cm $=800\mu$ and the distortion is $\Delta D=0.5\times(0.1)^3$ cm $=5\mu$ or a little under one percent. A simple correction can be applied for this error.

The final projector lens provides sufficient magnification to enlarge the diffraction pattern to a convenient size which is just too small for distortion in this lens to be significant.

The diffraction rings are made up of overlapping images of the electron source and therefore to give finely resolved rings the source must be small. If we operate the instrument under conditions of critical illumination we should expect to get no diffraction at all, as incoherent radiation is irradiating the object. In fact, a fair degree of coherence results from the imperfections in the cathode and condenser lenses, and even if this were not so, the Airy disk produced by the condenser lens aperture would give sufficient coherence for some pattern to result; the resolution would, however, be very poor.

If the condenser lens is switched off the electron gun virtual cathode is the source and this is demagnified about 50× by the objective into the back focal plane giving a ring width of about 1μ. To improve upon this, the condenser lens can produce an image of the source demagnified about 10×. The image is closer to the objective and hence the objective demagnification is reduced to 20× giving an over-all demagnification of 200× or an image size of about 0.25μ. This for the outer rings corresponds to a resolution of 1 in 3000 which is adequate.

Spherical aberration of the objective lens will have a further detrimental effect on the outer rings of the diffraction pattern. The diameter of the disk of confusion in the back focal plane is given by

$$\delta_S=d(C_S\alpha_D^3)=3C_S\alpha_D^2d\alpha.$$

Here α_D is the angle of diffraction and $d\alpha$ is the angle subtended by the intermediate diffraction aperture at the diffraction pattern. For the 250μ stop, $d\alpha$ becomes 0.002 radian, and if $\alpha_D=0.1$ radian, then $\delta_S=3\times0.5\times10^{-2}\times2\times10^{-3}=0.3\mu$.

If this error is added directly to that due to the finite source size, the resolving power of the system becomes 1 in 1500 with an improvement toward the center of the pattern.

E. Electron Optical Alignment

The alignment procedure employed with this instrument is very similar to that used on the Type E.M.2 microscopes.[1,7] The system is first aligned as a two-stage

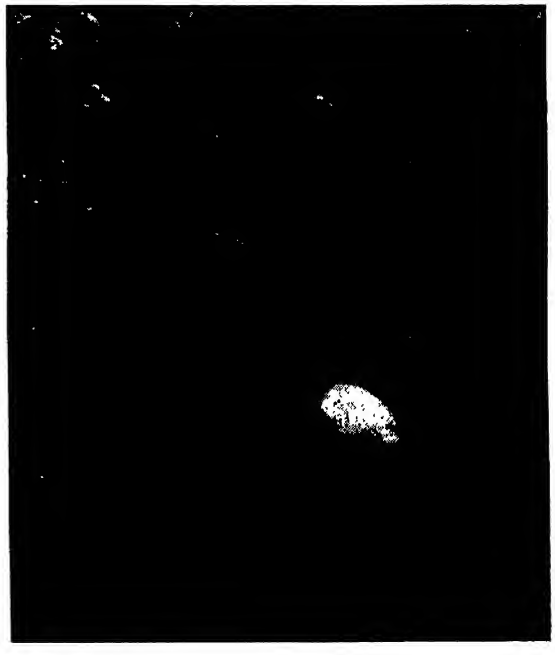

FIG. 9. Staphylococcal bacteriophage and staphylococcus, shadow cast at 4:1. (32,000 times, 75 kv.)

[7] M. E. Haine, "The electron optical system of the electron microscope," J. Sci. Inst. 24, No. 3 (March, 1947).

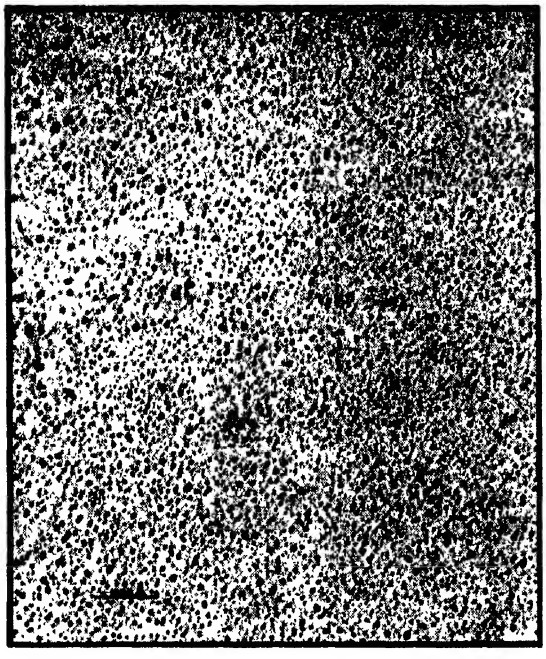

FIG. 10. Evaporated palladium gold. (72,000 times 75 kv.)

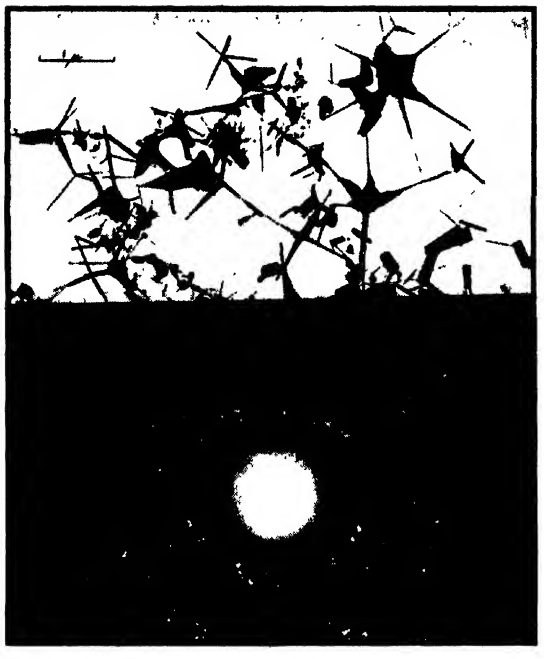

FIG. 11. Electron diffraction pattern of zinc oxide crystals, 100 kv.

microscope with the first projector lens switched off, using reversal of the objective lens current to locate the lens axis.

The first projector lens is then switched on at low power to give an image of the back focus of the objective lens in the image plane of the final projector (electron diffraction condition). Under these conditions the spot on the final screen will be displaced from the center if the first projector lens is not aligned with the axis of the objective lens. This is corrected by use of the intermediate section tilt. As this tilt is arranged to occur about the center of the second projector lens, the alignment of this lens and the objective is not upset. However, if the tilt required is large it may be necessary to repeat the initial adjustment.

The magnification can then be raised to 10 or 20,000 times and final adjustment of the gun tilt carried out.

CONCLUSION

In operation, we have found this instrument to give the promised flexibility and simplicity. The absence of air locks proves no disadvantage; the specimen or photographic plates can be changed in about three minutes while such operations as changing an aperture or a filament take very little longer.

In regard to resolving power, the average value obtained during a series of tests with heavy metal particles of about 25A diameter was approximately 35A with a best value of 25A. Edge contours have been recorded with half-widths of about 15A while spacings of as low as 12A between maxima and minima in Fresnel fringe systems have been obtained. These results indicate that a resolving power of better than 50A should be obtained under normal operating conditions.

Figures 9 and 10 show typical micrographs while Fig. 11 shows the micrograph and diffraction pattern, obtained from a field 7.0μ in diameter, of zinc oxide crystals.

ACKNOWLEDGMENTS

The authors wish to express their appreciation of the help afforded them in the development of this microscope by Mr. R. W. P. Tostevin, Mr. H. M. V. Young, and Mr. H. Nuttall, also to Mr. G. A. Barnett for his collaboration on the mechanical design.

In conclusion, the authors express thanks to Mr. F. R. Perry for his encouragement in this development, to Sir Arthur P. M. Fleming, Director, and to Mr. B. G. Churcher, Manager of Research Department, Metropolitan-Vickers Electrical Company, Ltd., for permission to publish the paper.

Comments on the Use of Latex Spheres as Size Standards in Electron Microscopy*

CHARLES H. GEROULD
Magnesium Laboratories, The Dow Chemical Company, Midland, Michigan
October 19, 1949

BACKUS and Williams[1,2] have reported the usefulness of Dow latex 580G, lot 3584, as a standard in the determination of magnification and shadow-casting angle in electron microscopy. They attributed to these latex spheres a size of 2590±25A. Since the unique value of this material became apparent, about 225 small samples have been distributed to laboratories in this country and abroad. Seventeen of these laboratories have made determinations of the average particle size and have submitted their results which have been tabulated in Table I. It is noted that these determinations include six different techniques; electron microscopy alone, combination of light and electron microscopy, light microscopy alone, interferometry with electron microscopy, light scattering and ultracentrifugation. It appears significant that thirteen of the seventeen determinations show an average size of 2588A with a range from 2520 to 2630A. The four other determinations range upward to 3200A.

It should be mentioned that more recent light scattering studies by the two laboratories listed have indicated that the procedure used is not reliable.

It has been reported[3] that the size of this latex may be affected by variations in the procedure of specimen preparation, such as degree of dilution, size of drop added to specimen, drying speed, etc. In order to check this possibility, sixteen experiments were performed in which the dilution of the 40 percent latex with water was varied between 1:250 and 1:4000, the size of the drop added to the specimen and the drying times varied to reasonable extremes, dilutions made from a drop of latex which had been allowed to nearly dry before diluting, and dilution of the settled and caked material found in the bottom of the latex bottle. The results indicated that none or, at the most, very few significant changes took place. Twelve experiments showed variation of less than 1 percent from the mean, two between 1 and 1.5 percent and two between 2 and 3 percent. These latter two experiments may be significant or they could be the result of instrumental fluctuation. However, in both of these cases, the 2 to 3 percent variation was a decrease in size as a result of the partial drying of a drop of latex before dilution, a procedure rarely encountered in actual practice.

[c] Instrumental Calibration—EM calibrated for magnification with specimen mentioned. Latex size determined using this calibration.

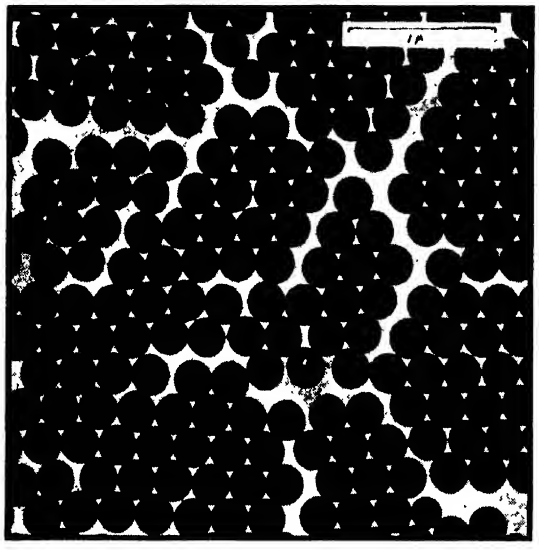

FIG. 1. Electron micrograph of single layer, latex particle array.

Since this unique batch of latex is of extremely limited quantity, the precautions in handling the material should be emphasized. Agglomeration is a danger and may be prevented by avoiding freezing, chemical contamination or change in pH. Agglomeration as a result of the evaporation of water from the undiluted latex is a hazard which is acute, especially in the 5 cc vials in which much of the latex has been distributed. Several laboratories have reported that their latex has completely dried even though the caps were apparently tight. It is suggested that either the bottles be periodically checked and kept filled to the top by additions of distilled water, or the whole sample be diluted 5:1 or 10:1.

The danger of bacterial contamination is not generally recognized. Experience has shown that certain bacteria can thrive and multiply in the latex resulting in eventual complete ruin of the material. This is difficult to combat, but special handling precautions and possibly refrigeration above 0°C will help.

As mentioned previously, a study was made on the effect of dilution ratio on particle size and no variation was found. However at dilutions of 1:500 and less, considerable fusing of the spheres resulted. In most cases, this fusing was slight near the wires of the supporting screen and severe in the center of the openings. An explanation may be that the surface active agents are present to such a concentration in the 1:500 or less dilutions that during drying, these agents are further concentrated to a point where they act as a plasticizer and cause fusing. It should be pointed out that the use of an atomizer may appreciably decrease this danger.

The danger of overheating in the electron microscope appears to be of importance only at the high intensities found with the biased gun. Fusing and distortion can result under such conditions. A much more real danger is found as a result of the specimen contamination which occurs under electron bombardment. These latex spheres make an ideal specimen for studying this phenomenon. Particles commonly show an increase in diameter of 4 percent to 5 percent after 20 minutes bombardment with a 300 microampere beam from a non-biased gun.

R. A. Kern and S. F. Kern† have recently discovered increases in the diameter of latex spheres as a result of shadowing, which cannot be explained by the mere thickness of the metal film on the particles. They have tentatively explained the size variations as being the result of an electrostatic charge on the unshadowed spheres which is removed by metal shadowing, providing it grounds the spheres. The possibility of such an effect should be carefully considered when these spheres are used in applications where shadowing is necessary.

Two electron micrographs are included which illustrate the particle arrays which are possible with spheres having the uniformity of diameter found in this material. Figure 1 shows a single layer particle array and Fig. 2 shows a multiple layer array in

FIG. 2. Electron micrograph of multiple layer, latex particle array. Shows areas of 1, 2, 3 and 4 layers of spheres.

which 1, 2, 3 and 4 layers of spheres can be seen. It is obvious that such arrays would be impossible without a high degree of uniformity of the spheres involved. One sphere of slightly different size will completely destroy the symmetry of the area around it.

At the present time, there are still some samples of this particular batch of latex 580G available to electron microscopists. They may be obtained by contacting the author.

Erratum: Relationship between Gough-Joule Coefficients and Moduli of Vulcanized Rubbers

[J. App. Phys. 20, 526 (1949)]

F. S. CONANT, G. L. HALL, AND G. R. THURMAN
Chemical and Physical Research Laboratories, The Firestone Tire and Rubber Company, Akron Ohio

IT has been pointed out by Dr. Sidney M. Katz of Textile Research Institute Laboratories that the thermodynamic reasoning leading to Eq. (8) of the above article is faulty, although the equation itself is valid. A correct thermodynamic derivation is possible, as Dr. Katz has demonstrated in a private communication. In view of the relatively simple mathematical derivation of Eq. (8), however, any involved thermodynamic approach appears unnecessary.

Frictional Loss in Visco-Elastic Substances

B. Gross
National Institute of Technology, Rio de Janeiro, Brazil
November 22, 1949

In two previous papers we have developed the phenomenological theory of linear visco-elastic behavior.[1] In this theory the elastic loss was associated exclusively with the relaxation mechanism which is also responsible for the frequency dependence of the dynamic modulus. On this basis the loss is uniquely determined when the dynamic modulus function is known. It seems, however, to be likely that another cause for elastic loss also exists, i.e. a "true" frictional mechanism which leads to a loss varying independently of the visco-elastic loss. The corresponding frictional force is assumed to be proportional to the rate of change of deformation and the proportionality factor, which is called frictional coefficient, is considered to be constant.[2] It might be instructive to examine experimental data for the presence of such a constant friction. The new loss component will be of importance at very high rates of deformation (or high frequencies). Therefore, the mathematical treatment now will have to take into account inertia forces too; this means that it must be based on the wave equation. But it will be sufficient to consider the unidimensional case only, because in the recent methods for the determination of the visco-elastic constants by means of sound waves the samples have the form of long thin strips which for all practical purposes can be considered as unidimensional ones.[3]

For a linear strip of material the unidimensional wave equation can be written in the form

$$q\rho\frac{\partial^2 u}{\partial t^2}dx=k, \tag{1}$$

where u is the displacement from equilibrium position of a cross section, ρ the density, and k the resultant force acting on a volume element of the sample, i.e. the difference of forces between x and $x+dx$.[4] The force now contains 3 components: (a) A component which corresponds to Hooke's law and contains the instantaneous elastic modulus E. (b) A component which takes account of the relaxation mechanism and contains the relaxation function $\bar{\varphi}(t)$. (c) A component which represents the frictional force and contains the constant frictional coefficient γ. Thus k is written

$$k=qE\frac{\partial^2 u}{\partial x^2}dx-q\int_{-\infty}^{t}\frac{\partial^2 u(x,\tau)}{\partial x^2}\bar{\varphi}(t-\tau)d\tau dx+\gamma q\frac{\partial^3 u}{\partial t\partial x^2}dx. \tag{2}$$

(1) and (2) together constitute an integro-differential equation which replaces the simpler equations of the former papers. While the general solution is involved, a particular solution of the form

$$u=u_0\exp(i\omega(t-x/c)-\alpha x) \tag{3}$$

is easily seen to exist; it represents a linear wave traveling from $x=0$ to $x=\infty$, of frequency ω, phase velocity c, and attenuation factor α. Substitution of (3) into (1) and (2) gives

$$(E-\bar{A})+i(\omega\gamma+\bar{B})=\frac{\rho\omega^2}{(\omega/c+i\alpha)^2}, \tag{4}$$

where $\bar{A}$ and $\bar{B}$ are, respectively, the storage factor and the loss factor already given in II:

$$\bar{A}(\omega)=\int_0^\infty \cos\omega\tau\bar{\varphi}(\tau)d\tau, \tag{5a}$$

$$\bar{B}(\omega)=\int_0^\infty \sin\omega\tau\bar{\varphi}(\tau)d\tau. \tag{5b}$$

Equation (4) is formally identical with Nolle's Eqs. (5). Introducing the complex elastic modulus $E^*=E_1+iE_2$ there is

$$E_1=E-\bar{A} \tag{6a}$$

$$E_2=\gamma\omega+\bar{B}. \tag{6b}$$

According to Eqs. (6), the Hookean mechanism contributes only to the real part of E^*, the frictional force to the coefficient of the imaginary part, and the relaxation mechanism to both of them. Since $\bar{A}(\infty)=0$, the instantaneous elastic modulus is obtained from a plot of E_1 *versus* frequency as the high frequency limit of E_1. $\bar{B}$ is 0 for both $\omega=0$ and $\omega=\infty$; $\gamma\omega$ is linearly increasing with frequency. Therefore, at very high frequencies where E_1 has become practically constant, E_2 should increase linearly with frequency. From the slope of the loss factor curve at high frequencies one then may read γ. The relations between $\bar{A}$ and $\bar{B}$ were already discussed in II. It will be interesting to calculate $\bar{B}$ from data of $\bar{A}$ and to see whether the result still leaves room for a component $\gamma\omega$.

Addendum: Interpretation of X-Ray Patterns of Cold-Worked Metal

[J. App. Phys. **20**, 885 (1949)]

B. L. Averbach and B. E. Warren
Massachusetts Institute of Technology, Cambridge, Massachusetts

In a letter under this title the next to the last sentence applied the Fourier coefficient method to the particle-size problem. "For a substance in which there is particle-size broadening only, the initial slope of the A_m *vs.* m curve gives an average particle size and the second derivative of the curve gives directly a size distribution." Unfortunately at the time of writing we were not aware that this same result had already been obtained by E. F. Bertaut[1] in France.

Bibliography on Offshore Petroleum Developments

E. N. Kemler
Southwest Research Institute, San Antonio, Texas
November 17, 1949

The Division of Oceanography and Meteorology of Southwest Research Institute recently published the first Bibliography on Offshore Petroleum Developments. Intended as a practical and useful guide, the Bibliography is a public service presentation of the Institute available to any organization, company, or individual whom it might benefit. Requests for copies should be directed to The Division of Oceanography and Meteorology, Southwest Research Institute, 312 Oil and Gas Building, Houston, Texas.

New Books

Modern Arms and Free Men

By Vannevar Bush. Pp. 273, Simon and Schuster, New York, 1949. Price $3.50.

Dr. Vannevar Bush has probably had a greater influence on *applied physics* than any other scientist of our time. His invention of the differential analyzer and its use for the solution of non-linear equations initiated the great developments in electrical calculating machines. He is famous for his leadership of the Carnegie Institution of Washington, where he has had a direct hand in the success of the 200-in. Mount Palomer telescope. He was chairman of the National Advisory Committee for Aeronautics during the critical pre-war years. But his greatest contribution is his wartime leadership of a substantial fraction of all U. S. scientists, as Director of the Office of Scientific Research and Development. In this position Dr. Bush's leadership made itself felt not only in the highest councils in Washington, but more importantly, through all levels of the vast OSRD organization, so that even the youngest men knew instinctively that all worth while developments would find effective use.

Dr. Bush gives us a very clear account of the continuing menace of the submarine, the combating of which remains the most pressing problem facing the navy of any maritime power in its mission to keep the sea lanes open for transport. In the first World War and again in the second, the German submarine held the outcome in doubt and it cost us heavily to overpower it. The technical development and tactics of sonar, radar, the sono-radio buoy, and the magnetic airborne detector, as well as greatly improved ship and aircraft-launched ordnance, finally turned the tide against the U-boat. But pro-submarine developments that came too late to re-establish the submarine's supremacy—the schnörkel, the long-range homing torpedo, and new types of fast, deep-traveling submarines are now in the hands of potential sea commerce raiders. The added fact that the submarine, along with the merchant ship, may well be the agent for delivery of the atomic bomb accounts for Dr. Bush's current insistence on vigorous anti-submarine developments.

The atomic bomb naturally occupies a central position in this book. In his considered judgment, Dr. Bush evaluates this as a weapon of extreme power but not absolute in the sense that it makes other modes of warfare obsolete. Gone, in his analysis, is the abject fear which paralyzes clear thinking and wise planning, and gone also are the overestimates which are equally fatal.

The atomic bomb presents a grave problem in its continuing strain on the peacetime economy of the nation. This is partly compensated for by the fact that of all war materials it is probably the best suited for stockpiling purposes and in addition holds potentially great possibilities for peacetime applications. In contrast to the submarine menace, the defense against the atomic bomb seems to Dr. Bush to have great promise in the future. The development of guided missiles with proximity-fused ordnance as well as the effective use of radar warning and attack systems backed up by jet fighters may well spell the doom not only of long-range atomic bombing, but also of all forms of mass bombing against an alert and fully equipped nation. That these defensive methods may be deciding factors is suggested by the experience in the Schweinfürt raid, and also in the late but very effective introduction of the proximity-fused shell for the defense of London and the battle of Antwerp. Guided missiles will thus not only extend the offensive range of artillery and the fire power of aircraft, but may even be decisive in dooming the future effectiveness of large naval ships, and in defending great cities. The use of guided missiles on intercontinental raids Dr. Bush rules out on the basis of their excessive cost as against other forms of attack.

Proper planning for a national emergency Dr. Bush emphasizes as the theme of this book. This includes a clear recognition that cost, in its broadest sense of the effective use of the manpower and industrial and scientific capacity of a nation, is the crucial element in war. He gives brief but clear examples of how the magnetron tube and early forms of radar and sonar were available to the British and ourselves but not to the Germans at the outbreak of the war. Furthermore, the fact that wartime developments in Germany failed not only to produce an atomic bomb, but more significantly that they failed to provide jet fighters in quantity for defense against bombing shows the fatal consequences of a system which ignores the power of free scientific inquiry. It is hoped that peacetime planning, and especially education, will fully realize the emphasis placed here by Bush, and elsewhere by Conant, for the necessity of proper educational opportunities for all gifted youth in the nation, regardless of their financial status. It may well be fatal to the national safety to waste their talents.

This is one of the most important books since the war. It should be required study for every person holding even a minor position in national planning, and it is to be hoped that it may be brought to the attention of many young people, some of whom may someday find themselves over night in positions of great responsibility in a national emergency.

R. S. Shankland
Case Institute of Technology

Journal
of
Applied Physics

Volume 21, Number 3 March, 1950

British Journal of Applied Physics

IT is a pleasure to welcome a new journal to the fold of physical literature. In January of this year there appeared Volume One, Number One, of the *British Journal of Applied Physics*. This new journal is published by the Institute of Physics in Great Britain under the editorship of Dr. H. R. Lang, the Secretary of the Institute. In a foreword in this first issue, Dr. T. C. Toy, President of the Institute of Physics, mentions the interest which the Institute has had in applied physics since 1918. The first fruit of this interest was the inauguration in 1923 of a series of monographs and lectures under the general title of "Physics in Industry." This was followed by the establishment of the Institute's *Journal of Scientific Instruments*. Now the parts of this journal related particularly to the new applications of physics and new developments have been separated and published together as the *British Journal of Applied Physics*.

The first issue of this new journal sets a high standard indeed. The two leading articles are of a general nature, one entitled "A Scientific Education" by Sir Philip Morris, and the other on "Some Chemical and Physical Properties of Rubber" by J. Moore. There then follow five original contributions on the Development and Deionization Time of Heavy-Current A.C. Arcs, Measurement of Opacity and Reflectivity for Printing Papers, Measurement of the Coefficient of Internal Friction of Solid Rods by a Resonance Method, The Application of Multiple Factor Analysis to Industrial Test Data, and a Note on the Interpretation of Multiple Factor Analysis. In addition, this issue reviews several new books of particular interest to applied physicists.

The new journal is printed on a high quality coated stock which allows excellent reproduction of halftones. The page size and general appearance are similar to that of the *Journal of Scientific Instruments*. A small number of advertisements are also included.

There is an interesting and significant parallel in the development of applied physics in Great Britain and in the United States. As mentioned, the Institute of Physics was established in Great Britain in 1918. In 1931 the several national organizations devoted to physics and its applications in this country established the American Institute of Physics. The first publication to come under the direct sponsorship of the American Institute was the *Review of Scientific Instruments*. An Advisory Council on Applied Physics was established, and the theme of the large conference celebrating the fifth anniversary of the founding of the American Institute was "Physics in Industry." Shortly thereafter, in 1937, the *Journal of Applied Physics* was launched. Now the parallel is completed with the publication of the *British Journal of Applied Physics*. Such a close parallel is indeed an indication of the real place that exists in each country for a journal devoted to the interests of the applied physicist. Significantly journals of almost the same name and purpose have recently been established in all of the principal countries of Europe.

We want in this brief note to congratulate Dr. Lang on this new venture of the Institute of Physics and join Dr. Toy in requesting "our many friends all over the world to support this journal by contributing to its pages, by subscribing to it, and by encouraging others to do so also."

ELMER HUTCHISSON

Microwave Angle Separation on a Two and One-Half Mile Overwater Path*

A. W. Straiton and A. H. LaGrone
The University of Texas, Austin, Texas
(Received August 29, 1949)

This paper describes the results of radio angle-separation measurements on a 2.50-mile path over Lake Buchanan near Austin, Texas. The measurements were made to test the angle-separation equipment developed at The University of Texas, and to compare these results with measurements obtained by rocking a 20-foot parabolic antenna.

I. INTRODUCTION

THE measurement of the angle-of-arrival of radio waves at near grazing angles is complicated by reflections from the ground. This paper describes measurements made to separate the direct wave from the ground-reflected wave, using a wave-length of 3.2 centimeters.

The measurements made in this report were for two rays arriving at angles separated by less than 0.5 degree. The magnitude of the reflected ray was measured to be 0.94 of the direct ray. Thus, these conditions of two rays of approximately equal magnitude arriving at such small angles of separation made the problem of their separation a very difficult one.

The angles measured by the phase-difference method are not singular, but are ambiguous. For a spacing of 5 feet and a wave-length of 3.2 centimeters, this ambiguity occurs every 1.2 degrees. This difficulty could be resolved by coarser methods of measurement.

Three different methods were used in the angle determinations.

1. The first method requires as data the relative phase and the relative signal strength of three vertically spaced antennas. This method will be referred to throughout this report as the "three-antenna method."

2. The second method requires as data the relative phase between two antennas, the signal strength at the two antennas relative to the maximum signal from a height-gain curve, and the minimum signal from a height-gain curve. This method will be referred to throughout this report as the "two-antenna method."

3. The third method requires as data the record of the signal received by a large antenna as its axis is tilted through an angle large enough to include the two-wave components. This method will be referred to throughout this report as the "amplitude method."

II. THEORY OF MEASUREMENT METHODS

1. Three-Antenna Method

This method assumes two plane or two spherical waves arriving at three vertically spaced antennas. If the resultant phase differences between the three antennas and the resultant relative signal strengths at the three antennas are known, the angles-of-arrival of each of the two-wave components, their relative magnitudes and their relative phase at the center antenna may be determined by calculations and charts. This mathematical relationship has been described elsewhere.[1,2]

Equipment has been built at the Electrical Engineering Research Laboratory of The University of Texas for obtaining these desired data. The basic phase-difference equipment has been described in Report 8,[3] and the operation characteristics of the three-antenna equipment has been described in Report 24.[4]

This method does not require moving the antenna system and hence gives instantaneous data.

2. Two-Antenna Method

The two-antenna method requires a height run over a wide enough range to include at least one signal strength minimum and one maximum. In addition, the phase difference between two points and the signal strength of these points relative to the signal strength maximum must be known.

For the five-foot spacing between antennas used in this work, the angle-of-arrival of the direct wave, θ_D, and the angle-of-arrival of the reflected wave, θ_R, are given by

$$\theta_D = -(1/300)(d\beta + A_z - A_0), \tag{1}$$

$$\theta_R = \theta_D - (1/300)(T_z - T_0). \tag{2}$$

In these equations, $d\beta$ is the phase of the upper antenna signal minus the phase of the lower antenna signal. A_z and T_z are terms which depend on the signal at the upper antenna relative to the maximum signal strength. A_0 and T_0 are the corresponding terms for the lower antenna. If the signal strength is increasing with height at the point in question, A is positive and T is negative. If the signal strength is decreasing with height, A is negative and T is positive.

The derivation of the basic relationships and the

charts for obtaining A and T are given elsewhere.[5] The minus sign in front of the right-hand expression of Eq. (1) was omitted in reference 5.

3. Amplitude Method

This method involves the use of a large antenna which is tilted so as to determine its scanning pattern in a vertical plane. The antenna used was a 20-foot parabolic antenna with a rectangular face. This antenna was used by the Bell Telephone Laboratories in their early microwave angle-of-arrival measurements,[6] and was subsequently made available to the Electrical Engineering Research Laboratory. It is assumed that maxima in the scanning pattern occur when the tilt is such that the axis of the parabola is pointed in the direction of an incoming wave component.

III. MEASUREMENT SITE

1. Location

The radio path chosen was across Lake Buchanan located about 65 miles from Austin. The length of the path was about two and one-half miles. This length of path was chosen because (1) it made possible a range of angles up to about 0.5 degree; (2) it was long enough to reduce the effect of wave curvature; and (3) it was short enough to make the effect of meteorological changes small.

2. Transmitter

The transmitter was located on a 50-foot tower approximately 20 feet from the water's edge, and had a minimum height of 11 feet above the water. The transmitter assembly used a 2K39 Klystron with a c.w. output of 200 milliwatts.

3. Receivers

The 60-foot receiving tower, with the three receiving antennas mounted on an elevator, was located about 300 feet from the water's edge. The minimum height of the center antenna was 22 feet above the lake level. The vertical spacing of the three-antenna array was five feet. A reference transmitter was moved in front of the receiving antenna and surveyed into position when a reference angle was needed.

The Bell Laboratories' antenna was located near the 60-foot receiving tower and about 250 feet from the water's edge. A synchronous motor was provided for rocking the antenna at a uniform rate. However, in taking the scanning patterns used in this report, the antenna was tilted by hand in order to obtain its position more accurately. The center of the 20-foot parabola was 30 feet above the water.

[5] Straiton, Gordon, and LaGrone, "A method of determining the angle-of-arrival," J. App. Phys. **19**, 524–533 (1948).

[6] W. M. Sharpless, "Measurement of the angle-of-arrival of microwaves," Proc. Inst. Radio Eng. **34**, 837–845 (1946).

4. Meteorological Station

In order to compensate for changes in the meteorological conditions near the ground, a meteorological station was set up near the receiving site. A tilted 60-foot mast imbedded at the water's edge permitted raising a recording psychrometer a short distance out from shore in the direction of the prevailing wind. An anemometer was located near by to make a record of the wind speed and direction.

5. Angles-of-Arrival under Standard Conditions

The angular separation of the direct and reflected rays is a function of the height of the transmitter and the path length for standard meteorological conditions. This angular separation is shown for various transmitter heights in Fig. 1.

The angles-of-arrival of the direct and reflected rays are functions of transmitter and receiver height and path length. These angles-of-arrival as a function of transmitter height are plotted in Fig. 1 for a number of receiver heights with correction applied for the refraction associated with standard meteorological conditions.

IV. RESULTS OF MEASUREMENTS

1. Three-Antenna Method

Measurements were made of the angle-of-arrival by the three-antenna method for 164 cases. These were made for various combinations of transmitter and re-

ceiver heights. More cases were considered with the receiver at 30 and 35 feet than at any other height, since this was approximately the height of the center of the 20-foot antenna. More cases were considered with the transmitter at 11 feet than any other height, since this presented the smallest angular separation of the direct and reflected rays.

From the phase differences and signal-strength ratios between the three antennas, the angles-of-arrival of the direct and reflected rays were calculated by the method of reference 1.

The modified index-of-refraction profile was determined from meteorological measurements made simultaneously with the radio measurements. Since the

changes in refraction with meteorological changes were small, linear values for index gradients were assumed for the height-range of the direct and of the reflected rays. The angles of Fig. 1 were corrected by use of the appropriate M-gradient, and the corrected values compared to those measured.

For a qualitative evaluation of the test, the results were grouped into four classes. The first was the group for which the radio measurements differed from the geometrical angles corrected for refraction by 0.02 degree or less. The second group included measurements for which the error was 0.06 degree or less, but greater than 0.02 degree. The third group included those with errors of 0.1 degree or less, but greater than 0.06 degree. The fourth group included those cases for which the error was greater than 0.1 degree. The groups might be classified as (1) extremely accurate, (2) acceptable, (3) inaccurate, and (4) useless.

The results of the 164 cases measured by the three-antenna method are shown in Table I. The division of the measurements between the four groups is shown in percentage in two ways at the foot of Table I. The first percentages are based on all of the measurements made. The second percentage excludes the cases for which the data would indicate that correct results could not be obtained. The number of cases omitted in the second percentage is shown in parentheses in the tabulation.

The excluded cases included several for which the direct and reflected waves are nearly in-phase or 180 degrees out-of-phase at the center antenna. It has been shown previously[1] that the method used becomes very inaccurate for these conditions. These conditions are known from the data to exist when the phase difference between the upper and middle and lower and middle antennas are equal, and the corresponding signal-strength ratios are equal.

All cases for which the ratio of the signal at two antennas exceeded 12 db were aslo excluded since the equipment was known to be inaccurate under these conditions. For a single-component wave arriving at the receiver, the signal-strength ratios will both be one and the phase difference between antenna pairs will be equal to each other. Under these conditions, the solution provided by the three-antenna method will be the true angle-of-arrival of the single-component wave plus a fictitious angle 0.3 degree above the true angle. In the case of the measurements made with the transmitter at 11 feet, the signal strength ratios are nearly one, and the angle between antenna pairs nearly equal to each other. This means that an extremely high degree of accuracy is required in obtaining the data if the angle-of-arrival of each component is to be determined. Apparently, this accuracy was not always met, and the result was that the apparatus measured only a single ray coming from approximately halfway between the transmitter and its reflection. The second angle did not exist but was introduced in the mathematical processes. This accounts for the fact that so many of the direct-ray measurement errors were between 0.02 and 0.06 degree, and the "reflected" ray errors were greater than 0.1 degree when the transmitter was at 11 feet.

The calculation of the angles-of-arrival by the three-antenna method requires subtracting the products of the signal-strength ratios and sines and cosines of the phase differences. When the products to be subtracted are of approximately the same magnitude, accuracy with which the difference is known is very low. For this reason, a very high degree of accuracy in the original data must be obtained. Cases where the difference of the two products was less than 0.1 were placed in the excluded group.

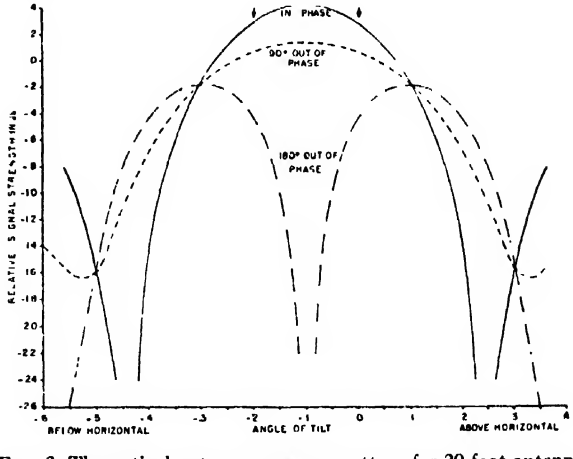

FIG. 3. Theoretical antenna response pattern for 20-foot antenna

TABLE III. Errors in angles-of-arrival of the direct and reflected rays.* Amplitude method.

Transmitter height	Separation angle	Direct ray $.00° < \alpha \leq .02°$	$.02° < \alpha \leq .06°$	$.06° < \alpha \leq .10°$	$.10° < \alpha$	Reflected ray $.00° < \rho \leq .02°$	$.02° < \rho \leq .06°$	$.06° < \rho \leq .10°$	$.10° < \rho$
11 feet	0.10°	0	0	0	1	0	1	0	0
21 feet	0.19°	0	0	1	2	1	1	0	1
33 feet	0.29°	0	0	0	2	0	0	0	2
43 feet	0.38°	0	0	1	1	0	0	1	1
53 feet	0.47°	1	1	0	0	0	0	2	0
		10%	10%	20%	60%	10%	20%	30%	40%

* Numbers in parentheses are the number of cases which were rejected. Percentages in parentheses are based on the number of accepted cases.

Although the results of this initial field test of the three-antenna method cannot be classed as highly satisfactory, it is felt that with improvements in the accuracy of the original data will come improvements in the accuracy of measuring the angles.

2. Two-Antenna Method

The two-antenna method required as data a height-gain curve and the phase difference between two points. The phase measurements of the three-antenna method provided the necessary phase difference data for the two-antenna method, and a height run after most of the three-antenna tests provided the necessary signal strength data.

One hundred and eighteen sets of measurements were made by the two-antenna method, and the results were classified in the same manner as for the three-antenna method. This classification is shown in Table II. Two sets of percentages are again shown: one for all the data, and one excluding the data for which the signal ratio between the antennas exceeded 12 db.

The height-gain curves agree precisely with those which would be obtained from two waves with a relative magnitude of 0.94. This equivalent reflection coefficient was virtually the same for all days, and was independent of transmitter and receiver heights.

The accuracy of the angle-of-arrival calculations by the two-antenna method is very satisfactory. However, this method has obviously disadvantages which limit its usefulness. A height-gain curve including signal strength maximum and minimum is not always obtainable. In addition, all of the needed data are not available instantaneously.

For fluctuating or changing conditions, this makes the angle determination difficult or impossible. However, the conditions of the present test made possible highly accurate evaluation of the angles-of-arrival by the two-antenna method.

3. Amplitude Method

Scanning patterns for the 20-foot antenna were made for a number of transmitter heights on a day when the atmospheric conditions were known to be nearly standard. These antenna patterns for five-foot intervals of the transmitter are shown in Fig. 2. The arrow in the diagram indicates the angle-of-arrival determined from geometry, corrected for refraction.

The angles-of-arrival as determined from the signal strength maxima are classified in Table III in the same way as for the previous methods.

As shown in a previous report,[7] the scanning patterns for two waves arriving simultaneously is greatly affected by the phase relationship of the two waves. This is illustrated by the theoretical scanning patterns shown in Fig. 3. When the two waves of nearly equal amplitude arrive in phase at the center of the antenna face, a single maximum results, positioned between the true angles-of-arrival. When the two arriving waves are 180 degrees out-of-phase at the center of the two antennas, two distinct maxima appear. However, these maxima indicate an angular separation of the two rays which is too large.

V. SUMMARY

The field test of the three-antenna angle-separating equipment showed that under the most desirable circumstances, the angles-of-arrival of two-wave components may be measured accurately. However, more accuracy is required in the original data if reliable results are to be obtained under all conditions.

The three-antenna system is basically a very significant one because it involves no time delay in taking the data. Because of this instantaneous action of the method, it is felt that further development is justified. Greater accuracy could be obtained by increasing the antenna spacing. This would, however, reduce the angle of ambiguity.

The two-antenna method showed a very high degree of accuracy and gave by far the best results of the three methods considered. However, the requirement of a height-run to determine the signal-strength maximum and minimum limits its usefulness.

The amplitude method appears to be unsatisfactory for separating two rays of nearly equal magnitude with angular separations comparable to the width of the basic antenna pattern. However, the difficulty of ambiguity of the measurement is eliminated in this method.

[7] LaGrone, Hamlin, and Straiton, "The indicated angle-of-arrival by phase front analysis," Report No. 12, Electrical Engineering Research Laboratory, The University of Texas, 1948.

The scanning patterns would not be reliable in a rapidly fluctuating field. The original experiments with the 20-foot antenna did not require the separation of two-wave components so nearly equal or separated by as small an angle as in the test described in this report.

VI. ACKNOWLEDGMENT

The Electrical Engineering Research Laboratory wishes to acknowledge its gratitude to the Bell Telephone Laboratories for the use of the parabolic antenna which provided the comparison test.

Immobility Phenomena and Reverse Driving Phenomena of the Electric Arc

SAKAE YAMAMURA

The Electrical Department, Faculty of Engineering, University of Tokyo, Tokyo, Japan

(Received June 22, 1949)

When an electric arc is driven by a magnetic field, under special conditions, curious phenomena are observed. An electric arc cannot be driven by the magnetic field when it is established at very small gaps between the electrodes. Neither can it be driven by the magnetic field for the instant just after the contacts have been broken. These phenomena are called immobility phenomena. In the present work, the immobility time and the driving velocity of the electric arc were measured under various air pressures. As the air pressure decreases, the immobility time increases and the driving velocity decreases. Under a certain low air pressure, the arc cannot be driven by the magnetic field. When the air pressure is lower than this critical value, the arc can be driven again by the magnetic field; but in this case, the arc moves in a direction that is opposite to the direction of the electromagnetic force. This phenomenon is called the reverse driving phenomenon. The causes for these phenomena are considered.

I. INTRODUCTION

WHEN an electric arc is established in the presence of the magnetic field, curious phenomena are observed. Under normal conditions, the arc moves in the same direction as the electromagnetic force. Under some special conditions, such as at a very small gap,[1] just after the contacts have been broken,[1,2] and at low air pressures,[3,4] the arc cannot be driven by the magnetic field. Scars on the electrodes made the electric arc remain stationary. Under still other conditions, the arc moves in a direction that is opposite to the direction of the electromagnetic force.

These phenomena were observed independently by several persons including the author.[1,3] But interrelations between these phenomena have been missed. Some of the experimental results and considerations about these phenomena will be presented in the following reports.

II. EXPERIMENTAL APPARATUS

A picture of the experimental apparatus that was used is shown in Fig. 1. The electric arc is established by separating two parallel copper electrodes. The electrodes are placed horizontally and are sealed in a glass vessel which is connected to a rotary vacuum pump. The driving magnetic field is applied perpendicularly to the arc as is shown by the arrow H in Fig. 1. The electrodes are pulled apart and shorted together by an electromagnet (there is no relation between this magnet and the driving magnetic field). The magnet which pulls apart and shorts together the electrodes is controlled by a rotary switch that is connected to the shaft of a rotating mirror. The image of the arc is focused through a lens and is reflected on the screen by a rotating mirror. Since the mirror is rotating, the image of the arc will repeatedly sweep from the bottom to the top of the screen. The rotating mirror revolves at a constant velocity. In this way, the loci of the images of several successive electric arcs will appear in the same position on the screen. If the arc is stationary, the locus of its image on the screen is a vertical line (as from a to b). If the arc is driven by the magnetic field, the locus of its image is an oblique line (as from b to c). The horizontal velocity of the arc can be determined by measuring the angle θ of the locus on the screen.

III. OBSERVATIONS

1. The Magnetic Driving of a Contact-Arc

An electric arc which is generated by breaking contacts is named a contact-arc. The movements of a contact-arc which was driven by the magnetic field were observed with the apparatus described in Section II. The locus of the image of the contact-arc was the same as the locus shown on the screen in Fig. 1. This locus indicates that the contact-arc is stationary for an instant just after the contacts have been broken; then it begins suddenly to be driven by the magnetic field. After being driven for a moment, the arc goes out. This phenomenon was named the immobility phenomenon.[1,2] The author proposes to name it the momentary immobility phenomenon to distinguish it from the permanent immobility phenomenon. The permanent immobility phenomenon will be discussed later.

[1] S. Yamamura, J. Inst. Elec. Eng. Japan **61**, 660 (1941).
[2] S. Fukuda, J. Inst. Elec. Eng. Japan **62**, 161 (1942).
[3] S. Yamamura, Report of Annual Meeting of Inst. Elec. Eng. Japan, 16 (1948).
[4] G. J. Himler and G. L. Cohn, Elec. Eng. **67**, 1148 (1948).

The immobility time and the driving velocity of the contact-arc were measured under various air pressures. Figure 2 shows one example of these measurements.

As the air pressure decreases, the driving velocity decreases and the immobility time increases. At a certain pressure (in Fig. 2, 350 mm Hg), the electric arc cannot be driven by the magnetic field, and it remains permanently stationary. This phenomenon is called the permanent immobility phenomenon.

When the pressure is reduced below this critical value (350 mm Hg), the arc can be driven again. But

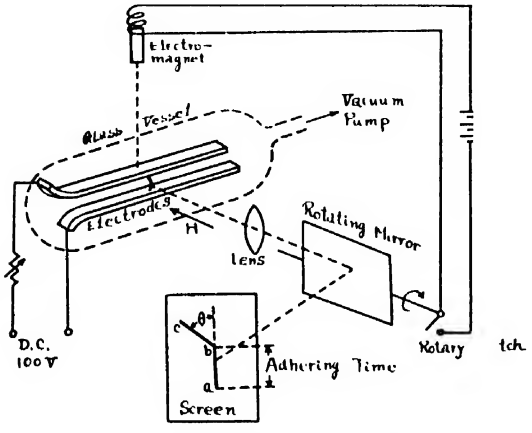

FIG. 1. Apparatus for experimenting with the magnetic driving of the electric arc.

in this case, the arc moves in a direction that is opposite to the direction of the electromagnetic force. This phenomenon is called the reverse driving phenomenon.

As the air pressure decreases further, the reverse driving velocity increases greatly and the immobility time decreases to almost a zero value, as one can determine from Fig. 2.

The same sequence of phenomena occurs when the arc current and the driving magnetic field are of different values; but, in these cases, the critical air pressure at which permanent immobility occurs is different. These relations are shown in Fig. 3. The critical air pressure (the pressure at which permanent immobility occurs) increases as the magnetic field intensity increases. This is contrary to the statements of Himler and Cohn,[4] who reported that the critical air pressure decreased as the magnetic field increased.

The same experiments were performed with several different electrode materials to decide whether they would show permanent immobility and reverse driving. One example using aluminum electrodes is shown in Fig. 4. The aluminum electrodes have a wider pressure range where permanent immobility occurs.

All of the experimental results are summarized in Table I. The materials are arranged as grouped by Druyvesteyn and Penning.[5] These authors arranged the various metals into nine groups according to the mobility of the cathode spot of the metal.

Permanent immobility was observed with all of the materials that were examined. When the air pressure was reduced to 50 mm Hg, reverse driving was observed in all of the groups except groups I and II.

2. Some Other Immobility Phenomena of the Electric Arc

When an electric arc is established at a very small gap between the two parallel electrodes, it cannot be driven by the magnetic field. In this case, even under a normal atmospheric pressure, permanent immobility occurs.

Since a molten metal bridge exists between the electrodes which are separated very slowly, the arc does not appear until the electrodes have been separated to the displacement (D_1) which is shown by the broken line in Fig. 5. The continuous line of Fig. 5 indicates the displacement (D_2) of the movable electrode at which the arc begins to move quickly. Between displacements (D_1) and (D_2) the arc cannot be driven by the magnetic field.

Scars on the electrodes, especially on the cathode, also make the electric arc remain stationary.

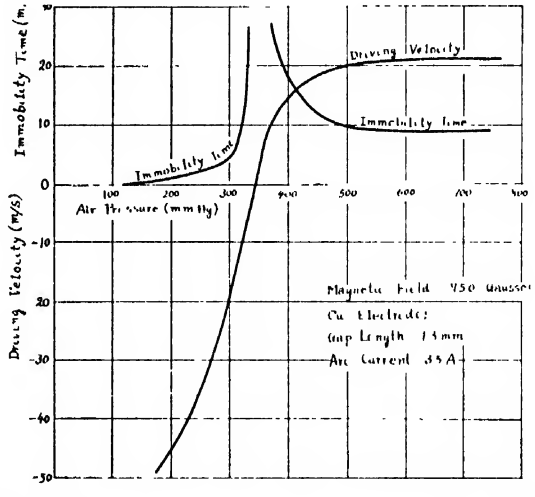

FIG. 2. The relations between the air pressure, the immobility time and the driving velocity of the contact-arc.

IV. CONSIDERATIONS

C. G. Smith[6] reported about the reverse driving of the cathode spot of a mercury arc. He explained this phenomenon by using the negative Righi-Leduc effect, but his explanation does not seem plausible. Not only do the metals with a negative coefficient of the Righi-Leduc effect (for instance Mg, Cu and Ag), but also the metals with a positive coefficient (for instance Fe) show reverse driving. It is impossible that the coeffi-

* According to C. G. Smith (see reference 6).

cient of the Righi-Leduc effect changes its sign from positive to negative with any change of air pressure.

Our explanation involves the electron diffusion theory. Himler and Cohn[4] and the author[3] applied almost the same explanation. An enlarged picture of a cathode spot is shown in Fig. 6. When the magnetic field is applied perpendicularly from the front to the back of the paper, the loci of electrons leaving the cathode are bent to the right side by the magnetic field as is shown in Fig. 6. Thus there ensues the rightward movement of the arc, which is the normal magnetic driving of the arc.

When the atmospheric pressure is much lower, that is, when the mean free path of the electrons is longer, the path of the electrons appears to be influenced to a great degree by the magnetic field. Many electrons with energy corresponding to the cathode fall, diffuse outwards in the positive space charge cloud. The loci of these electrons are bent by the transversal magnetic field as is shown in Fig. 6. The electrons diffusing to the left side are accelerated by the electric field, and thus these electrons efficiently ionize the gas molecules by collision. The electrons diffusing to the right side are decelerated by the electric field because these electrons are moving in an opposite direction to the electric field. Thus the electrons moving to the right side cannot efficiently ionize the gas molecules by collision. In this way, the positive space charge cloud spreads to the left side.

If this leftward spreading of the positive space charge cloud overcomes the rightward spreading (the normal magnetic driving of the arc), then reverse driving ensues, If these two spreadings balance each other, then permanent immobility ensues. These phenomena can occur only when the diffusing electrons have a comparatively long mean free path, and when their loci are bent notably by the magnetic field. Let us check this.

From Fig. 3 we can see that the critical air pressure at which permanent immobility occurs is 100–200 mm Hg at 360 gausses. The electron mean free path (λ_0) in the atmosphere is 3.6×10^{-5} cm at 0°C. The temperature of the positive column of the arc is 5000–10,000°K. A great many electrons in the positive space charge cloud, which have been accelerated by the cathode fall, have a very high temperature. Since this is true, the temperature of the gas molecules in the positive space charge cloud would be higher than the temperature of the positive column. Therefore the temperature of the gas molecules could be assumed to be 10,000°K. Then the electron mean free path (λ_r) at 100 mm Hg is

$$\lambda_r=\lambda_0\times\frac{760}{p}\times\frac{T}{273}=3.6\times10^{-5}\times\frac{760}{100}\times\frac{10{,}000}{273}=1.0\times10^{-2}\text{ cm}. \quad (1)$$

The radius R of a circle, which an electron with the energy of V electron-volts follows under the influence of the perpendicular magnetic field of H gausses, is

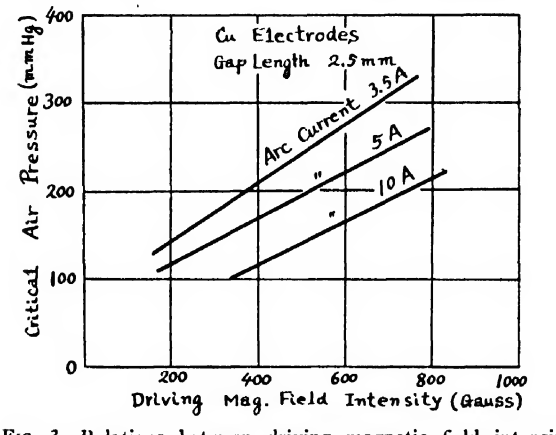

FIG. 3. Relations between driving magnetic field intensity and critical air pressure at which the permanent immobility occurs.

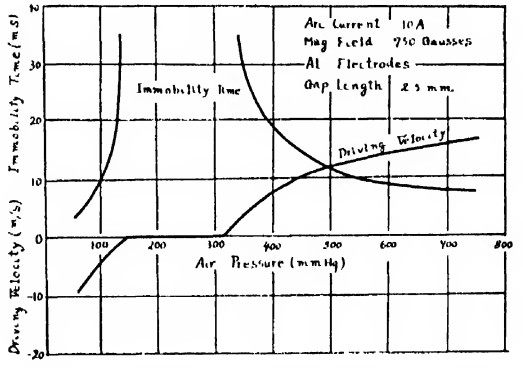

FIG. 4. The same relations as in Fig. 2. But the electrodes are made of aluminum.

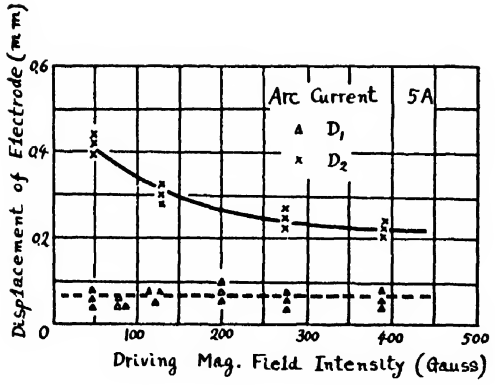

FIG. 5. Relations between driving magnetic field intensity, and electrode displacement D_1 at which an electric arc appears, and electrode displacement D_2 at which an electric arc begins to be driven. The electrodes are clean.

given by the formula

$$R=\frac{3.4(V)^{\frac{1}{2}}}{H}\ \text{cm}. \tag{2}$$

Many of the electrons diffusing outward in the positive space charge cloud have been accelerated by the cathode fall before they make an elastic collision with a gas molecule. The energy of the diffusing electrons (the electrons that have left the cathode fall) may be assumed to be 8 electron-volts. This corresponds to the cathode fall of the copper electrode. When H is 360 gausses, then

$$R=\frac{3.4(8)^{\frac{1}{2}}}{360}=2.7\times10^{-2}\ \text{cm}. \tag{3}$$

The electron mean free path and the radius are nearly equal. Thus it is probable that the loci of the many diffusing electrons are bent notably by the magnetic field as shown in Fig. 6. Although it is accompanied by some uncertainties due to complications in the cathode spot, this calculation would confirm the electron diffusion theory of reverse driving and of the immobility phenomena under a low air pressure.

As the driving magnetic field increases, the radius R of the circular loci of the electrons given by Eq. (2) becomes smaller. Thus permanent immobility will occur at a higher air pressure with an increase in the driving magnetic field.

Momentary immobility of the electric arc might be due to the fact that the temperature of the cathode spot might be very high when the arc is first established. Thus for an instant, the electron mean free path is relatively long and much curved by the magnetic field. Permanent immobility at very small gaps may be attributed to the same reason. That is, the gas temperature is very high.

Easily vaporizable metals (groups III, IV in Table I) have a relatively long time of momentary immobility. Very easily vaporizable metals (group II in Table I) have a very long time of momentary immobility and show no reverse driving. Materials with a thermoemissive cathode spot (group I in Table I) show no reverse driving.

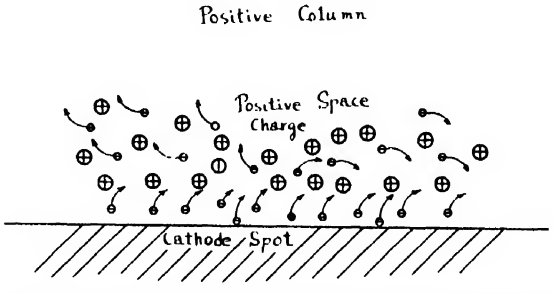

FIG. 6. Enlarged picture of the cathode spot. ⊕ positive ions. ⊖ electrons. The magnetic field is directed perpendicularly from the front to the back of the paper.

V. CONCLUSION

From the characteristics of the immobility phenomena and reverse driving phenomena which were reported, it is evident that they must be taken into consideration in the magne-blast circuit breaker. Momentary immobility not only would lengthen the interrupting time of the breaker, but it would also damage the most important parts of the contacts. Permanent immobility would make the breaker lose its interrupting ability at an altitude of several thousand meters. An air blast could protect the breaker from these phenomena effectively.

There remain many matters to prove experimentally. Further experiments and details of practical considerations mentioned will be reported later.

The author expresses his sincere thanks to Professors H. Yamashita, S. Fukuda, and S. Hoh for their guidance.

The author thanks sincerely Mr. J. P. LeGeros for his kind help with the manuscript. The author also thanks Mr. M. Yasui very much for his effective assistance.

Measurements of Mechanical Properties of Polyisobutylene at Audiofrequencies by a Twin Transducer*

ROBERT S. MARVIN,† EDWIN R. FITZGERALD,‡ AND JOHN D. FERRY
Departments of Chemistry and Physics, University of Wisconsin, Madison, Wisconsin
(Received July 25, 1949)

Apparatus has been developed for measuring the dynamic viscosity and rigidity of soft rubber-like solids in small oscillating deformations. A plate rigidly attached between two identical coils in two permanent magnets shears a pair of disk-shaped samples when a driving current is passed through one coil. The open circuit voltage from the other coil is compared in amplitude and phase with the driving current by a method in which all measurements are in the form of settings of a potential divider. The apparatus has two advantages over the more familiar resonance devices: (a) the amplitudes of motion, which need not be measured directly, are extremely small, thus minimizing any non-linear effects, or temperature change due to heat dissipation; (b) a continuous range of frequencies, spaced as closely as desired, is available without adjusting masses. The dynamic rigidity and viscosity of two samples of polyisobutylene, of molecular weights 1.2 and 0.47 million, have been measured at 15, 25, and 35°C at frequencies from 20 to 600 cycles/sec., with a reproducibility of five percent or better. The rigidity increases and the viscosity decreases with increasing frequency. Both decrease with increasing temperature, and are almost independent of molecular weight. The temperature dependence is quantitatively explained by the assumption that stresses relax by flow processes whose apparent activation energies are all identical with that characterizing the steady flow viscosity.

INTRODUCTION

THE interpretation of equilibrium rubber-like elasticity in terms of a three-dimensional network is well established.[1,2] In agreement with this theory, uncrosslinked linear polymers such as raw rubber and polyisobutylene have no equilibrium elasticity; when a sample is held at constant strain, the stress decays to zero.[3] Nevertheless, these unvulcanized rubbers show elasticity under dynamic or non-equilibrium conditions;[4] in a polyisobutylene of molecular weight about one million, the stress-strain ratio 12 sec. after application of stress[3] corresponds to an elasticity modulus of about 5×10^6 dyne/cm^2, and dynamic measurements at 100 cycles/sec. correspond to a dynamic Young's modulus of about 12×10^6 (see below), as compared with equilibrium values of the order of 10×10^6 for typical vulcanized rubbers. The origin of this non-equilibrium elasticity is not well understood. Knowledge of the phenomenon can be advanced by quantitative measurements of mechanical properties in small oscillating deformations.

Although many experimental methods for measuring dynamic properties of rubber-like solids have been described recently,[5–7] most are not very well adapted for study, over a range of audiofrequencies, of uncrosslinked materials which cannot support static stress even for relatively brief periods. For measurements on such soft polymers, as well as on swollen gels and highly concentrated solutions, we have constructed a twin electromagnetic transducer. This instrument has the advantages that the shear strains employed are very small (of the order of 10^{-5} to 10^{-3}), measurements can be made over a continuously variable frequency range (not being restricted to operation at mechanical resonance), and all the data are obtained in a particularly simple and precise form—as settings of a potential divider.

DESCRIPTION OF APPARATUS

Twin voice coils, wound on Lucite forms, are joined by short brass tubes to a brass plate, about one inch square (Fig. 1), and are suspended by eight piano wires, diameter 0.007 in., attached to small plates soldered to the tubes. The wires are adjusted under moderate tension so the coils are accurately centered in the air gaps of twin loudspeaker magnets (Jensen[8] Model PMB S3575). Identical disk-shaped samples can be strained in shear between the central brass plate and the ends of two fixed brass cylinders. The latter are held by a split steel block, also bolted to the base plate, and can be clamped by tightening two screws through the block, one of which is shown. Before clamping, the cylinders are advanced by calibrated lead screws, and the distance between cylinder and plate, representing the thickness of the sample, can be read on each side on circular scales.

A photograph of the apparatus with one magnet removed is shown in Fig. 2. The base plate rests in a box of sawdust on a concrete block mounted on cork. For temperature control, the apparatus is covered by a Celotex box connected by a rubber bellows to an air thermostat. The temperature of the central steel block, measured by a thermometer in an oil-filled well, is controlled to ±0.3°C or better. Tests with a thermocouple have shown that under the conditions of our experiments (which involve extremely

small amplitudes of oscillation and hence very little heat dissipation) the temperature of the sample and the block are identical within 0.05°.

When an alternating e.m.f. is applied to one coil, the samples are subjected to sinusoidally varying shear strain, and an e.m.f. is generated in the second coil. To calculate the dynamic mechanical properties of the samples from transducer relationships, it is necessary to compare the applied and generated voltages in amplitude and phase. For this purpose, the electrical circuit shown in Fig. 3 is employed. The oscillator is a Hewlett-Packard[9] Model 200 CR. Four non-inductive resistors in series form a potential divider represented by R_1 and R_4, which is followed by a three-dial decade voltage divider R_2, General Radio[10] Type 654A, with a total impedance of 10,000 ohms. If we consider the input impedance at $VTVM$ as infinite (it is actually 0.5 megohm, and this approximation involves a maximum error of 0.5 percent) the potential E_1 appearing at the output of the decade box R_2 will be αRI_1, where α is the fractional setting of the decade box, $1/R = 1/R_1 + 1/R_2$, and I_1 is the current through the driving coil. The values of the resistors composing R_1 and R_3 were chosen so that R would be exactly 1, 10, or 100 ohms, plus a fourth resistance of about 1000 ohms to give the proper load across the oscillator. The potential E_1 is opposed to the e.m.f. of the driven coil, $\mathbf{E}_2$, and the resultant $\mathbf{E}_r$ is read on a Ballantine[11] Model 302 vacuum tube voltmeter, preceded by a Model 220 amplifier.[11] The high input impedance of the amplifier insures that no appreciable current is drawn from the driven coil. By means of a switch, E_1 may also be read separately. All connections are carefully shielded.

THEORY AND CALCULATIONS

From the principles of electromagnetic transducers[12] it can be readily shown that

$$\mathbf{E}_2 = (B_1 l_1 B_2 l_2 \times 10^{-9}/\mathbf{Z_M}) I_1, \tag{1}$$

where B_1 and B_2 are the magnetic field strengths of the speakers, l_1 and l_2 the lengths of wires in the coils, and $\mathbf{Z_M}$ the mechanical impedance defined as the ratio of the driving force on coil 1 to the velocity of coil 2. The real part of $\mathbf{E}_2$ is taken in phase with I_1. The voltmeter provides only the absolute value, $|\mathbf{E}_2|$. However, its components can be separated by opposing it to E_1 (which is in phase with I_1 and therefore written as real) as described and using the following procedure.

Denoting $B_1 l_1 B_2 l_2 \times 10^{-9}$ by K^2, and using the admittance $\mathbf{Y_M} = 1/\mathbf{Z_M} = Y_M' - iY_M''$, we have $\mathbf{E}_2 = K^2(Y_M' - iY_M'')I_1$, and the resultant voltage $\mathbf{E}_r$ is

$$\mathbf{E}_r = E_1 - \mathbf{E}_2 = [\alpha R - K^2 Y_M' + iK^2 Y_M'']I_1. \tag{2}$$

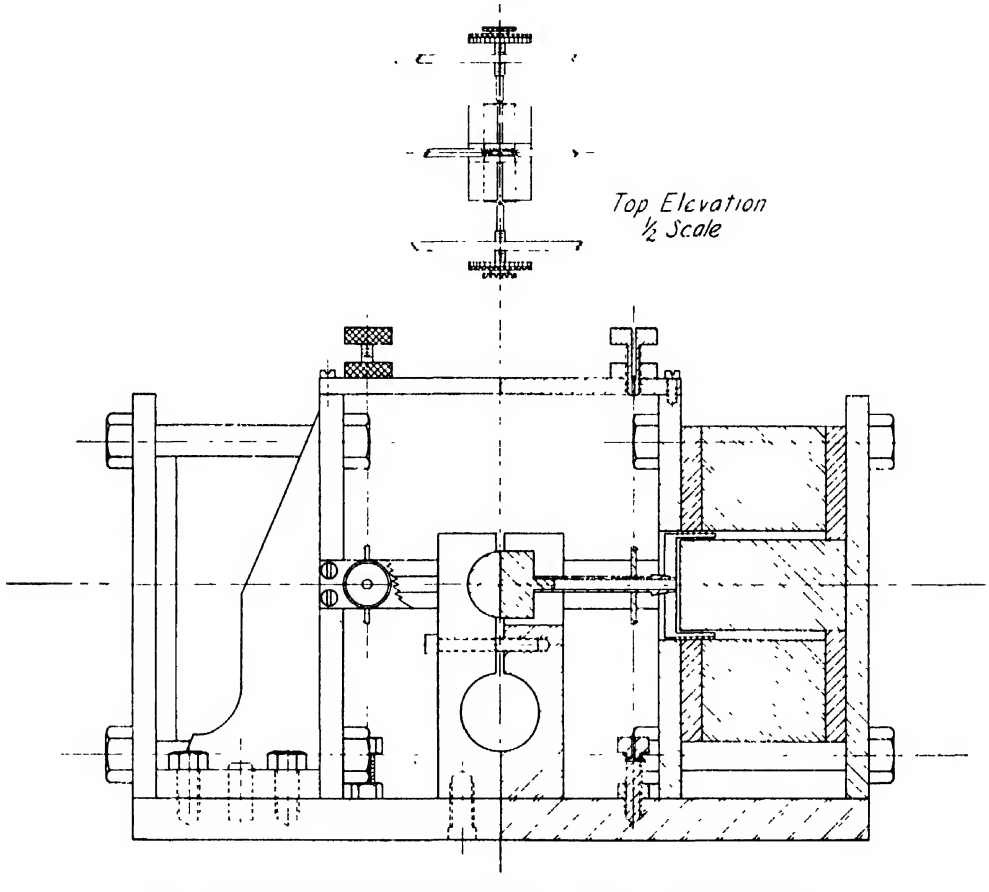

FIG. 1. Quarter-section drawing of twin transducer. Base plate is 12 in. long.

[11] Ballantine Laboratories, Inc., Boonton, New Jersey.
[12] W. P. Mason, *Electromechanical Transducers and Wave Filters* (D. Van Nostrand and Company, Inc., New York, 1942).

When the potential divider setting α is varied at constant driving current and frequency, $|\mathbf{E}_r|$ goes through a minimum when the first two terms in the coefficient of I_1 cancel. At this point, the divider setting determines K^2Y_M' and the voltmeter reading determines K^2Y_M''; the coil e.m.f. $|\mathbf{E}_2|$ provides a check calculation:

$$K^2Y_M' = (\alpha R)_{\min}$$
$$K^2Y_M'' = |\mathbf{E}_r|_{\min}/I_1$$
$$K^2(Y_M'^2+Y_M''^2)^{\frac{1}{2}} = K^2|\mathbf{Y_M}| = |\mathbf{E}_2|/I_1. \qquad (3)$$

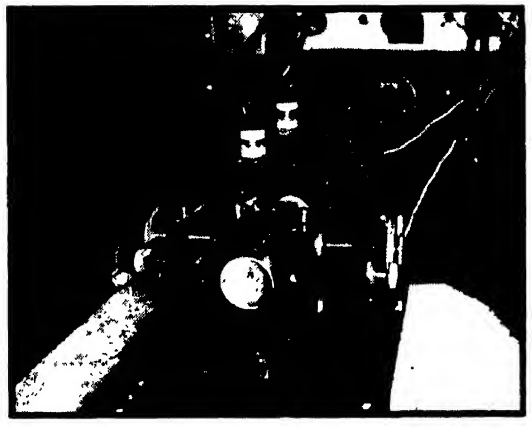

FIG. 2. Photograph of twin transducer with one magnet removed.

Since only ratios of voltage to current are required, the voltmeter scale readings for $|\mathbf{E}_r|$ and $|\mathbf{E}_2|$ are in practice matched by adjusting the potential divider with $\mathbf{E}_2$ switched out, at constant I_1, and the ratios $|\mathbf{E}_r|/I_1$ and $|\mathbf{E}_2|/I_1$ are thus obtained directly without relying upon calibration of the voltmeter scale. The check given by the last of Eqs. (3) is within one percent unless fluctuation in I_1 or frequency has occurred during the measurements.

The minimum is rather shallow; in some cases its location is facilitated by placing a resistance in series with the d.c. output of the vacuum tube voltmeter, and measuring the voltage drop across this resistance with an ordinary potentiometer and sensitive galvanometer.

The mechanical properties of the material subjected to sinusoidally varying shear are described by the dynamic rigidity, G' (real part of the complex dynamic shear modulus), and the dynamic viscosity, η' (real part of the complex dynamic viscosity), which have been defined elsewhere.[13,14] If the mass of the samples can be neglected, or their thickness is small compared to the wave-length of shear waves in the material, these quantities are related to the mechanical admittance as follows:

$$Y_M'/|\mathbf{Y_M}|^2 = R_M = R_M^0 + 2(A/h)\eta' \qquad (4)$$
$$Y_M''/|\mathbf{Y_M}|^2 = X_M = X_M^0 - 2(A/h)G'/\omega \qquad (5)$$

where R_M and R_M^0 are the mechanical resistances of the moving system with and without samples, X_M and X_M^0 are the corresponding mechanical reactances, A and h are the area and thickness of the two identical disk-shaped samples, and ω is the circular frequency. If the propagation of an incipient shear wave in the sample is taken into account, the contribution of the samples to the mechanical impedance is given by a hyperbolic cotangent function[15] which can be expanded to give a better approximation replacing Eq. (5):

$$Y_M''/|\mathbf{Y_M}|^2 = X_M = X_M^0 - 2(A/h)G'/\omega + 2\omega m/3 \qquad (6)$$

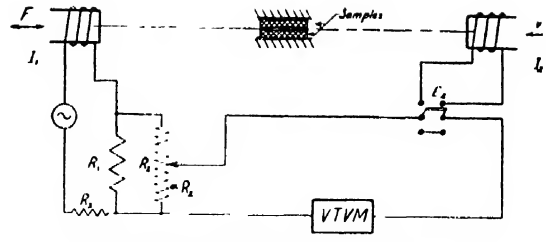

FIG. 3. Electrical circuit used with transducer.

where m is the mass of each sample. In practice, Eqs. (4) and (6) are employed, although the contribution of the term in m is slight (cf. Table I).

CALIBRATION

At each frequency, three apparatus constants are required: K^2, R_M^0, and X_M^0. The ratios R_M^0/K^2 and X_M^0/K^2 are readily determined from measurements without samples, using Eqs. (3)–(5). These values are plotted against the frequency in Fig. 4. Some isolated determinations showed that they were the same at 25° and 35°C.

The above discussion has tacitly assumed that the contributions of samples and apparatus to mechanical resistance and reactance are simply additive, with no interaction. If the coils, tubes, and plate moved as a rigid unit, this would be the case, and, moreover, X_M^0 would be equal to $\omega M - s_1/\omega$, where M is the mass of the coil-tube-plate assembly (68.2 g), and s_1 the elastance of the supporting wires. At frequencies well above the resonance $\omega_0 = (s_1/M)^{\frac{1}{2}}$, which corresponds to $\nu \simeq 24$ cycles/sec., X_M^0 should be simply ωM. Figure 4 shows that this is a good approximation up to about 200 cycles/sec.; however, at higher frequencies X_M^0/K^2 falls off from the $\omega M/K^2$ line, goes through a maximum, and falls to zero at about 3000 cycles/sec. (not shown). This behavior is attributed to a mode of vibration in which the coils move in and out symmetrically about a node at the plate, owing to compliance of the tubes, with a resonance frequency of about 3000 cycles/sec.[16] Because of this complication, no measurements of G' have been reported above 600 cycles/sec. with the present apparatus. Up to this frequency, the additivity expressed in Eqs. (4)–(6) has been assumed; its validity is shown by the agreement in G' and η' calculated from measurements on samples of different sizes (see below).

The constant K^2 is obtained by plotting $\omega Y_M''/|\mathbf{Y_M}|K^2 (= \omega X_M^0/K^2)$, determined from measurements without samples, against ω^2. If the coil-tube-plate assembly moves as a rigid unit, this should give a straight line with a slope of M/K^2 and an intercept of $-s_1/K^2$. From 20 to 100 cycles/sec. an excellent line is obtained from whose slope K^2 is found to be 8.5×10^4 ohm-dyne-sec.-cm^{-1}. This value is considered to be independent of frequency.[17, 17a]

[16] There are other indications that, even at fairly low frequencies, the mechanical impedance does not correspond to simple motion of a rigid rod, for which X_M would be $\omega M - S_M/\omega$, where $S_M = s_1 + 2(A/h)G'$. (1) There is a sharp discontinuity in the slope of the X_M^0/K^2 calibration curve at about 680 cycles (Fig. 5). (2) Values of G' obtained by applying the simple equation above to the value of the resonance frequency observed with a sample are about ten percent higher than those obtained from Eqs. (3) and (6). (3) If very thin samples are employed, two or even three resonances are observed below 1000 cycles, indicating strong interaction with the high frequency resonances. No such samples were used in obtaining the data reported here.

[17] A more elaborate analysis of calibration measurements at high frequencies, in which the compliance of the tubes is taken into account, shows that K^2 is independent of frequency at least up to 1500 cycles.

RESULTS ON POLYISOBUTYLENE

Two unfractionated samples of polyisobutylene were studied at 15°, 25°, and 35°C. The first (viscosity-average molecular weight 1.2 million[18]) was furnished through the kindness of Dr. John Rehner, Jr., Esso Laboratories. The second (viscosity-average molecular weight 0.47 million[18]), originally from Dr. Rehner's laboratory, was kindly given us by Dr. Rodney D. Andrews, Princeton University. Portions were compressed to sheets of uniform thickness (the relaxation of stress hastened by warming to 60°), and disks were cut by dies. In each case the disk was weighed and its volume was calculated, taking the density as 0.91. The volume divided by the square of the thickness after compression (determined by the cylinder lead screws in the apparatus, and often checked in place with a thickness gauge) gives the ratio A/h.

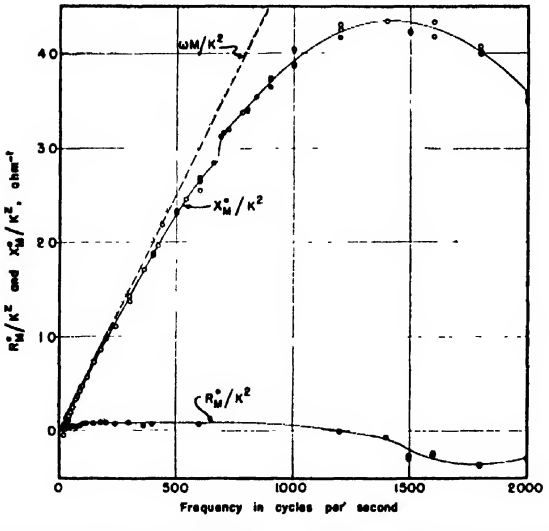

FIG. 4. $R_M{}^0/K^2$ and $X_M{}^0/K^2$ plotted against frequency, at 25°C. The dashed line represents $\omega M/K^2$.

To insure contact between the samples and the plate and cylinders, the disks were usually compressed about ten percent after introduction, and allowed to stand several hours to permit the compressive stress to relax. Tests showed that the dynamic properties did not change during this relaxation, however. The polyisobutylene was sufficiently tacky to make excellent mechanical contact following this procedure; in fact, it was not easy to remove the disks after completion of measurements.

Table I gives an example of the magnitudes of R_M and $R_M{}^0$ and of η' calculated from their difference, as well as the corresponding quantities X_M, $X_M{}^0$, and G'. The magnitude of $R_M{}^0$ is never large enough so that its subtraction seriously affects the accuracy of η'. At low frequencies, $X_M{}^0$ is not a serious correction, but with increasing frequency its contribution to X_M of course becomes greater until their difference becomes too small to determine G' with adequate precision.

Values of G' and η' for the high molecular weight sample at three temperatures are plotted against the logarithm of the frequency in Figs. 5 and 6, and the same quantities for the low molecular weight sample in Figs. 7 and 8. In each case, two different sets of disks have been employed, with A/h ratios differing by a factor of two to four. The agreement of the values of G' and η' obtained, shown by the tagged points, justifies the use of Eqs. (4) and (6) within the frequency range employed.

Individual readings on the same sample are generally reproducible within about one percent, giving an error of about two percent in the values of R_M and X_M. Values for different samples show slightly more deviation, probably reflecting an additional error in the

the advantage that the compliances of coils and connector are included with K^2 in a single calibration which is of course a function of frequency. No assumption of additivity of impedances is necessary. The method requires addition of masses for calibration at the center of the connector; this is not possible with our present apparatus, whose construction was completed before the appearance of Trent's work.

[18] We are indebted to Dr. J. N. Ashworth and Mr. M. F. Johnson for the molecular weight values.

measurement of h, the sample thickness. Very few values for the pairs of samples shown in Figs. 5–8 are more than five percent apart, and this seems to be a safe figure to take for the reproducibility of the values reported here.

These data were obtained with a constant driving current of 10 ma; the peak amplitude and velocity of course varied depending on the total mechanical impedance and the frequency. The shear and rate of shear were always so small, however, that linear viscoelastic behavior[13,14] is to be expected, and the quantities measured should be independent of amplitude. In several cases this was confirmed by varying I_1 over a factor of four, with no resultant change in R_M or X_M.

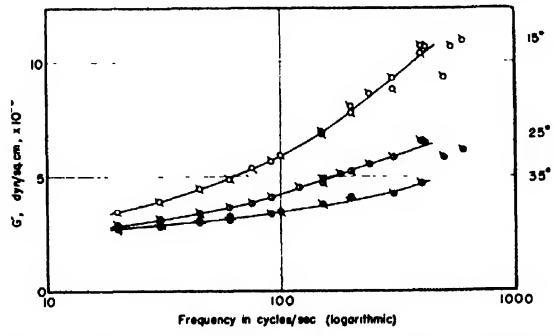

FIG. 5. Real part of dynamic rigidity of polyisobutylene, $\bar{M}_\eta = 1.2\times10^6$, plotted against the logarithm of the frequency. Upward tags, $2A/h = 20.3$; downward tags, $2A/h = 5.20$.

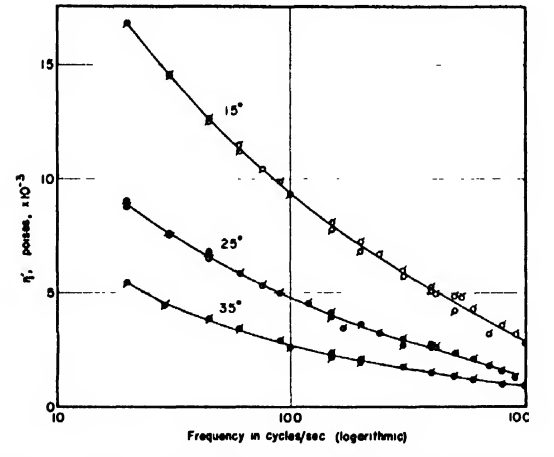

FIG. 6. Real part of dynamic viscosity of polyisobutylene, $\bar{M}_\eta = 1.2\times10^6$, plotted against the logarithm of the frequency. Key to tags same as in Fig. 5.

At each temperature and molecular weight, G' increases and η' decreases with increasing frequency. At any given frequency, both G' and η' decrease markedly with increasing temperature. An increase in molecular weight from 0.47 to 1.2 million increases G' by less than 20 percent, and has very little effect on η'.

DISCUSSION

There appear to be no other data in the literature on uncrosslinked rubbers with which the above results can be compared. It is of interest, however, to compare them qualitatively with similar data for vulcanized rubbers. Both G' and η' for polyisobutylene are found to be of the same order of magnitude as values for various cured rubbers (natural, GR-S, and butyl) at comparable frequency and temperature, derived from the measurements of Dillon, Prettyman, and Hall,[19] Nolle,[20] and Guth.[21] A quantitative comparison is difficult to make at present because chemical constitution has a considerable influence on the detailed behavior, though not apparently the order of magnitude, of G' and η'.

Dependence on Temperature

The variation of both G' and η' of polyisobutylene with temperature can be quantitatively explained by a single assumption, that stresses in the material relax by a variety of flow processes but the temperature de-

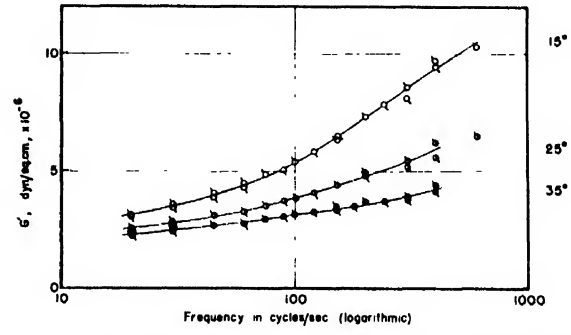

FIG. 7. Real part of dynamic rigidity of polyisobutylene, $\bar{M}_\eta = 0.47\times10^6$, plotted against the logarithm of the frequency. Upward tags, $2A/h = 24.5$; downward tags, $2A/h = 13.8$.

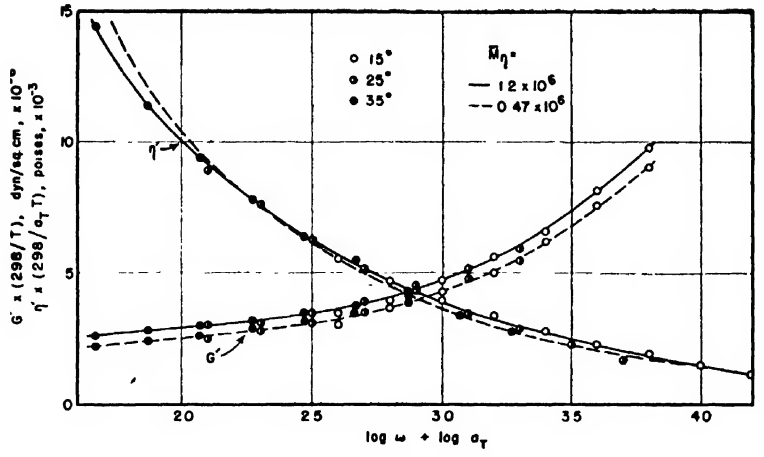

FIG. 9. Superposition of data at different temperatures: $G'(298/T)$ and $\eta'(298/a_T T)$ plotted against $\log\omega+\log a_T$. At 15°C, $a_T=3.16$; at 35°C, $a_T=0.38$. The points plotted for η' correspond to the solid curve ($\bar{M}_\eta=1.2\times10^6$); the points corresponding to the dashed curve ($\bar{M}_\eta=0.47\times10^6$) have been omitted to avoid confusion.

pendence of every such process is the same and identical with that of the steady flow viscosity. It is convenient to discuss the mechanical behavior in terms of an arbitrary distribution function of relaxation times, $G(\tau)$, such that the instantaneous rigidity is $\int_0^\infty G(\tau)d\tau$ and the steady flow viscosity is $\int_0^\infty \tau G(\tau)d\tau$. This has been employed by Andrews[3] and Kuhn,[22] and it is equivalent to the generalized Maxwell model of Alfrey and Doty;[23] that is, every spring $G(\tau)d\tau$ is relaxed by a dashpot $\tau G(\tau)d\tau$. In this case

$$G'=\int_0^\infty [G(\tau)\omega^2\tau^2/(1+\omega^2\tau^2)]d\tau$$

$$\text{and}\quad \eta'=\int_0^\infty [\tau G(\tau)/(1+\omega^2\tau^2)]d\tau.$$

Now, a change in temperature has two separate effects; it shifts the dispersion function to a different frequency region by altering the dimensionless variable $\omega\tau$, and it also changes the magnitudes of G' and η' by altering $G(\tau)$ and $\tau G(\tau)$, respectively. We will suppose that the rigidity mechanisms are of the nature of rubberlike elasticity and therefore that every $G(\tau)$ is proportional to the absolute temperature; this gives a slightly better fit with the data than does the assumption that the rigidity is independent of temperature, although the experimental temperature range is too small to test it critically. Then if a temperature change from T_0 to T (on the absolute scale) changes every relaxation time by a factor a_T, every contribution to G' will be multiplied by T/T_0 and shifted along a logarithmic frequency scale a distance $-\log a_T$; every contribution to η' will be multiplied by $a_T T/T_0$ and also shifted $-\log a_T$ along the $\log\omega$-axis. Moreover, the steady flow viscosity, η, will also be changed by the factor $a_T T/T_0$. Accordingly, choosing $T_0=298$°K, if we plot $G'(298/T)$ and $\eta'(298/a_T T)$ against $\log\omega+\log a_T$, data at all different temperatures should superpose.

Very successful superposition of both G' and η' for both molecular weights is obtained by selecting a_T values of 3.16 at 15°C and 0.37 at 35°C (Fig. 9). These values also fit in quite well with the temperature dependence of the steady flow viscosity of polyisobutylene given by Fox and Flory,[21] who showed that the apparent activation energy for viscous flow is independent of molecular weight and equal to 19.3 kcal. at 0° and 13.7 kcal. at 50°C. From the relation $\eta/\eta_{298}=a_T T/298$ we calculate 19 kcal. at 20° and 16.5 kcal. at 30°C. The values obtained by Andrews[3] from stress relaxation measurements are also from 15 to 16 kcal. in the range from 30° to 100°C. It appears therefore that all the flow processes in the relaxation spectrum which are reflected in these various measurements have the same temperature dependence.

Dependence on Molecular Weight

Figure 9 also emphasizes the very slight dependence of G' and η' on molecular weight. This indicates that the dynamic mechanical behavior involves primarily entanglements of molecular segments which are short compared with the total length, and that the loose ends of the molecules have relatively little significance. On this basis, it would be expected that η' would show still less dependence than G', as is indeed observed, because the contributions to η' come largely from mechanisms with short relaxation times (corresponding probably to shorter segments), while the contributions to G' come largely from mechanisms with long relaxation times (corresponding to long segments which could be perceptibly influenced by loose ends). By contrast, the steady flow viscosities of these two samples (if the viscosity average molecular weight can be assumed approximately proportional to the weight average) should differ by over a factor of ten,[24] and it is obvious from casual inspection of the samples that they do. This of course reflects the fact that the difficulty of moving entire molecules past each other increases markedly with molecular weight. Since η' must ap-

[22] Kuhn, Künzle, and Preissmann, Helv. Chim. Acta **30**, 307, 464 (1947).
[23] T. Alfrey and P. Doty, J. App. Phys. **16**, 700 (1945).
[24] T. G. Fox and P. J. Flory, J. Am. Chem. Soc. **70**, 2384 (1948).

proach η as $\omega \rightarrow 0$, the curves for η' must diverge widely at lower frequencies. Since η is of the order of 10^9 to 10^{10} poises,[24] and the maximum value of η' found here is about 10^4, the dispersion must extend well below the frequency range covered experimentally.

Dependence on Frequency

Figure 9 provides a picture of the dispersion functions for G' and η' over about two decades of frequency. There is at present no theoretical basis for interpretation of this dispersion. The relaxation distribution function derived by Kirkwood,[25] and the semi-empirical function of Kuhn,[22] are devised for crosslinked rubbers, and are not applicable to a linear polymer; tests have shown that neither fits our data for polyisobutylene. The "step" function used by Andrews[3] to describe stress relaxation in polyisobutylene provides (for frequencies not too close to the reciprocals of the cut-off times) that G' should be a linear function of $\log\omega$ and η' should be inversely proportional to ω; neither of these relations is even approximately fulfilled.

If a relaxation distribution function, either theoretical or empirical, can be obtained to fit our dynamic data, it should also apply to the transient stress relaxation data of Andrews,[3] with the reservation that his experiments involved extension rather than shear and represented a far greater extent of strain. However, a considerable gap in time scale remains to be bridged between the shortest transient measurement (about ten seconds) and the longest period in dynamic measurement (about one-twentieth of a second). Experimental data in this range are needed to provide a complete picture from which the mechanism of elasticity and elastic loss in uncrosslinked rubbers may be deduced.

ACKNOWLEDGMENT

This work was supported in part by a grant from Research Corporation, and in part by the Research Committee of the Graduate School of the University of Wisconsin from funds supplied by the Wisconsin Alumni Research Foundation. We are deeply indebted to Mr. Frederic W. Schremp for help in the detailed design of the apparatus, and to Mr. Thomas R. Lloyd for painstaking work in its construction. Professor F. T. Adler and Professor W. T. Thomson have given valuable advice in problems relating to mechanical resonances in the apparatus. We are grateful to Carbide and Carbon Chemicals Corporation for support through its Fellowship in Physical Chemistry.

The Dielectric Strength of Gaseous Fluorocarbons

W. A. Wilson, J. H. Simons, and T. J. Brice

Fluorine Laboratories, The Pennsylvania State College, State College, Pennsylvania

(Received August 16, 1949)

The sixty-cycle dielectric strengths of some gaseous fluorocarbons have been measured between three differently shaped electrode pairs at pressures up to three atmospheres. The breakdown potentials for propforane, butforane, and pentforane were found, in most instances, to be equal to or greater than those for sulfur hexafluoride under comparable conditions, and to be far greater than those for nitrogen. Fluorocarbons thus have possible uses as gaseous insulators in high voltage apparatus.

A CONSIDERABLE amount of research has been carried out during the past few years in evaluating the dielectric strengths of various gaseous materials. Rodine and Herb[1] found that if carbon tetrachloride vapors were added to air or nitrogen, the dielectric strength was raised considerably. Charlton and Cooper[2] measured the dielectric strength of numerous gases and found that the Freon compounds had much higher dielectric strengths than nitrogen under the same experimental conditions. Camilli and Chapman[3] have found that sulfur hexafluoride and dichloromethforane have dielectric strengths much higher than nitrogen, and, when the gases were under about three atmospheres pressure, the dielectric strengths of these compounds approached values obtained for transformer oils. These results have been utilized commercially by insulating certain high voltage condensers, transformers, and electrostatic generators with various compressed gases.

During this research, the sixty-cycle dielectric strengths of various fluorocarbon gases and vapors were measured. Propforane, butforane, and pentforane were found, in most instances, to have dielectric strengths equal to or greater than sulfur hexafluoride under similar conditions.

The experiments were carried out in three glass cells containing copper electrode pairs of different shapes. One cell contained flat, circular disks of 0.477-inch diameters, the second had hemispheres of 0.5-inch radii, and the third had a hemisphere of 0.5-inch radius and a pointed 0.149-inch rod as electrodes. The pointed

end was a section of a right cone with 15°27′ semiangle and bases having diameters of 0.036 inch and 0.149 inch. The electrodes were sealed symmetrically about common axes into round bottom Pyrex flasks and subsequently sealed to a portable vacuum system. A 100 ml flask was used for the disk electrodes, and one liter flasks were used for the other cells. These electrode shapes are similar to those generally used for this type of measurement.[3] The pair of hemispheres gives an approximately uniform field, while the hemisphere-rod arrangement gives a very non-uniform field.

A small laboratory transformer was used for producing voltages less than 35 kv. For higher voltages, a transformer capable of producing 150 kv was used. The voltage measurements were made with an accuracy of ±5 percent.

The fluorocarbons were prepared by the electrochemical process described by Simons.[4] The samples used were fractions of narrow boiling range from distillations through efficient columns. Molecular weight values were within ±0.5 percent of the theoretical values. The samples were dried over P_2O_5 before distillation and again just prior to the dielectric strength measurements.

At the dielectric breakdown potential, arcing between the electrodes occurs. It was noticed that, except in the case of methforane, this arcing in fluorocarbons resulted in the formation of a thin layer of black material, probably carbon, on the surfaces of the electrodes and the glass flask; and that a pressure rise of about one per cent of the total pressure occurred. This latter observation seemed to indicate that lower molecular weight fluorocarbons formed to a slight extent during arcing. Since the last of a series of five breakdown potentials on a given gas sample was essentially the same as the first, it was evident that small amounts of these materials did not noticeably affect the dielectric strength of the fluorocarbon. In addition, the dielectric breakdown potentials of fresh gas samples were found to be the same, within experimental error, in a cell coated with the solid as in a new, uncoated cell.

The dielectric strengths are plotted against pressure on Figs. 1 to 5. Each plot represents the results obtained using a different electrode pair or a different electrode gap spacing. Sulfur hexafluoride and nitrogen were tested for comparison.

The tests using the disk electrodes (Fig. 1) were carried out at a gap spacing of 0.125 inch. The dielectric strength of the fluorocarbons increased with increasing molecular weight, and all the fluorocarbons had values higher than those for nitrogen. Butforane and pentforane had dielectric strengths higher than sulfur hexa-

fluoride. The dielectric strength of propforane was lower than that of sulfur hexafluoride at pressures less than one atmosphere and higher than that of sulfur hexafluoride at pressures above one atmosphere.

The tests using the pair of hemispheres (Figs. 2 and 4) were carried out at gap spacings of 0.100 inch and 0.250 inch. The breakdown potentials obtained at equal pressures were roughly proportional to the gap spacing. The dielectric strength of propforane was somewhat lower than that of sulfur hexafluoride at all pressures used. The general pattern of relative dielectric strength values for the other compounds was the same as obtained with the pair of disks.

The tests using the hemisphere-point electrode pair (Figs. 3 and 5) were also carried out at gap spacing of 0.100 inch and 0.250 inch. As was expected, the breakdown potentials obtained when using this electrode pair were lower than those obtained when using the symmetrical electrode pairs which produced more uniform fields. When tested with this pair of electrodes, the dielectric strength of propforane was higher than that of sulfur hexafluoride at all pressures used. The pattern of relative values for the other compounds was the same as was obtained with the other electrode pairs.

An interesting correlation of the dielectric strengths of fluorocarbons is illustrated in Fig. 6. The dielectric strengths of fluorocarbons (taken from Fig. 1) are plotted against their gas densities. As a first approximation, the dielectric strength is proportional to the gas density, independent of the compound. Similar treatment of the data obtained when using the other electrode pairs gave similar results.

ACKNOWLEDGMENT

The authors wish to thank Professor R. E. Armington of the Electrical Engineering Department of The Pennsylvania State College for his assistance in obtaining the measurements reported here and the Electrical Engineering Department for allowing the use of their high voltage transformer.

This work was done under the sponsorship of the Minnesota Mining & Manufacturing Company, St. Paul, Minnesota.

Complex Stressing of Polyethylene

I. L. Hopkins, W. O. Baker, and J. B. Howard
Bell Telephone Laboratories, Inc., Murray Hill, New Jersey
(Received August 17, 1949)

Polyethylene of such molecular weight and structure that it readily fibers or cold draws to 300–600 percent elongation by usual uniaxial, tensile stressing may react quite differently under biaxial tension. When biaxial tension in 1:1 ratio is applied to a diaphragm, some polymers show brittle fracture with <20 percent elongation at break. However, if the average molecular weight of such polyethylenes is shifted upward by crude fractionation, or an initially higher average is used, the polymers orient under complex stresses. Then, they usually elongate several hundred percent before rupture. Variations in crystallinity are also significant, although most technical polyethylene soon attains at room temperature enough crystallinity so that this factor does not cause big differences.

Although the whole study is so far preliminary, x-ray scattering of stressed samples suggests that preferred glide on certain crystallite planes tends to occur as the yield point approaches. These are such as to inhibit smooth alignment of the long chain axis in the direction of stressing. This could lead to brittleness.

Apparatus for complex stressing of sheets and tubes is described. Strains are taken from coordinates printed on the sample by the silk screen process. High speed stressing was also observed. The speed of retraction of amorphous polyethylene chains approaches that of rubber.

THE usual tensile strength or stress-strain measurement for plastics and rubbers involves uniaxial stretching of a long, thin strip. With such tension, polyethylene, and other microcrystalline polymers such as the polyamides and polyesters, give a steep initial stress *vs.* strain curve, up to 20–50 percent elongation. Then, "yield" occurs, and a quite flat curve delineates cold-drawing or fibering, marked by crystallite orientation. Finally, between 400 and 700 percent elongation, depending on the polymer, rate of stressing, degree of crystallinity, etc., the curve bends upward again and rupture soon occurs.[1,2]

However, two-directional or biaxial stress-strain properties have also been observed for rubber[3,4,5,6] and for thin Nylon films.[7] In these cases, while the form of the stress-strain curve is different than with uniaxial tension, the strains at rupture have apparently the usual values—of several hundred percent.

With polyethylene, we have found that biaxial stressing of some commercial grades (determined by some function of average molecular weight and chain linearity, such as melt viscosity), causes brittle fracture at 30 percent elongation or less. This is with a polymer having simple tensile properties of curves *C*—uniaxial in Fig. 1, wherein it breaks only after 300–500 percent elongation. Somewhat higher molecular weight polymer, however, shows much higher elongation at rupture, perhaps even approaching the lower uniaxial values. An example of this appears in curves *A* of Fig. 1. In these curves, the end point does *not* indicate rupture, as it does in curves *C*, except for the uniaxial tension curves *A*. Rather, on curves *A* for biaxial tension, the end of the curve denotes yield, where an oriented bubble begins to form on the stressed diaphragm. Accordingly, the material of curves *A* begins to orient at ~70 percent elongation, and draws down to 200 percent or more in the bubble before rupture. Nevertheless, its uniaxial curve is seen, in Fig. 1, to come quite close to that of material *C*.

The relative differences in average molecular weight of these two polymers are represented in Table I, by their inherent viscosities.

$$(\ln\eta_r)/C$$

in *m*-xylene (90 percent) at 85°C, with $C=0.5$ g/100-cc solution, and with η_r = time of flow of solution/time of flow of solvent.

The inherent viscosity values agree with the *uniaxial* stress-strain data of Fig. 1 in showing that both materials *A* and *C* are well within what is commonly called the "super-polymer" "cold drawing" range. Biaxial stresses thus have brought out a wholly unexpected and dramatic sensitivity of this sort of me-

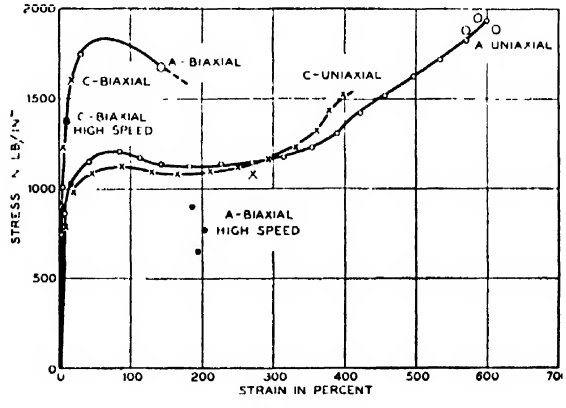

FIG. 1. Stress-strain curves of polyethylenes *A* and *C* under uniaxial and biaxial tension. (Large circles (for *A*) and crosses (for *C*) are rupture points, except that the large circle for *A*-biaxial is the yield point.)

chanical behavior to average molecular weight as reflected in over-all molecular cohesion. Interestingly, the inherent viscosity for polymer *C* is actually higher than that for polymer *A*. The melt viscosities are reversed, however, with polymer *A* higher; it may be a more branched material although the over-all degreees of crystallinity of the two as judged by x-ray scattering, are similar. Further, polymer *A* has a definitely smaller fraction of low molecular weight, soluble in boiling chloroform, than polymer *C*; this is important, as judged from scores of similar comparisons made in this study.

For instance, polymer *D* in Table I showed, like polymer *C*, low elongation and brittle fracture under biaxial tension. It was then dissolved in pure trichloroethylene, and the system equilibrated at 43.8°C. Sixty-one percent by weight of the original sample was insoluble at this temperature; it had the properties of *D'* in Table I. The fraction of *D'* soluble in boiling chloroform was reduced fourfold from that of *D*, and the polymer was converted to high elongation cold-drawing behavior. However, its stress at yield was no higher than that of the unfractionated material (at rupture). By contrast, polymer *D''* represents the 25 percent of polymer *D* insoluble in trichloroethylene between 43.8° and 25°C. Its density is a little higher than that of *D'*; its inherent viscosity is a little higher than that of the parent *D*; this may mean more chain linearity and crystallinity. But the portion soluble in boiling $CHCl_3$ has risen to 19 percent and the ultimate elongation under biaxial stress has fallen to 28 percent, accompanied by brittle fracture.

A', in Table I, reflects still another interesting aspect of biaxial mechanics. It is the fraction, 91.5 percent of polymer *A*, insoluble in the benzene-isopropanol azeotrope at its boiling point. The portion of *A'* soluble in boiling $CHCl_3$ is tiny, the density is still low, however, as well as inherent viscosity—some balance between removal of easily soluble species, but retention of (presumably) branched species appears. Hence, the material exhibits the orientation and tenacity of the parent *A*, but the elongation at yield *drops* sharply. This is a very typical behavior of "tough" polyethylene, and should not be confused with an approach to the low elongation at simultaneous yield and rupture of the polymers showing brittle fractures. In other words, as a function of average molecular weight and structure, the elongation at yield of polyethylene goes through a maximum, while the ultimate tenacity increases continuously.

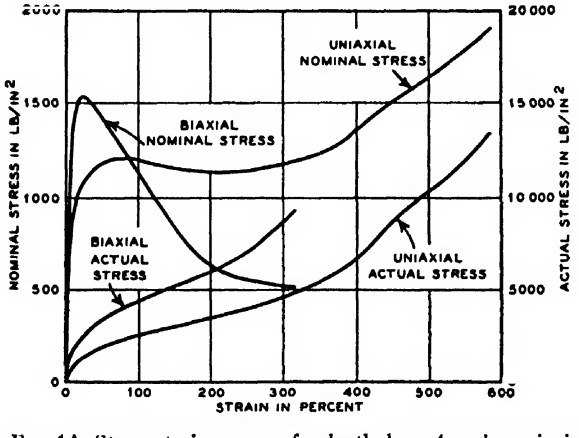

FIG. 1A. Stress-strain curves of polyethylene *A* under uniaxial tension, and biaxial tension with liquid medium. The biaxial nominal stress curve passes through and somewhat beyond the area of rupture points determined by the high speed tests with nitrogen as the pressure medium.

TABLE I. Properties of polyethylene under biaxial tension.

Polymer	Density 25°C	$\ln\eta_r/C$	Percent soluble in boiling chloroform (N.F.P.)*	Strain at "yield" %	Strain at rupture %	Stress at "yield" p.s.i.
A	0.9191	0.933	9.6	70	~200	1600
A' (=91.5% of *A*)	0.9171	0.974	1.9	44	~200	1670

* Amount soluble under empirical conditions.

This would have to be established finally by detailed fractionation of polyethylene; this has been explored, but not solved for reasons well recognized.[8] However, some additional examples of reaction of unfractionated, commercial-type polyethylenes to biaxial stress appear in Fig. 2. Apparently, with these molecular weight distributions, brittle fractures and low elongations do not occur much above an inherent viscosity of 1.0. Then, the above effect, where the still higher molecular weight polymers again show reduced elongations at yield, although they orient highly before rupture, appears at the extreme right in Fig. 2. Many additional points to those in Fig. 2 have been obtained, but they still do not allow construction of what might be a convex-upward correlation curve. A new correlation technique,[9] which has been especially useful in experimental studies of this kind, shows that extreme, or peripheral, association is probable in Fig. 2, however.

EXPERIMENTAL METHOD

Biaxial stresses were applied by N_2 gas pressure on a polymer disk. The cell in which the disks, in the range 0.080-in. to 0.140-in. thick, were clamped is shown in Fig. 3. The sample was illuminated by floodlights, behind heat-absorbing glass plates. It was photographed during straining, sometimes with a movie camera, but usually at intervals with the fixed camera shown behind the lights. Stress measurements were recorded by holding up a card bearing a definite figure for gas pressure (250 is shown in figure) and photographing the

[9] P. S. Olmstead and J. W. Tukey, Ann. Math. Statistics 18, 495 (1947).

card and the strained specimen just when the gas gauge reached the given figure.

The specimens were either clear polyethylene or a compound containing 1 percent or 2 percent by weight of fine carbon black, which had no effect on these physical properties. They were compression molded so as to be isotropic and free from included stresses. At first, 0.10-in. coordinate grids were photographed on them after coating with emulsion. However, it was found that the silk screen method of printing, long used for posters and textiles, worked very well with either a black or white ink containing a chlorinated rubber base. The ink had no effect of either crazing or swelling the

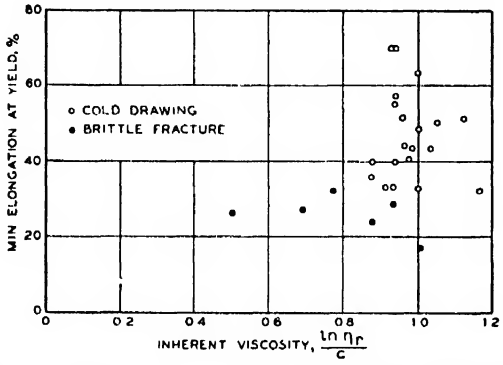

FIG. 2. Minimum elongation at yield under biaxial tension plotted against inherent viscosity of dilute solutions of polyethylene of various average molecular weights.

polymer. These coordinates appear on the specimen shown in Fig. 3. Figure 4 shows typical drawn (upper and lower left) *vs.* brittle (lower right, with stick to mark crack) fractures. The white disk in Fig. 4 showed the reduced elongation at yield encountered for samples of high melt viscosity. Figure 3 shows a mirror obliquely placed along side the specimen holder so that the bulge of the diaphragm could be measured on the photograph along with the expansion of coordinates. From this, the stress in p.s.i. was computed as

$$PR/2t,$$

P being gas pressure in p.s.i., R, the radius of the (spherical) bulge and t, the thickness of the sheet in inches. Strain was obtained directly from the expansion of coordinates, which was the same in both directions (1:1 ratio) in most experiments. Some measurements were also done in a device in which cylindrical tubes of the polymer were blown up. This apparatus is shown in Fig. 5, with a polyethylene tube of 1 in. outside diameter and $\frac{1}{16}$-in. wall thickness. Coordinates were again printed directly on the specimen. Here, the principal stresses have a 2:1 ratio, but the results were quite comparable to the 1:1 ratio situation.

The rate of stressing was such that the pressure gauge rose uniformly over a period of 60 ± 10 sec. followed by abrupt rupture. Some experiments ten times as slow gave similar results and stress relaxation became significant for long periods; the present results suggest a study of stress relaxation under biaxial tension compared to the usual uniaxial case. Also, effects from very rapid straining were investigated. It was particularly desired here to be able to photograph the strains on the bubble which appeared as the high elongation samples oriented. This bubble is what blew into the crater shown on the upper sample of Fig. 4. Even with slow rates of over-all stressing with gas pressure, this bubble always appeared and burst so fast that ordinary photographs did not slow its growth. Hence, high speed

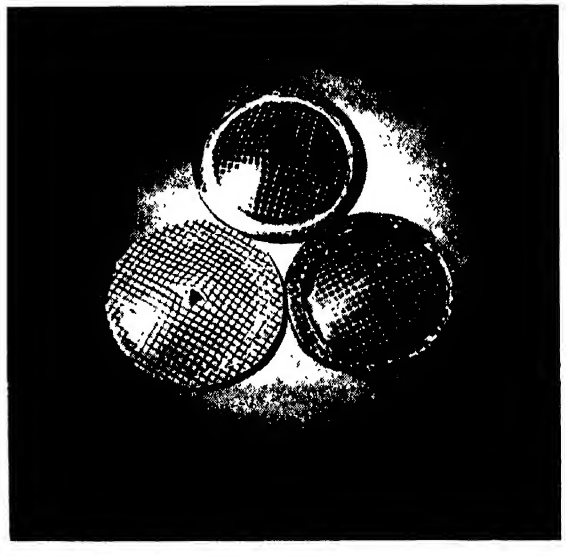

FIG. 4. Polyethylene disks ruptured by biaxial stress. Upper, moderate molecular weight, high yield strain, extensive cold drawing. Lower right, marginal molecular weight, low "yield" strain coinciding with brittle rupture, no cold drawing (stick is in crack to force it open for view).

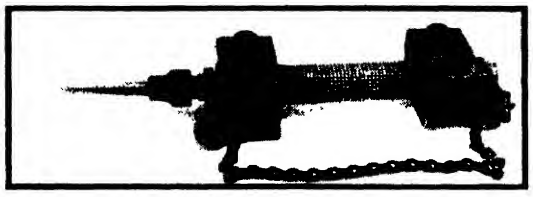

FIG. 5. Device for applying gas or hydraulic pressure to polymer tube bearing coordinates. Tube is clamped into fittings within steel blocks. (Here, rupture often occurs in position away from a single camera.)

photographs, with the Fastax camera, were made of specimens stressed and ruptured by sudden opening of the gas valve. The whole time from initial pressure to breaking was about 0.15 sec.; the bubble formed so rapidly that its life was roughly 10^{-3} sec. However, a few measurements of the coordinates on the bubble could be made, both as it formed and as the diaphragm relaxed after bursting. They are shown on Fig. 1 in terms of stress-strain assuming (1) that the stress-strain curve up to the point of yield (bubble formation) or brittle fracture is the same as in slower tests, (2) hence the pressures are the same at this point and in the case of the formation of a bubble do not change appreciably over the brief time interval required for the formation and bursting of the bubble, (3) that from the measured radius of the bubble and the assumed pressure, the stress in the bubble may be computed and (4) the strain in the bubble (ultimate elongation of the material) can be approximated by the over-all bubble dimensions. More appear on Fig. 6, where strains directly measured from the Fastax frames are plotted against time. The recovery from 130 percent back to about 50 percent total strain takes about 6 milliseconds. This is the same order·velocity as for free contraction of soft rubber.[10,11] Probably amorphous chains of polyethylene are responsible; they are acting kinetic theory-wise compared to the usual sluggish "plastic" behavior of the polymer. In this connection, it will be noted later that biaxially stretched polyethylene seems to show an unusual orientation of the amorphous components (compared to their only slight orientation in an ordinary drawn fiber).

The high speed data still show the large relative differences in the polymers *A* and *C*. *C* breaks at 20 percent elongation, with brittle fracture, while *A* yields at a higher value, and cold draws to about 150–200 percent, as the points on the graph show, before breaking. Accordingly, failure of polymer *A* was not converted to brittle fracture by an "impact rupture" 10^4 times faster than the usual test. Incidentally, the growth of the brittle crack in polymer *C* could just about be seen in 10^{-4} sec. None of these data means, of course, that the apparent tenacity of the polymer is insensitive to the total *time* of stressing[12,13] (as in fatigue).

A modified apparatus is now being studied in which water (or aqueous anti-freeze solutions for low temperatures) is being used for pressure instead of gas. In this way, very little energy is stored during stressing, and the bubble formation for samples which orient, as well as the bulging of all samples, can be better controlled. Experiments done with water instead of nitrogen as the pressure transmitting medium bring test specimens

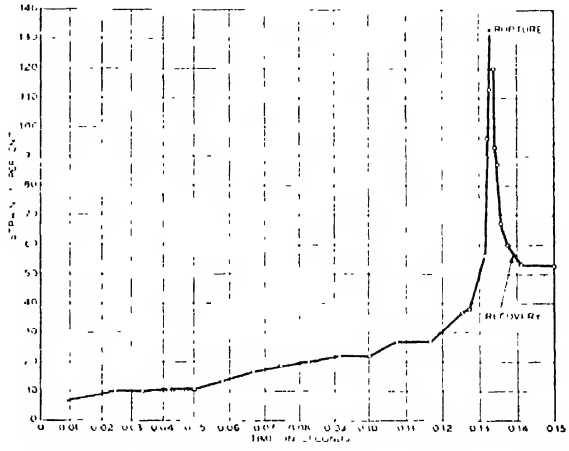

FIG. 6. Rate of straining of polyethylene diaphragm suddenly blown out by high gas pressure. The blown bubble itself remained highly oriented; recovery is for the rest of the surface.

gradually to the rupture point, rather than merely to the yield point, and show that biaxial strains of over 400 percent may be attained. Stress-strain curves for polyethylene *A* are shown in Fig. 1A. The biaxial nominal stress-strain curve of Fig. 1A passes through the biaxial high-speed rupture points of Fig. 1, confirming qualitatively the assumptions under which these points were calculated.

Reason for Biaxial Brittleness

Pending work in progress, and examination of other materials, only tentative qualitative explanations can be given for dependence of the elongation of polyethylene on stress complexity. In contrast to an assembly of long chain molecules like amorphous rubber, polyethylene at 25°C contains a major volume of small crystallites (100–300A in dimensions) and a minor volume of disordered matter. Hence, response of these crystallites to external stress, rather than gradual progressive orientation of individual chains as when rubber is stretched, is the critical process which will determine whether brittle fracture or cold drawing will occur. Of course, ultimately the long chain axes themselves line up in the direction of uniaxial fibering, as the

[13] T. Alfrey, *Mechanical Behavior of High Polymers* (Interscience Publishers, Inc., New York 1948), p. 481 ff.

crystallites are so oriented.[14] The mechanism of this adjustment,[15] the "shoulder" on cold drawn strips,[16] the dimensional changes on drawing, and stress-strain variations on redrawing[16] have also been considered in terms of crystallinity. But, less attention has been given to the striking structural changes in the early part of the uniaxial stress-strain curve, where it begins to flatten out on Fig. 1. Here, the long chain axes in the crystallites are actually put *at a large angle* ($\sim 70°$) *to the direction of external stress*[17,18] by the preferred glide on certain crystal planes. Thus, in the early stages of orientation, the x-ray reflections from 110 planes are split, up off the equator, while the other strong feature, the 200 reflections concentrate down on the equator.[17] At higher temperatures, where thermal agitation has disordered the crystallites[15,17] this anomalous orientation is absent,[18] and the long chain axes progressively align with the direction of stress.

Now, if such anisotropy of slip as this occurs during uniaxial pulling, it seems that under biaxial tension, a skewed orientation would result in which much of the pull between the chains was lateral. This would tend to pull them apart in the easiest way (since van der Waals bonds would support most of the stress). Hence, dependence of strength on molecular weight would be even more critical than in the uniaxial case.

Of course the "anomalous" orientation found at the beginning of uniaxial stressing of ordinary specimens (1 mm or more thick) may already reflect complex stressing. This is because of the appreciable shear attending stretching of such "thick" samples. An electron diffraction investigation of stretched polyethylene film initially about 1000A thick showed only progressive, normal, orientation of 110 planes,[19] but these films had some orientation during preparation. It would be interesting to see if such thin films, initially strictly isotropic, showed "anomalous" orientation from just stretching at 25°C.

In any case, x-ray scattering of polyethylene which has been sheared, or biaxially stretched (with some attendant shear), should show this competitive or "blocked" crystallite gliding. It does appear in the diagrams of Fig. 7. First, Fig. 7A shows the usual fiber diagram of highly, uniaxially, oriented polyethylene. The strong 110 and 200 reflections are well concentrated on the equator. The pattern (all are with crystal-monochromatized Cu $K\alpha$-radiation) also clearly exhibits the *unoriented*, amorphous components of the polymer.

Figure 7B is the diagram from a small sample roughly normal to the plane of principal shear in a tube which was twisted to failure. This tube was

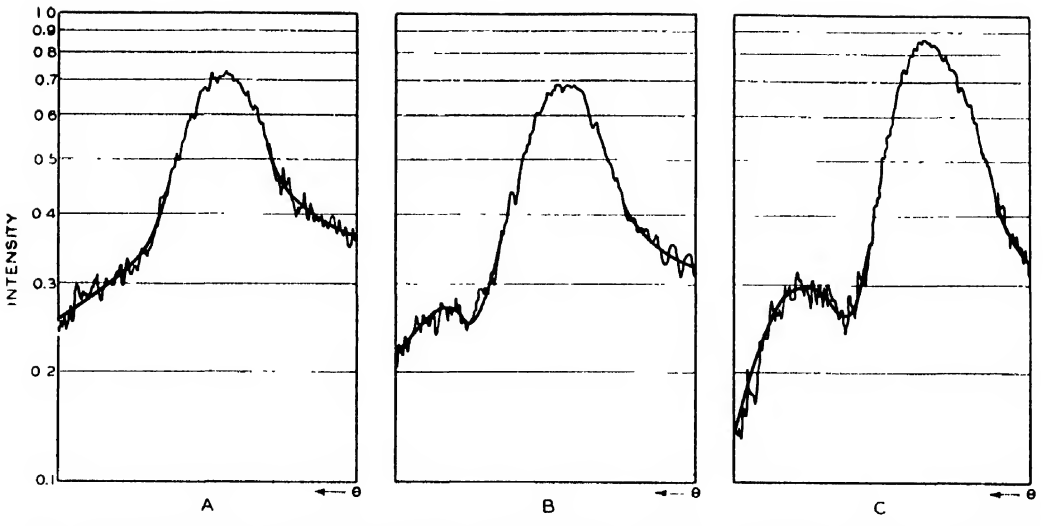

FIG. 8. Microphotometer tracings (uncorrected) showing x-ray scattering of principal features of unoriented polyethylene (A) immediately after quenching from melt to −78°C., (B) after same sample has stood 24 hr. at 25°C, (C) after annealing below melting point, and coming slowly at 25°C.

½ in. outside diameter, ¼ in. inside diameter, and about 12 in. long. It was twisted from the ends and sheared through near the middle. The B sample was at the rupture, and shows roughly normal alignment, although with a wide angular distribution and tapering of 110 and 200 intensities. Figure C is quite different, however. It shows what the polymer went through in getting to the final orientation just before rupture. It was obtained from a sample just back of the B sample. The 110 reflections are split, and also skewed with respect to the 200. The long chain axes by no means smoothly and gradually oriented in the direction of the principal shearing stress. However, Fig. 7D, whose sample came from a region of still lower shear than the C sample, shows that from the very outset these planes started to orient without "blocking."

Figures 7E–H exhibit these effects for specimens adjacent to the rupture of biaxially stressed disks which cold-drew or "bubbled," as shown at the top of Fig. 4. Samples were cut from the lips of the large circular bubble like that in Fig. 4. They were cut as little strips whose length lay along a radius of the test disk. Accordingly, they were somewhat tapered in thickness because of the drawing down at the rupture. When mounted with long axis vertical (like the fiber diagram of Fig. 7A), and the plane of the strip (and thus disk) normal to the x-ray beam, patterns like Fig. 7E result. From this point of view, the chain axes lie as though they had tried to form rings around the pole of the inflated disk. Figure 7F shows a similar diagram for a sample from a higher molecular weight polymer, such as in the white disk in Fig. 4. Here the stress at rupture was about 2000 p.s.i., as compared to 1500–1600 p.s.i. for the black, drawn disk. The orientation was more complete, but otherwise similar. When these radial strips were turned 90° around their length, so that the x-ray beam entered parallel to the plane of the strip (and the disk), diagrams like Fig. 7G were found. These indicate the "two-way" or cross-hatched orientation which has occurred in the plane. This is presumably because the crystallites have attempted to glide in the directions of principal stresses, but have been blocked because of the gliding anisotropy noted before. This results, again, in much of the external tensions being *across* chain axis and unless the molecular weight is quite high, remarkable brittle, unoriented fractures such as those of the third disk in Fig. 4 occur. The off-equator spacings in Fig. 7G are the familiar 4.17A and 3.70A of the *n*-paraffin lattice. The equatorial spacings are, however, the strong 4.17A (110) and a fuzzy fea-

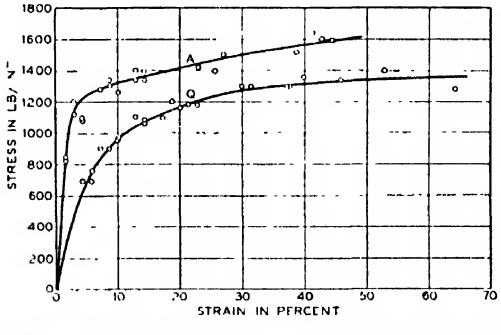

FIG. 9. Stress-strain curves of annealed and quenched polyethylene.

ture which has a Bragg spacing of 4.6A—presumably *oriented amorphous* chains whose unoriented halo scattering appears in Fig. 7A. This stretching out of amorphous chains may account for the quick, rubber-like contraction noted in connection with Fig. 6. Figure 7H shows the orientation appearing when the x-ray beam is parallel to the plane of and directed along the radius of the disk at the rupture.

DEGREE OF CRYSTALLINITY AND COMPLEX STRESSING

If preferred crystallite glide is so significant in reaction of polyethylene to complex stressing, large variations in crystallinity should be reflected in stress-strain properties. Degree of crystallinity of essentially simple chain polymers may be influenced in two ways. First, equilibrium crystallinity may diminish (or transform) with increase in temperature.[15,17,20,21] Secondly, *metastable* reduction in crystallinity occurs in quenched or

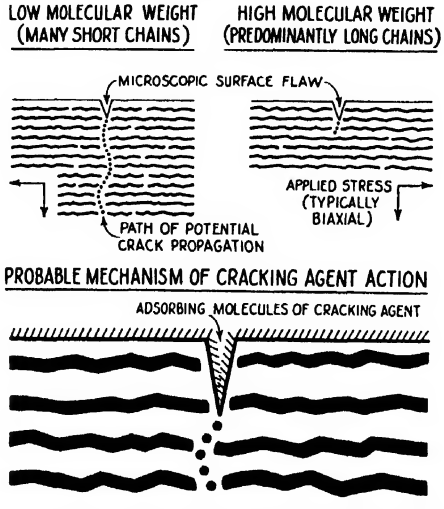

FIG. 10. Simplified scheme of possible cross section of sheet of biaxially stressed polyethylene (in which one of the stress arrows should be imagined as perpendicular to the page). Crack propagation is shown by dotted lines; electron micrographs of crack replicas indicate that paths may run around crystallites or spherulites. Cross-sectional size of cracking agent molecules should be considered as about same as that of polymer molecules. Replicas have shown that tiny surface flaws are present.

shock-cooled samples.[17,22] The latter condition is particularly important as it arises, often in uncontrolled ways, in technical processing of thermoplastics. However, while the life of these metastable states of order may be very long (years) for polar polymers like the polyamides and cellulose derivatives it is short for weakly-interacting chains like polyethylene. Thus, while spherulites may not be able to grow, and hence quenched samples of polyethylene may stay quite transparent, lateral ordering of the chains occurs rapidly at 25°C.

This is shown by the microphotometer tracings of x-ray diagrams, in Fig. 8. Specimen A was thoroughly quenched, by much more rapid cooling than could occur in practice. The 200 spacing is hardly resolved, and the 110 is diffuse with a half-breadth of 8.7 (in arbitrary units; the half-breadths were obtained after subtracting background corrections). While this sample had a lower yield stress than the same polymer annealed to condition C, its ultimate stress-strain properties were not radically different. Further, after 24 hr. at 25°C, the sample had re-ordered to give the pattern represented by Fig. 8B. The 200 spacing feature is resolved, although weak with a half-breadth of 7.4, while the 110 has intensified and sharpened to 7.7. This change indicates (1) that important physical differences in polyethylenes which have been processed with different thermal history will be lost after a few days standing at room temperature (this refers to lateral ordering, *not* to any long chain axis orientation or "molding strains"); (2) the energy differences between the metastable condition A and more ordered condition B are small, since activation energy for extensive transformation seems to be provided by kT at 25°C. This agrees with the small difference in physical properties between the two states, in contrast to the polar polymer case.[16]

Finally, the curve of Fig. 8C is for a sample which was allowed to solidify slowly, and was held at an elevated temperature for several hours. The 110 feature now has a half-breadth of 6.9, and the 200 of 7.4. This sample had maximum growth of spherulites, as well as presumably roughly[20] equilibrium crystallinity, but the conclusion is that over-all molecular order is not notably more than would eventually be reached by a practical sample standing at room temperature. Also, it was found that a polymer of molecular weight properties in the low elongation-brittle fracture class of Figs. 1 and 2 was not converted to a tougher, cold-drawing behavior by extreme quenching, and testing after standing a day. No doubt a polyethylene just on the verge of being able to orient under complex stressing, in the annealed condition could be oriented after thorough quenching. But these circumstances do not often arise; curves 8A and 8C represent practically the whole range of metastable states of the present type of commercial polyethylene. Detailed studies of polymers covering the 8A-8C extremes showed biaxial stress-strain curves of the latter lying about 240 p.s.i. above the disordered samples. Moduli from the first, linear portions of the curves were 13,200 p.s.i. for the quenched and 34,800 p.s.i. for the annealed polymers. The complete stress-strain curves appear in Fig. 9.

Stable reductions in degree of crystallinity at elevated temperatures are currently being studied in relation to complex stressing at those temperatures. Presumably near 100°C there will be easier and more isotropic crystallite orientation than at 24°C.[18] The over-all reduction in crystallites also shows up in stress-strain properties.[23] Hence, many of the effects in this report may be changed at other temperatures.

CRACKING AGENTS AND COMPLEX STRESSING

Crazing or micro-cracking of polymers has been long studied, especially in technical development of rigid

[20] R. B. Richards, Trans. Faraday Soc. 41, 127 (1945).
[21] Raine, Richards, and Ryder, Trans. Faraday Soc. 41, 56 (1945).

[23] Stein, Krimm, and Tobolsky, Textile Research J. 19, 8 (1949).

polymers such as polystyrene and polymethyl methacrylate, and in many finishes. It arises from shrinkage stresses when volatile components (such as unreacted monomers) escape, from external stresses,[24] and from internal stresses reflecting inhomogeneous molecular packing.[25] Spectacular acceleration of crazing occurs with application of many organic liquids or their vapors to the surface of these polymers, under either internal or external stress.[24,25] Stressed polyethylene (of certain molecular weight range) also shows this brittle cracking, by "mobile polar liquids."[8] The present work has revealed that complex stresses are strikingly effective in this surface-agent attack; biaxial tension causes extensive cracking in the presence of alcohols, esters, organic salts, etc., many times faster than uniaxial tension. However, as with the effects of biaxial tension alone the effects with surface-agents are also sensitively affected by molecular weight.

Cracking liquids have been called "surface-agents" above, following a mechanism postulated for crazing action, in connection with earlier work.[25] This is shown schematically in Fig. 10, where the "lyophilic" or non-polar parts of the adsorbed molecules of cracking liquid are assumed to penetrate the outermost layers of polyethylene chains. These adsorbed molecules presumably tend to spread to form Langmuir-type films. As they cover the polymer surface, they run along into tiny flaws and cracks and, at the apex of these cracks, probably exert a film spreading pressure. This film pressure, along with weakening of the polymer mole cohesion near the apex by swelling by the non-polar portions of the sorbed molecule, may add to an external stress to yield crack propagation. Biaxial external stresses, whatever the reason, cause especially rapid cracking in the presence of such agents.

Likewise, solvents like benzene, toluene, etc., which can actually swell polyethylene, even at room temperature, cause brittle fracture under biaxial stress. This seems to be just a weakening of the intrinsic structure, however, perhaps because of the drastic lowering of number average molecular weight in such a "plasticized" system. (Before complete penetration, these solvents presumably act as surface agents.)

GENERAL SIGNIFICANCE

Reactions of other microcrystalline polymers to complex stresses is being explored. Many queer cases of brittle failures in use by polymers normally considered (by uniaxial criteria) to be tough may have come from biaxial stressing in service. Certain brittle point tests (the test for incidence of brittle fracture, usually in rubbery materials at low temperatures) also seem to introduce varying amounts of biaxial tension in the bent sample. This may be one of the poorly controlled elements in brittle point evaluation. Likewise the great sensitivity to cracking agents of polymers already studied under complex stresses suggests that effects of liquid immersion baths in brittle tests may have been underestimated.

Bending of cable sheaths causes mostly biaxial stressing as do many common deformations of tubes, bottles, and the like. Likewise, paints and lacquers on tubular or other surfaces which are bent can become subject to intense biaxial stressing. In these cases, the strains are often small enough so that the given polymer material is commonly thought to have much reserve elongation before rupture, *again based on conventional uniaxial tests.* The present work at least indicates that many of these usual engineering practices must be re-examined. In the case of cable sheath, a complete upward revision of ideas of acceptable molecular weight polymer was necessary because of effects of complex stressing when the cable was bent and twisted.

Frozen, crystallized natural rubber is being studied to see if rubber crystallites not *formed* in the direction of stress show blocking. This would be a variation of the normal behavior found for initially amorphous rubber biaxially extended up through its presumed stress-crystallization point.[6]

Several technical tests such as paper bursting tests operate under complex stresses. Microcrystalline polymer films, especially those of interest because of low moisture permeability, such as polyethylene, rubber hydrochloride, polytetrafluorethylene, and polytrifluoro-monochlorethylene may show special properties in these tests.

ACKNOWLEDGMENTS

D.C. Characteristics of Silicon and Germanium Point Contact Crystal Rectifiers. Part I. Experimental*

H. J. YEARIAN
Physics Department, Purdue University, Lafayette, Indiana
(Received August 29, 1949)

Typical d.c. current-voltage characteristics obtained for Si and Ge crystal rectifiers are described. A survey of the published theories of the rectifier shows that none of them will account for the principal features of the observed characteristics. The most obvious discrepancy is in the low resistance direction of flow where the logarithm of the current rises with increasing voltage at only a fraction of the rate indicated by the theories. The need for a more flexible theory is pointed out and the conditions which it must meet, both as a function of voltage and temperature are outlined.

THE development of microwave radar has been accompanied by wide use of point contact crystal rectifiers, and a revived interest in the details of their behavior. Since a complete understanding of their operation at high frequencies must be predicated upon their low frequency properties, extensive investigations of their d.c. characteristics have been made.

It is the purpose of Part I to give typical d.c. characteristic data of silicon and germanium rectifiers, the two types of interest at present in the microwave region,** and to show that the published theories of the rectifier do not account for the important features of these characteristics. Part II† will discuss an extension of the diode theory, the so-called multicontact theory, which is in agreement with the experiments.

The usual rectifier for high frequency applications consists of a metal point of approximately 10μ-diameter, in contact with a suitably alloyed crystal of silicon or germanium semi-conductor. The ratio of current at a given applied voltage in the low resistance, or forward, direction to that in the high resistance, or backward, direction, may be several hundred. The silicon now in use is a hole, or P type, conductor for which the direction of easy flow of electrons across the rectifying junction is from metal to semi-conductor. The polarity is opposite for germanium, since this material is used as an electron, or N type, conductor.

In series with the variable resistance of the rectifying barrier is the resistance encountered as the current spreads outward from the contact into the semi-conductor. This "spreading resistance" has a value, $R_s=\rho/(2d)$, where ρ is the resistivity of the semi-conductor and d is the diameter of the contact. All experimental data must be corrected for the potential drop in this resistance before comparison with theories of the rectifying barrier.

A number of theories of the rectifying contact have been developed[1] which differ in their treatment of the problem according to the assumptions made concerning the nature of the rectifying barrier or blocking layer.

The barrier may be assumed to be an artificial insulating layer on the surface of the semi-conductor, or a depletion layer formed near the surface by absence of the impurity centers which produce the conductivity of the semi-conductor. It may also be assumed to be the natural barrier formed when direct contact is made between a semi-conductor and a metal having a different work function.

The electron potential energy diagrams for these cases are shown schematically in Fig. 1, for an N type semi-conductor. Analogous diagrams may be made for the P type.

For the usual densities of donator states slightly below the bottom of the conduction band of the semi-conductor, the Fermi level lies approximately half way between the donator levels and the bottom of the conduction band. Well within the semi-conductor, when at equilibrium with no voltage applied, this level must lie at the same height as the top of the Fermi lake in the metal. When, therefore, the work function of the semi-conductor is less than that of the metal,†† a potential barrier is formed of height equal to the difference of the work functions, the contact potential, V_c.‡ With an insulating layer on the surface of the semi-

* This work was performed under OSRD Contract OEMsr-362 and was reported in an NDRC Report dated December 3, 1942, PB5189.

** The "High Back Voltage" type of germanium rectifiers have high frequency properties which are significantly different from the microwave type, but the low voltage d.c. characteristics are similar and most of the conclusions of this paper will apply. †† These are the work functions under existing conditions, not necessarily those for clean surfaces.

‡ J. Bardeen has investigated the effect of energy states on the surface of the semi-conductor (Surface States and Rectification at a Metal Semi-Conductor Contact, Phys. Rev. **71**, 717 (1947)) and has shown that the barrier height may be nearly independent of the metal work function. No major changes in the results of the rectifier theories outlined below will be occasioned by introduction of the surface states if "V_c" and "contact potential" are interpreted as meaning the height of the potential barrier, however formed.

conductor, either due to an artificial layer of an insulator or to a depletion of donators, there results a nearly linear variation of potential across this region. With no insulator nor depleted layer, when contact is made electrons near the surface will go over to the metal, leaving a positive space charge due to ionized donators. The potential fall in this case is quadratic and the barrier has a thickness, D, of approximately

$$D=[\epsilon V_c/(2\pi e\mathcal{N}^+)]^{\frac{1}{2}}, \quad (1)$$

where ϵ is the dielectric constant and $\mathcal{N}^+$ the density of ionized donators.

The theories may be further differentiated according to the assumption of a thin, or a relatively thick barrier layer.

For the case of an insulator sufficiently thin that electrons may tunnel through, Wilson,[1] and also Mott[1] have shown that if the current and the voltage across the contact are taken positive for electrons flowing from semi-conductor to metal, the net current density is

$$j=-4\pi me(kT)^2ph^{-3} \times\exp(-V_c/kT)[\exp(-eV/kT)-1], \quad (2)$$

where p is the transmission coefficient of the barrier, V is the voltage across the barrier (applied voltage V_a minus the potential drop in the spreading resistance) and the other constants have their usual significance.

As has been pointed out by Mott, this result is contrary to experiment since for an N type semi-conductor it gives the low resistance direction as corresponding to the flow of electrons from metal to SC $(-V)$ whereas, experimentally, this is the high resistance direction. Tunneling effects cannot, therefore, be the fundamental source of the rectification. Such effects are of importance, however, in the detailed analysis of the characteristic in the backward direction and will be discussed below.

In the case of a depletion layer for which the thickness, D, is large compared with the electron mean free path, so that conditions of diffusion exist in the barrier region, Mott[1] finds for the current density

$$j=ebn_0(V_c-V)D^{-1}[\exp(eV/kT)-1], \quad (3)$$

where b is the electron mobility in the semi-conductor and n_0 the electron density at the boundary of the semi-conductor in the absence of current.

In the forward direction for $0<V<V_c$, Eq. (3) is similar in behavior to that for tunneling, but the sign is reversed as experiment requires. The exponential is the dominant term, so that the slope of the curve ln$i$ *versus* V, $V\gg kT/e$, should be only slightly less than e/kT. In the backward direction, $V<0<V_c$, the current should quickly approach an approximately ohmic behavior of differential resistance $D/(ebn_0)$ determined by the first factor. The back current asymptote extrapolated to $V=0$ should give an intercept ebn_0V_c/D, the current in each direction across the barrier at zero applied voltage.

The effect of image force is to lower the barrier and this will have the effect of making the backward current increase more rapidly than indicated by Eqs. (2) or (3).

The theory of the thick natural barrier has been considered in detail by Schottky and collaborators[1] especially for the low voltage region. For semi-conductors of the "exhausted" type, in which the donators are completely ionized, the characteristic may be written in the form

$$j=\sigma_b(8\pi e\mathcal{N}/\epsilon)^{\frac{1}{2}}(V_c-V)^{\frac{1}{2}}[\exp(eV/kT)-1] \times\{1-\exp[-e(V_c-V)/kT]\}^{-1}, \quad (4)$$

where $\mathcal{N}$ is the density of (completely) ionized donators and σ_b is the conductivity of the semi-conductor at the boundary. For $V_c\gg kT/e$ and $V\ll V_c$, the denominator is approximately unity. The square root varies only slowly, so that in the forward direction, V positive, the current increase is nearly exponential with a logarithmic slope of $\approx e/kT$. In the backward direction the current should increase slowly according to the square root.

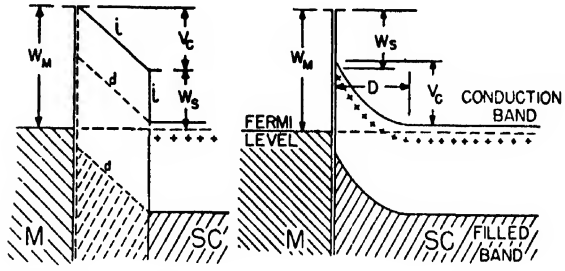

FIG. 1. Potential barrier between metal, M, and N type semi-conductor, SC, at equilibrium with no voltage applied. W_m and W_s, work functions of metal and semi-conductor; D, thickness of natural barrier; $V_c=W_m-W_s$, barrier height; +++ donator levels. Left, insulator (full lines i) between M and SC with potential differences V_c across insulating barrier; left (dotted lines d) depleted layer of SC next metal with potential difference V_c across this layer; right, natural barrier of height V_c. Levels at right of each figure will be moved up or down by amount of positive or negative voltage, respectively, applied across the contact.

When the donators are not completely ionized, the so-called reserve region, Schottky and Spenke[1] have shown that at low voltages the factor corresponding to the logarithmic slope e/kT becomes $e/(\delta kT)$, where δ may vary up to three as a maximum. They also show that as the higher forward voltage region is approached, the characteristic curves for the reserve and exhausted cases merge. The logarithmic slope as measured at voltages above 0.1–0.2 volt, therefore, should be $\approx e/kT$ in either case. It is likewise shown that in this region there is no essential difference between the theories for depletion and non-depletion of donators. This is in agreement with the similarity of Eqs. (3) and (4) in the forward direction.

If the natural barrier is thin compared with the electron mean free path in the semi-conductor an electron makes no collisions in the barrier region, and the problem may be treated as that of a diode. This theory has

been developed by Bethe[2] and Sachs[3] and gives the result

$$j=j_0\exp(-eV_c/kT)[\exp(eV/kT)-1], \qquad (5)$$

where j_0 is the thermal current density in the semi-conductor, $j_0=ne[kT/2\pi m)]^{\frac{1}{2}}$ and n is the electron density in the conduction band. The terms of Eq. (5) outside the brackets represent the electron current over the top of the barrier from metal to semi-conductor and with no voltage applied, the equal current in the opposite direction. As the voltage is varied the first current is constant (without image force or tunneling effects) while that from semi-conductor to metal varies exponentially with voltage. This theory therefore also gives a logarithmic slope in the forward direction of e/kT, while the current density in the backward direction quickly increases to a saturation value $j_0\exp(-eV_c/kT)$.

The intermediate case of a natural barrier which is comparable in thickness with the mean free path has been investigated by Herzfeld[4] to show that the current will differ from that of the pure diode theory, Eq. (5), by less than five percent in the range ± 1 volt.

The forward characteristics predicted by all of these theories are much the same and the current may be approximately represented by

$$i=i_0[\exp(eV/kT)-1], \qquad (6)$$

where i_0 may vary slowly with voltage and is strongly dependent on temperature and contact potential.

The backward characteristics range from the saturation type of Eq. (5) to the approximately ohmic type of Eq. (3). These will be modified in the direction of increased currents by image force and tunneling effects.

A decision between the thick or thin natural barrier, and between exhausted or reserve region theories can be made from measurements of the Hall coefficient, R, and resistivity, ρ, as functions of temperature. From these data one may calculate the mean free path 1; the depth, ΔE, of the donator levels below the bottom of the conduction band or of acceptor levels above the top of the full band in the case of N and P semi-

conductors, respectively; the electron density, n; the density of donator or acceptor levels, N, and by Eq. (1) the natural barrier thickness, D. These data for several samples of silicon and germanium at 300°K are abstracted in Table I from the work of K. Lark-Horovitz and collaborators.[5] The thickness, D, is calculated for $V_c=0.3$ volt. The distance x_0 over which the potential barrier rises by kT/e is included, since this may be the more nearly correct critical distance to be compared with 1.[2]

In germanium the mean free path is three to ten times x_0, and in silicon approximately equal to x_0. In view of the work of Herzfeld,[4] the diode theory should, therefore, apply to these materials if the rectification is due to a natural barrier.

[5] K. Lark-Horovitz, "Preparation of semi-conductors and development of crystal rectifiers," NDRC Report 14–585, Purdue University.

That an insulator on the surface, or a depletion layer, is necessary for rectification in these materials seems highly improbable, since the general features of their characteristic curves are not at all sensitive to surface treatment. A freshly broken surface of a homogeneous single crystal may give characteristics quite the same as does a suitably polished and etched surface. There are surface treatments in use which could result in a depleted or insulating layer, but these treatments are not essential to the rectification. In any case, characteristics of the type of Eq. (6) are to be expected in at least the forward direction.

Experimental characteristics of typical silicon and germanium point contact rectifiers are shown in Fig. 2. In the forward direction the plot is made semi-logarithmic as well as linear to facilitate comparison with Eq. (6).

The original current data is plotted against the applied voltage V_a, and this voltage corrected to $V=V_a-iR_s$ where R_s is the spreading resistance in series with the contact. Since the effective diameter of the contact cannot be determined with adequate precision to calculate this correction satisfactorily, it is made by trial to give as regular a corrected curve as possible. According to the theories, as represented in Eq. (6), the corrected semi-log plot should be linear for $V \gg kT/e$ ($kT/e=1/40$ volt at 300°K). It is nearly always possible to find a value of R_s (6.5 ohms, Fig. 2) consistent with that calculated from the measured diameter, which will give a linear corrected curve in the usual range of V_a. As is indicated in the figure, however, this linear portion is usually not a continuation of the lower part where the spreading resistance is negligible. The upper slope for normal rectifiers tends to be somewhat less than the slope of the lower part. This is particularly true for germanium. If one attempts to make the upper slope as large as the lower by using a larger value of R_s, (13 ohms, Fig. 2) the corrected curve will usually begin to bend backward to give a negative differential resistance at applied voltages in the neighborhood of one volt. With some R_s between these values one could expect to obtain a corrected curve which approaches a vertical line corresponding to $V=V_c$ as an asymptote. Such a curve is approximated in Fig. 2 with $R_s=7.7$ ohms. This is equivalent to constructing the asymptote of differential resistance 7.7 ohms on the linear plot, cutting the voltage axis at V_c.

To make satisfactorily accurate determinations of R_s and V_c by either of these constructions would require data to higher voltages than is usually attainable because of erratic behavior of the contact. The interpretation of such data is also uncertain due to the strong dependence of the semi-conductor resistivity on temperature. In the case of germanium, the linear plots frequently show no definite region of truly constant slope, but the slope continues to increase as the voltage is raised to values for which it is certain there will be disturbances caused by heating.‡‡ This corresponds in the above analysis to a decrease in the effective R_s and an increase in effective V_c as the applied voltage is increased. In view of these difficulties, perhaps the best one can say at present is that the straight line correction on the semi-log plot gives a minimum value of R_s, and that which produces a negative differential resistance gives a maximum value appropriate to the voltage range used. These uncertainties at the upper part of the characteristic do not affect it appreciably below 0.4–0.5 volts, however, so that comparison with theory can be made in this range.

According to Eq. (6), if a current i_0 is added to the observed forward current, a straight line of slope e/kT should be obtained on a semi-logarithmic plot. Usually it is possible, as is indicated in Fig. 2, to find such a current which will yield a linear region of considerable length. Let us denote this current which corresponds to i_0, by I_F in order to distinguish it from a similar current, I_B, obtained from the backward characteristic. Also denote the slope of the corrected curve by α.

The curves of Fig. 2 are quite typical of silicon and germanium rectifiers. While linear regions of ln$i$ extending over five powers of ten in current have been found, a range of one hundred to one thousand is more common. Characteristics are found which deviate from this linear behavior, usually in the sense of two oppositely curved portions, convex upward at the low currents and convex downward at the higher currents, but these are the exception.

These characteristics are in qualitative agreement with the prediction of theory, but the quantitative agreement is very poor. The result common to all theories discussed above is that the logarithmic slope should be very approximately $\alpha=e/kT=40$ volts^{-1} at 300°K. The experimental slopes are always less than this. The value shown in Fig. 2 of approximately one half e/kT is typical as is evident from the data listed in Table II. Occasional higher values of α do occur, but the one of .88 e/kT quoted for sample 462 is exceedingly rare. Much less uncommon are values down to one-fifth or one-sixth e/kT. Use of Pt-Ir alloy for the metal in contact with germanium has some tendency to increase the value of α as compared with that obtained with tungsten.

It is evident that the approach to the linear portion of the curve is much less rapid than is indicated by the theories, so that the data can usually be represented by a characteristic of the form $i=I_F[\exp(\alpha V)-1]$.

The wide range of I_F indicated in the table is not inconsistent with the diode theory. One may set $I_F=i_0.1=Aj_0\exp(-eV_c/kT)$ where A is the area of the contact. Using 10^{-6} cm^2 as an average value of A and with $j_0\simeq 10^6$ amp/cm^2 computed from the Hall

‡‡ This apparent inconstancy of spreading resistance is under investigation, particularly for the "high back voltage" type rectifier. See reference 5; Ralph Bray, Phys. Rev. 74, 1218 (1948).

coefficient measurements, one finds a range of I_F from 1 ma to 0.2μa corresponds to a variation of V_c between 0.17 and 0.39 volt. These are reasonable limits, not in disagreement with the estimates to be made from the spreading resistance correction discussed above.

Granting, however, the I_F is correct, it follows from the exponential dependence of the current on α, that with α one-half e/kT the current at 0.3 volts is $\frac{1}{4}$ percent of the theoretical value, and for α one-third e/kT, it is only 1/30 percent of theoretical. Clearly some modification of the theories is necessary.

A similar disagreement has long been known in the low voltage region; e.g., Wagner, Schottky and Spenke[1]. Although for a reserve semi-conductor one has flexibility in α (Schottky α_1) by the factor of $\frac{1}{3}$, values for Cu_2O, MoS, TeO_2, etc., are found as low as $\frac{1}{8}e/kT$. It may be possible in the low voltage region to account for the remaining discrepancies by the assumption of essentially ohmic imperfections in the barrier. In the higher voltage region, this solution is not possible, since the minimum resistance which can be assigned from the back characteristic will contribute nearly insignificant currents to the forward characteristic at voltages above about 0.1 volt. In the rather favorable example of Fig. 2, if currents equivalent to the entire back current are subtracted from the forward characteristic, the value of α is increased from 18 to only 20.4 volts^{-1}.

The back direction characteristic in Fig. 2 has been plotted on an enlarged linear scale. It is evident that the current does not saturate as required by the simple diode theory, but in general it may be analyzed into a diode component, an ohmic component, and a rapidly increasing component or "tail." The latter part is frequently nearly exponential in character and may, therefore, be ascribed to tunneling through a thin barrier, as suggested by the reversed rectification in this case, Eq. (2), or it may be due to the effect of image force in lowering the barrier. These processes will be discussed below.

The diode-like component, I_B, and the resistance of the ohmic component, R_B, are listed in Table II. It is evident, contrary to the diode theory, that I_B is not the same as I_F. It may be larger or smaller, but is usually smaller, particularly at low temperature. Determination of a new I_F from the forward characteristic after correcting for the ohmic contribution to it, as discussed above, does not in general bring the two currents into coincidence.

The existence of the important ohmic component of the back current suggests that the barrier is of the thick depleted layer type leading to Eq. (3). From the data given and the discussion above, however, it seems highly unlikely that this is necessarily the case. It would rather seem that irregularities which have an essentially ohmic behavior must exist in the thin natural barrier.

The diode theory, with the assumption of such ohmic regions, combined with some form of tunneling and image force barrier lowering should give agreement with the back direction characteristic. Introduction of such modifications also affects the forward characteristic. The ohmic regions themselves will not appreciably reduce the discrepancy between the theoretical and experimental logarithmic slope, as was shown above, but the other effects might be expected to do so.

The effect of barrier lowering by image force has been investigated by Bethe[2] and others[3, 6] and the tunnel effect by Courant.[6] The effect of image force is to lower the barrier by an increasing amount as the voltage is reduced in the forward direction or increased in the backward direction. The tunnel effect may be expressed as an additional lowering.

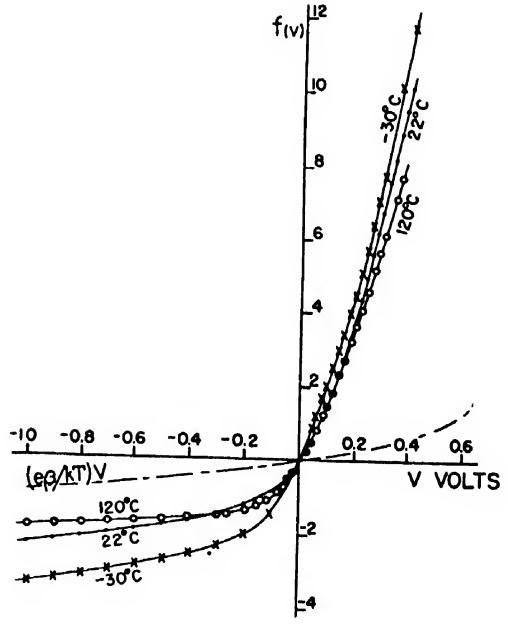

FIG. 3. Typical behavior of the exponent $f(V)$ in a corrective term, $\exp[-f(V)]$, to bring the simple diode theory into agreement with experiment (Data of 5Id-4, Table II). Dashed curve shows the type of correction afforded by the barrier lowering modification of the theory.

The total potential lowering from the original value V_c, may be expressed as $\Delta V_c=\beta(V_c-V)$ where β[Courant $(1-\theta)$] is positive and nearly constant for $V\ll V_c$, and increases slowly as V approaches V_c. Subtracting this correction from the V_c of Eq. (5) gives

$$j=j_0\exp[-e(1-\beta)V_c/kT]\exp(-e\beta V/kT)\times[\exp(eV/kT)-1] \quad (7)$$

instead of Eq. (5). For comparison with experiment,

[6] E. D. Courant, NDRC Division 14 report MIT May 17, 1943. See also Phys. Rev. 69, 684 (1946). In this abstract the sign of the corrective exponent should be positive. The impression which might be given by the abstract that there is agreement between the corrected theory and experiment, is misleading. The full paper shows that the essential discrepancy still exists, as discussed herein.

instead of Eq. (6) one should then use

$$i=i_0' \exp(e\beta V/kT)[\exp(eV/kT)-1], \qquad (8)$$

where i_0' is nearly constant except for $V\simeq V_c$.

As was mentioned earlier, this additional factor is of the correct form to agree with the observed "tail" in the back direction. For negative V the variation of the term in brackets is negligible and the back current increases exponentially. As nearly as one can divorce this effect from the diode and ohmic parts, the experimental data require values of β of approximately 0.01 to 0.05. It seems possible to obtain values of this order from the theory.

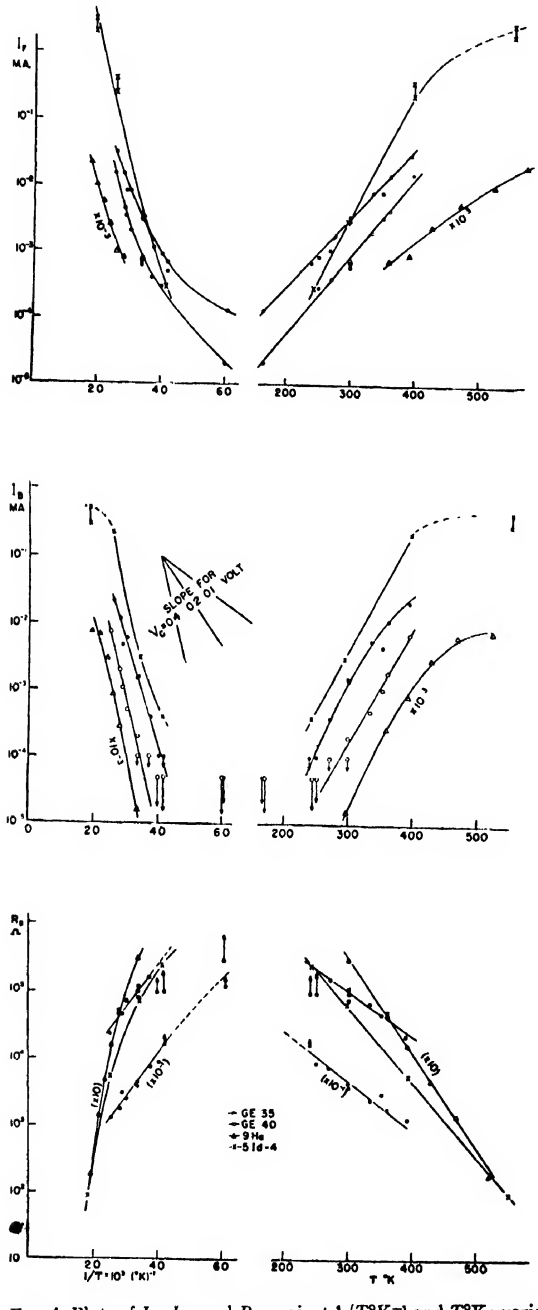

FIG. 4. Plots of I_F, I_B, and R_B against $1/T°K^{-1}$ and $T°K$; variation with reciprocal of temperature is not always linear and slopes of I_F and I_B are not equal.

In the forward direction there would also seem to be an improvement over the simple theory. On expanding Eq. (8)

$$i=i_0'\{\exp[e(1-\beta)V/kT]-\exp[-e\beta V/kT]\} \qquad (9)$$

and since for $V\gg e/kT$ the second term is negligible, one obtains an exponential characteristic whose logarithmic slope has been reduced from e/kT to $(1-\beta)e/kT$.

The reduction possible by this correction cannot, however, be made sufficient to agree with experiment. The values of α usually found range downward from approximately $0.5e/kT$. This requires values of β of 0.5 and larger. For $\beta=0.5$ the predicted value of $\alpha=(1-\beta)e/kT=0.5e/kT$, but in this case Eq. (9) shows that the backward characteristic, V negative, is identical with the forward characteristic and there would be no true rectification. The required values of β larger than 0.5 would give a reversal of sign of rectification. Moreover, quantitative estimates¶ of the magnitude of β show that it cannot be as large as 0.5, except for very low values of V_c.

To be in agreement with experiment, in the terminology of Eq. (8), β would have to increase from $\approx$0.1–0.05 for negative V, to $\approx$0.5–0.7 or more for positive V. While the theories give a variation in this sense, it is negligible in amount compared with the required variation.

The experimental data may be used to determine an empirical function, $-f(V)$, to replace $-e\beta V/kT$ in the corrective term of Eq. (8). The function can be determined only to within an additive constant, because of the uncertainties in the area of contact and contact potential included in i_0'. The curves of Fig. 3, for a germanium rectifier at three different temperatures, have, therefore, been arbitrarily displaced to pass through the origin. In contrast with this rapidly varying function required by experiment, the simple diode theory gives a constant value for $f(V)$ and the barrier lowering theories give a curve which slowly increases in slope as the voltage is increased toward V_c.

The characteristics of a number of crystals have been obtained at various temperatures. Considerable difficulty is encountered in maintaining the same contact over a wide range of temperatures. Some of the more reliable data are listed in Table II.

At the high temperatures, analysis according to Fig. 2 is difficult, because the spreading resistance uncertainty affects a large part of the forward characteristics and also because the measurements in the back direction do not always extend far enough to differentiate between ohmic current and diode current, due to the

¶ References 5 and 6; also V. F. Weisskopf, NDRC Report 14–133 (May 12, 1943).

extremely rapid increase of the latter with temperature. At the low temperatures the back current may become too small for accurate determinations. In these cases ranges of values are given.

The general behavior is that α decreases and I_F and I_B increase very rapidly with increasing temperature, as would be expected from the theories. R_B decreases with increasing temperature, so that whatever mechanism is assumed to provide this ohmic component, it must have an effective resistivity which is very temperature sensitive. The large changes with temperature are demonstrated in the $f(V)$ plots of Fig. 3, remembering that $f(V)$ is the argument of an exponential.

Examination of the values of α in Table II shows that these rectifiers are of different types. For 5Id2, 5Id4, and 9Ha, the ratio of α to the simple theory value, $s=\alpha kT/e$, in general falls with increase of temperature. There is some indication of an initial rise with a maximum at $\approx 400°$K. GE-35 and 40, on the other hand, show a nearly constant value of α, so that the ratio s rises with temperature. Physically, GE-35 and 40 differ from the others in that a condenser discharge had been passed through the contact and the junction was thought to be at least partially welded.||

The variations of I_B, I_F, and R_B with temperature are shown in semi-logarithmic plots as functions of T and $1/T$ in Fig. 4. The apparent disturbance at the highest temperatures may be due partially to physical changes in the contact, although the data were reasonably reproducible. In spite of the limited nature of the data, there seems to be a somewhat better agreement with an equation of the form $\exp(CT)$ than with $\exp(-K/T)$, particularly for I_F, whereas I_F and I_B should each be equal to i_0, and yield a negative exponential in $1/T$, according to Eq. (5). The slope of the log plot against $1/T$ should be $-eV_c/k$ except for possible variation in n, and the small effect of the $T^{\frac{1}{2}}$ coefficient. (The Hall effect data indicate that n is nearly constant over the range of these measurements.) The order of magnitude of V_c required by the data is from 0.1 to 0.65 volts. This range obtained from the temperature variation is reasonably consistent with the range of 0.17 to 0.39 volts estimated earlier from I_F itself. There is, however, no detailed correlation. The values of A and n involved in i_0 are certainly of the same order of magnitude for these samples and a large value of i_0 (I_F or I_B), corresponding to a small V_c should be associated with a small negative slope on the $1/T$ diagram. The lines should tend to radiate from a common point (Ajo) on the $1/T=0$ axis.

From this discussion it becomes evident that a satisfactory theory of the silicon or germanium rectifier must allow the logarithmic slope of the forward characteristic to be reduced below e/kT by a factor which is in itself temperature dependent. The intercepts corresponding to I_F and I_B must not be required to be equal, and must vary approximately exponentially with T. The theory must also provide a mechanism for an ohmic current, as well as a diode component, in the back direction, and the resistance of this component must vary exponentially with temperature, instead of having the relatively slow variation of the semiconductor resistivity.

Part II will be concerned with the development of a diode theory to meet these conditions. The development is based upon a proposal of H. A. Bethe that one abandon consideration of the contact as being a perfectly homogeneous one with all parts having the same contact potential, and adopt the point of view that it consists of more or less isolated regions having lower contact potentials than their surroundings. These regions should be considered to be very small spots ranging in contact potential from very low values up to (or beyond) the values normally expected.

It is essential to consider that the current through any such spot is limited by the local spreading resistance in series with it, or by the fact that the current density through it has a maximum value of j_0. A graphical construction will quickly show that with suitable distributions of the number and size of spots having a given contact potential, one can obtain an α of any value less than e/kT. The temperature dependence of α may be attained by varying the distribution functions. An ohmic component is provided by the contributions of the spots having zero or negative contact potential, for which there is no barrier, and its temperature dependence by the variation with temperature of the number or size of these spots.

Electric Breakdown in CO_2 from Low Pressures to the Liquid State*

D. R. Young†
Laboratory for Insulation Research, Massachusetts Institute of Technology, Cambridge, Massachusetts
(Received September 26, 1949)

The electric breakdown in CO_2 has been investigated from low pressures through the critical point into the liquid state. Paschen's similarity law is verified for low pressures. At high pressures small departures are observed for long gap-lengths and large departures for small gap-lengths. Simultaneously the scatter of the breakdown voltage becomes independent of illumination and the breakdown strength dependent on the cathode material; this appears due to the onset of field emission. Measurements of prebreakdown currents have yielded values for Townsend's first coefficient as well as for the field emission constants. For small gap-lengths the prebreakdown currents are higher than the normal field emission equation predicts, indicating some new process effective at short gap-lengths. The transition from the gaseous to the liquid state does not produce a discontinuous change of the breakdown voltage.

INTRODUCTION

THREE experimental variables describe the d.c. breakdown characteristics of gases in uniform fields after the gas type, the electrode material, and the source of primary ionization have been chosen: the breakdown voltage v, the gas density ρ, and the electrode spacing d. Paschen established experimentally,[1] that the breakdown voltage of a spark gap is a function of the product ρd only, $v=f(\rho d)$. This equation, in which Paschen used pressure instead of the density, is called the Paschen similarity law. It states that the voltage drop per free path is the important variable.

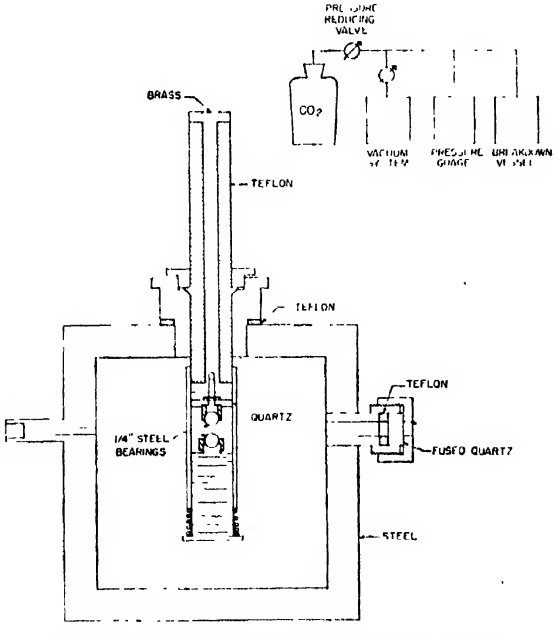

FIG. 1. Schematic diagram of breakdown equipment.

This law cannot hold at high pressures as von Hippel has pointed out.[2] The breakdown field strength in atmospheric air amounts to about 3×10^4 v/cm. For solids and liquids, with the density several thousand times higher, the breakdown strength has risen only to the order of 10^6 v/cm. Hence, instead of about 1.5 v per free path in gases, only 0.01 0.1 v is required for breakdown over the corresponding path lengths in condensed phases. It seems that the breakdown mechanism has changed from the Townsend type, in which the ionization is held in check by electronic excitation processes, to a new mechanism in which the vibration states of the solids and liquids appear to play a decisive role. This latter mechanism has been the object of investigation in this laboratory for some time.[3,4] It is the aim of the research presented here to learn more about

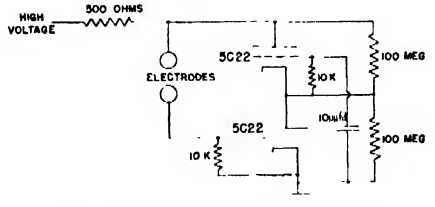

FIG. 2. Electrode protection circuit.

the transition region between the breakdown types in gases and in liquids.

Carbon dioxide was used as the test material since its critical point is readily accessible and its equation of state well known.

EQUIPMENT AND MEASURING TECHNIQUES FOR BREAKDOWN IN THE GASEOUS STATE

A schematic diagram of the apparatus used for the breakdown measurements is shown in Fig. 1. The equipment was evacuated before the CO_2 was admitted. For measurement of pressure a mercury column was used in the lower pressure range (up to two atmospheres)

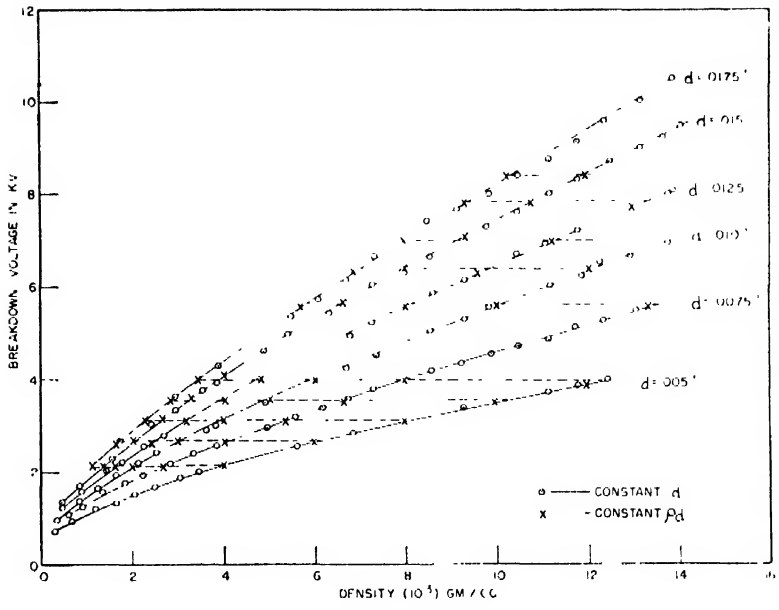

FIG. 3. Breakdown voltage *vs.* density with gap-length as parameter

and Clapp pressure gauges, calibrated by a dead-weight tester, above this limit.

Initially the high voltage insulator of the breakdown vessel was made of polystyrene, but it proved soluble in liquid CO_2 and was therefore replaced by Teflon. Steel ball bearings 0.250 in. diameter served as electrodes since their polish is excellent and their low cost makes them expendable.

Since preliminary experiments indicated that the insulating materials used were not rigid enough to insure an accurate separation if they had to support the pressure, the electrode holder was designed as shown in Fig. 1. The spacing was adjusted by the spring-loaded screw on the lower electrode, and calibration marks 0.0005 in. apart were included. It was possible to adjust the spacing with an accuracy of about ± 0.0002 in.

Teflon was used for the pressure seals with excellent results if the gaskets were entirely confined. A quartz window allowed illumination of the cathode by ultraviolet light.

Without current limitation each breakdown damages the electrode surface and requires its reconditioning. To avoid this damage to the electrodes, the high voltage was removed about 10^{-7} sec. after initiation of the breakdown, by using two hydrogen thyratrons (Sylvania 5C22) in series, triggered by the breakdown current (Fig. 2). Two thyratrons were required since the voltages used exceeded the rating for a single tube.

The high voltage was measured with a multi-range current amplifier used in conjunction with a 10^9-ohm standard resistance. The standard resistance was made up of 100 10^7-ohm one percent resistors which were mounted in 15 copper shells stacked in series. Measure-

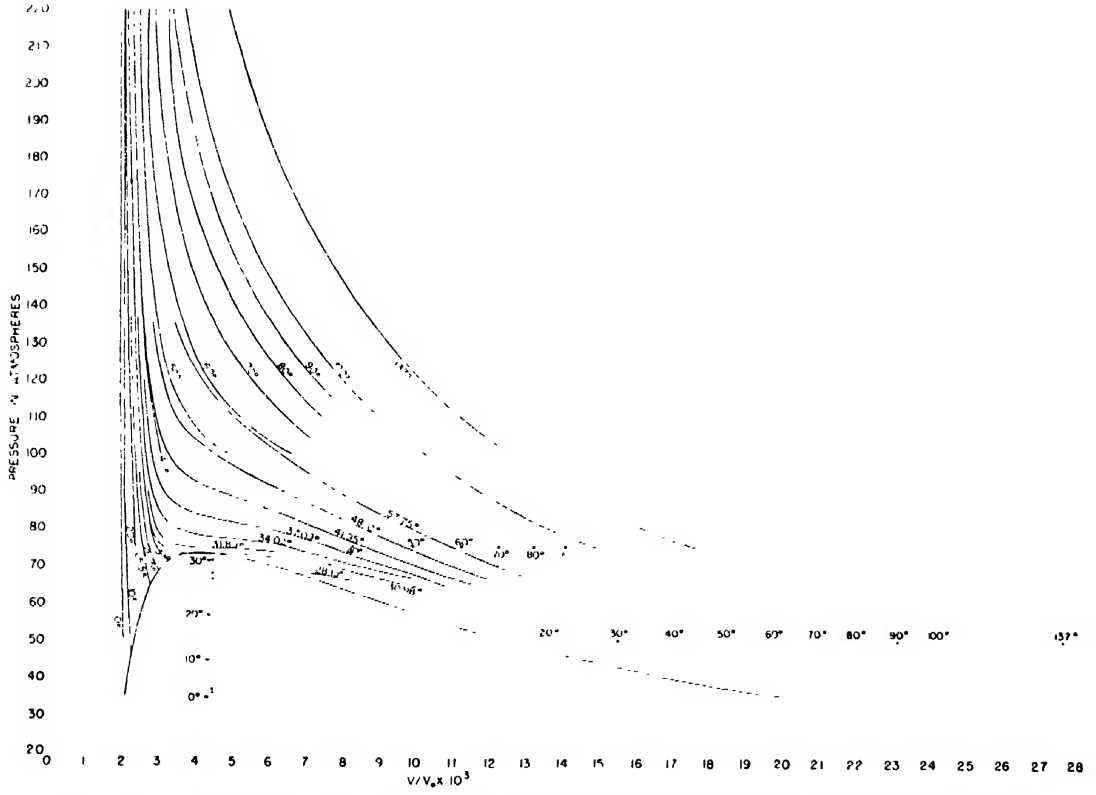

FIG. 6. Pressure-volume data from *International Critical Tables* (see reference 7) in vicinity of critical point

ments of the over-all resistance indicated that it was accurate to within one percent. The shell mounting reduced the field surrounding the resistors and thus prevented corona from this cause.

To reduce the scatter in breakdown voltage due to a scarcity of initiating electrons, the cathode was illuminated by ultraviolet light from a mercury arc. The ratio of electrode diameter to gap-length was kept large enough to assure uniform field geometry.

BREAKDOWN MEASUREMENTS AT LOW GAS PRESSURES

In Fig. 3 the measured breakdown voltage is plotted as a function of gas density with the gap-spacing as parameter. In this region the ideal gas law holds: $P=1.865T\rho$ where P is given in atmospheres, ρ in g/cm, and T in degrees K.

It can be seen that the curves of constant $d\rho$ are horizontal lines, indicating that Paschen's law is obeyed in this region. Consequently, the data of Fig. 3 can be combined into a single characteristic of breakdown voltage *vs.* ρd. Figure 4 shows this curve and its extension to lower pressures taken from the paper of Quinn.[5]

[5] R. B. Quinn, Phys. Rev. **55**, 482 (1939).

BREAKDOWN MEASUREMENTS AT HIGH PRESSURES

For this pressure range the most accurate equation of state is the Beattie-Bridgman equation[6]

$$P=\frac{RT(1-\epsilon)}{V^2}(V+B)-\frac{A}{V^2}, \qquad (1)$$

where $A=A_0(1-a/V)$, $B=B_0(1-b/V)$, and $\epsilon=c/VT^3$,

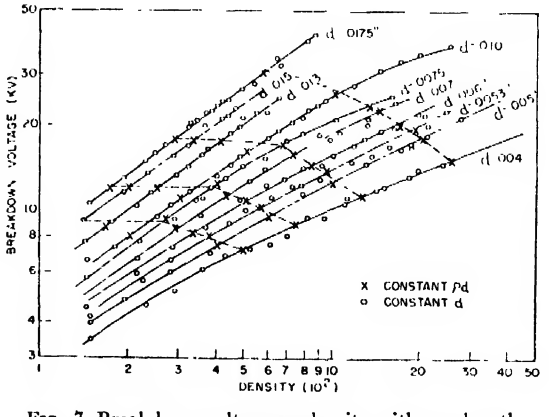

FIG. 7. Breakdown voltage *vs.* density with gap-length as parameter.

[6] J. A. Beattie and O. C. Bridgman, J. Am. Chem. Soc. **49**, 1665 (1927).

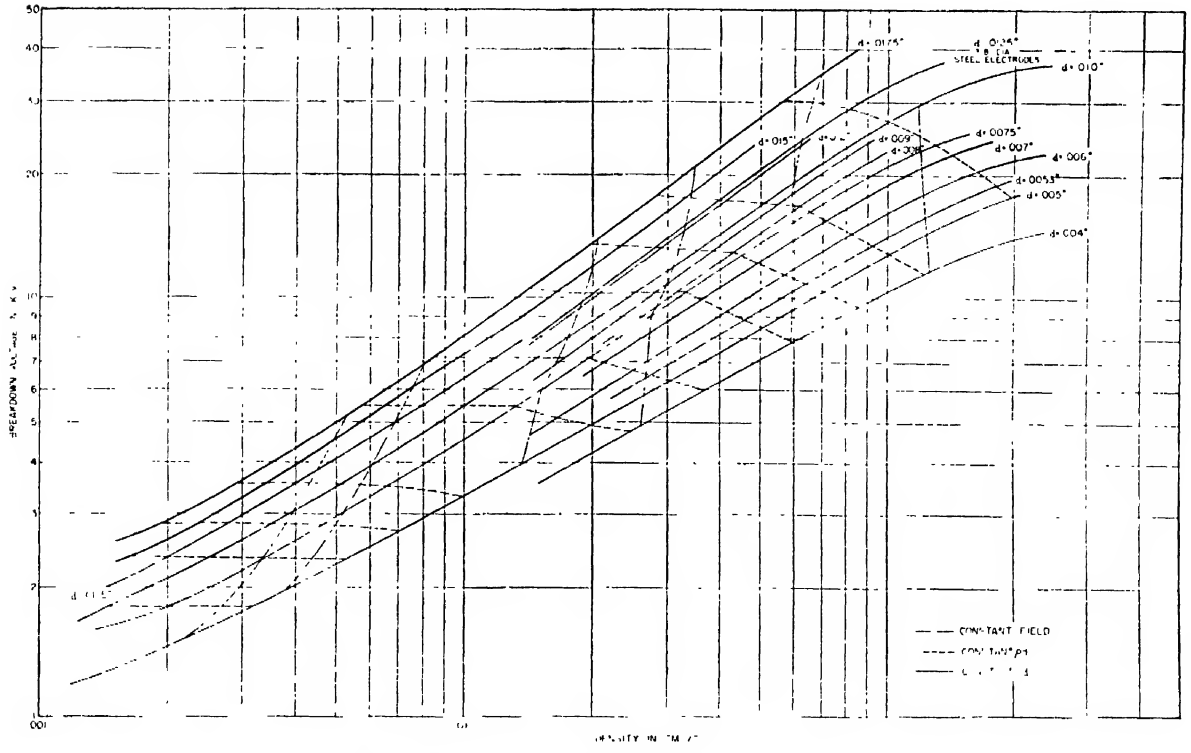

FIG. 8. Breakdown *vs.* density for various gap-lengths.

with P given in atmospheres, V in cc/g, T in degrees K. For CO_2, $R=1.865$, $B_0=2.381$, $b=1.6443$, $A_0=2586.0$, $a=1.6210$, and $C=15\times10^6$. According to Eq. (1) the ideal gas law is valid at room temperature to within one percent for pressures up to three atmospheres. Figure 5 shows the pressure-density relation according to the Beattie-Bridgman equation for various temperatures. In the vicinity of the critical point the relation between pressure and density must be established experimentally. Pertinent data are given in the *International Critical Tables*[7] as plotted in Fig. 6; the relative volume V/V_0 (abscissa) where V_0 refers to the volume at $T=0°C$, and $P=$one atmosphere. The density is correspondingly

$$\rho=\frac{1}{(508V/V_0)}\quad[\text{g/cc}]. \tag{2}$$

The range covered by these measurements extends from densities of 0.01 to 0.24 g/cc (that is, to the density of the vapor above the liquid at room temperature) (Fig. 7).

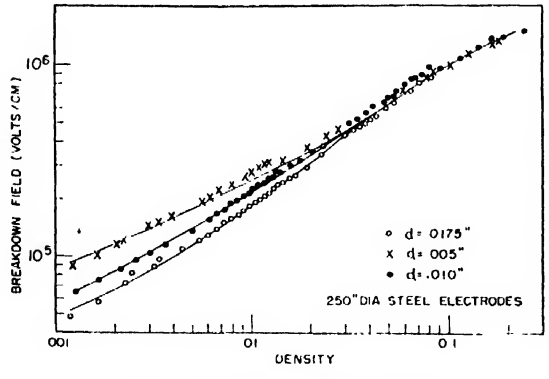

FIG. 9. Breakdown field *vs.* density.

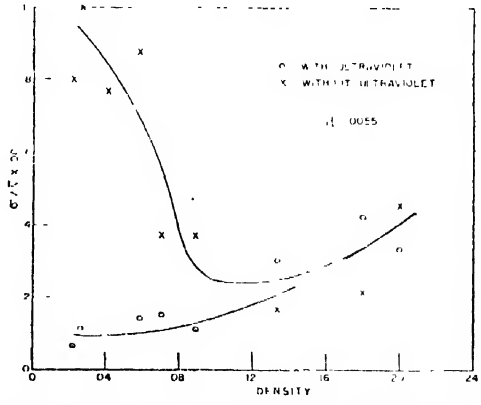

FIG. 10. Effect of illumination on scatter of breakdown voltage measurements.

[7] *International Critical Tables* (McGraw-Hill Book Company, Inc., New York, 1926).

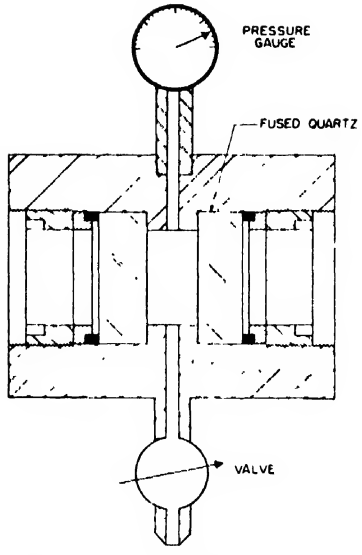

FIG. 11. High pressure absorption cell.

For long gap-lengths small departures from Paschen's law are observed as the deviation from the horizontal of the $d\rho$=constant curves indicates; for small gap-lengths these departures are much larger.

In Fig. 8 the high and low pressure data are combined to show the systematic increase of the deviations. In addition to the ρd curves, lines of constant field strength are indicated. It is seen that for small gap-lengths and high densities these lines are vertical, indicating that the breakdown voltage is determined by the average field strength for a given density, independent of the gap-spacing. If the breakdown field strength is plotted as a function of density, the lines for different gap-spacings consequently converge for high densities (Fig. 9).

If the standard deviation σ is plotted as a function of the density, with the cathode either illuminated or not by ultraviolet light, the curves shown in Fig. 10 are obtained. It is evident that, for the higher densities, the ultraviolet light has no effect.

The ineffectiveness of illumination might be caused by an increase of the ultraviolet absorption with gas density which would prevent the light from reaching the cathode. Since no absorption data were available for CO_2 covering this pressure range, measurements were made using a Cary recording spectrophotometer and the gas chamber shown in Fig. 11. The quartz windows were selected for transparency and had a cut-off limit near 2000A. There was no measurable absorption up to the saturation pressure at room temperature for wave-lengths down to 2000A, which rules out this explanation.

Another possible explanation for the data in Fig. 10 is that field emission provides the necessary initiating electrons. Breakdown measurements were therefore made using zinc-coated cathodes because zinc has a relatively low work function. They were prepared by evaporating zinc on steel ball bearings previously heated to 350°C in a high vacuum in order to obtain the same quality of surface as in the previous experiments. In Fig. 12 the results are compared with those using steel cathodes. At high gas densities the breakdown voltage is appreciably reduced by using zinc-coated electrodes, as would be expected.

At the higher densities the breakdown voltages for

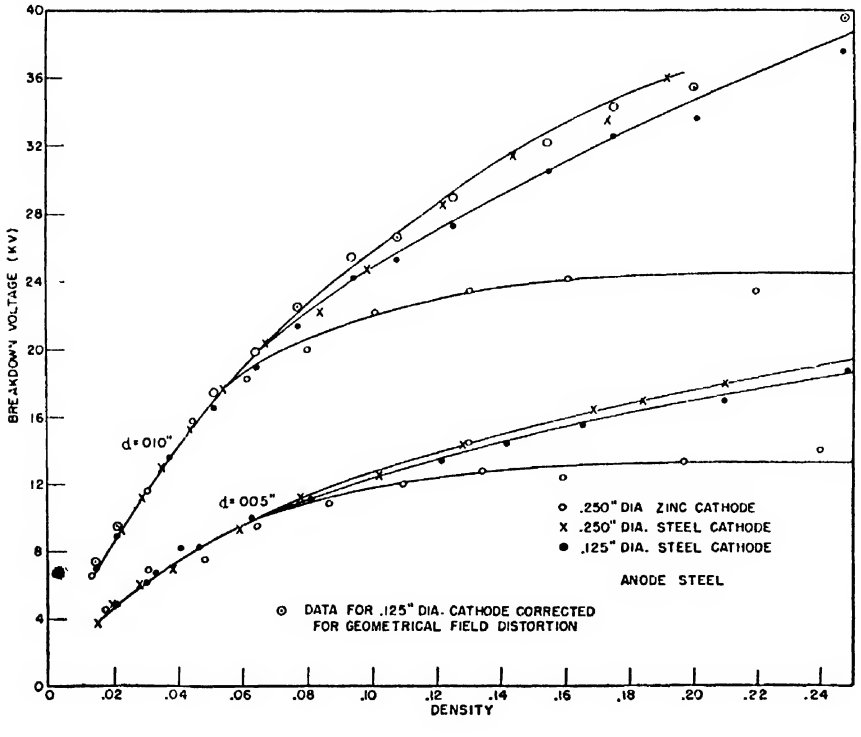

FIG. 12. Breakdown voltage measurements comparing various cathodes.

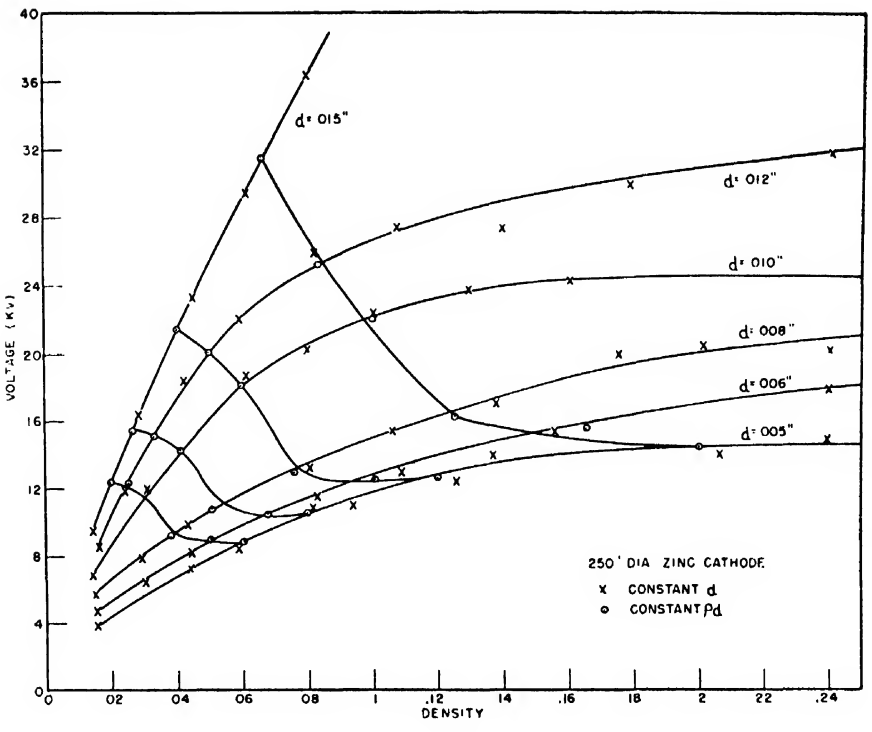

FIG. 13. Breakdown voltage *vs.* density for zinc cathode with gap-length as parameter.

0.125-in. diameter steel electrodes lie lower than those for the 0.250-in. steel electrodes. This is due to the geometrical field distortion for these electrode configurations. The data for the 0.125-in. balls, corrected for geometrical field distortion, yield the same results as for 0.250-in. cathodes (cf. Fig. 12). The breakdown voltage is not influenced by changing the anode metal or by using a 0.125-in. diameter anode instead of the 0.250-in. one.

In Fig. 13 additional breakdown curves for zinc cathodes are given which illustrate the very early failure of Paschen's law.

CURRENT MEASUREMENTS AT HIGH PRESSURES

The prebreakdown currents that flow, when only the α- and γ-type processes of Townsend are present, are proportional to the cathode illumination and are not self-sustaining. If the current is initiated by field emission, there will be a resulting current that does not depend on cathode illumination. A study of prebreakdown currents was initiated, therefore, to check the "field emission hypothesis" suggested above.

A single-stage current amplifier using a Victoreen Instrument Company VX-41A-type tube was constructed to measure the current. The amplifier was operated entirely by self-enclosed batteries with associated meters and adjustable resistors so that changes in battery voltage could be compensated for without change in the calibration of the amplifier (Fig. 14). The indicating instrument used was a 0–10 microammeter. The zero drift was negligible and the calibration remained constant over long periods of time.

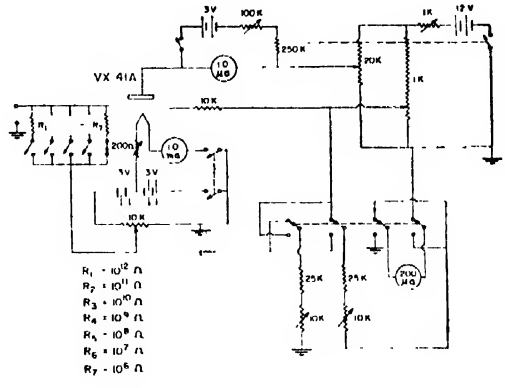

FIG. 14. Current amplifier.

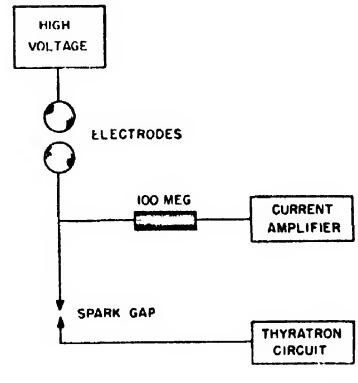

FIG. 15. Protection circuit used in conjunction with current amplifier.

The battery drain was small enough to keep the rate of change of the battery voltage negligible for several hours.

In order to use the protecting circuit described earlier, it was necessary to provide for a triggering voltage in a manner not disturbing to the current measurements (Fig. 15). If breakdown should occur, the small gap fires and supplies the necessary triggering voltage for current limitation and protection of the instrument.

The displacement current charging the electrode capacity of the breakdown gap caused considerable trouble. Instabilities in the high voltage supply, causing displacement current to flow, made the current readings erratic even though the line voltage was regulated by a Sorensen constant voltage transformer. To minimize this difficulty the measurements were made at night. During the course of a particular run (at each

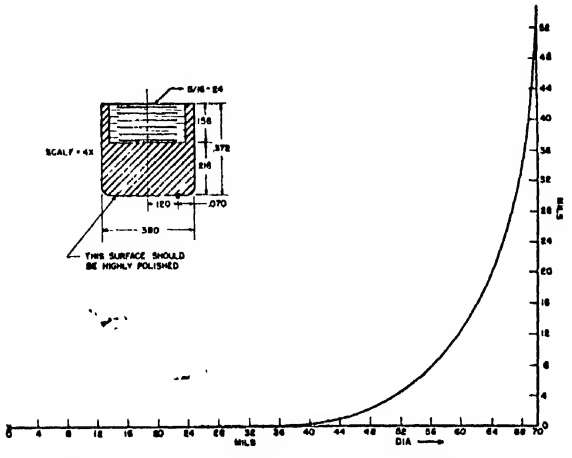

FIG. 16. Electrodes shaped according to Rogowsky's curves (see reference 8).

setting of the applied voltage) it was necessary to wait until the electrode capacity charged up to the new voltage before a reading could be taken. These waiting times amounted to several minutes in the case of the smallest currents. A more sentitive indicating instrument would allow the use of smaller grid resistances and reduce this trouble.

The breakdown vessel was directly attached to the amplifier to eliminate disturbances introduced by connecting cables, and provision was made to bring out an insulated connecting wire from the lower electrode

through a pressure seal of the same construction as used at the high voltage terminal (cf. Fig. 1).

Steel electrodes shaped to give a uniform field‡ were used to provide a more definite surface area than that offered by spherical electrodes (Fig. 16).[8] Designed for a maximum spacing of 0.020 in., the electrodes then serve also for smaller spacings.

As other workers have already reported,[9] field emis-

Combining the usual equation for field emission with the Townsend equation for impact ionization one obtains:

$$i = ae^{-b/E}e^{\alpha d}. \tag{3}$$

In Figs. 17 to 19 the logarithm of the current is plotted as a function of the voltage for different gap-lengths and curves of constant field strength are drawn. It is noted that straight lines result in this logarithmic plot as anticipated, but only for the longer gap-lengths. It is possible to calculate the Townsend first coefficient

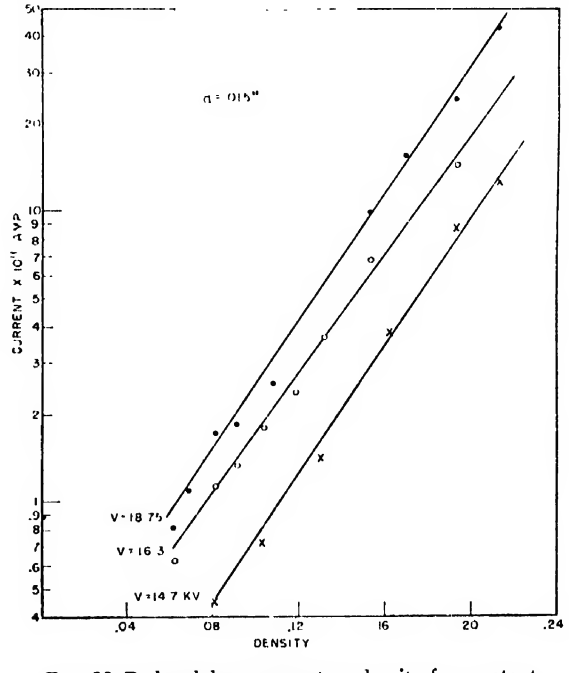

FIG. 23. Prebreakdown current *vs.* density for constant voltage and gap-length.

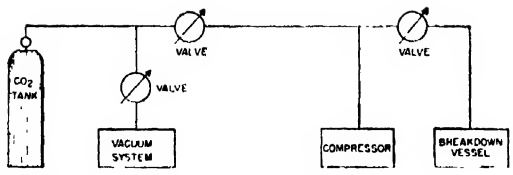

FIG. 24. Experimental apparatus for liquid breakdown.

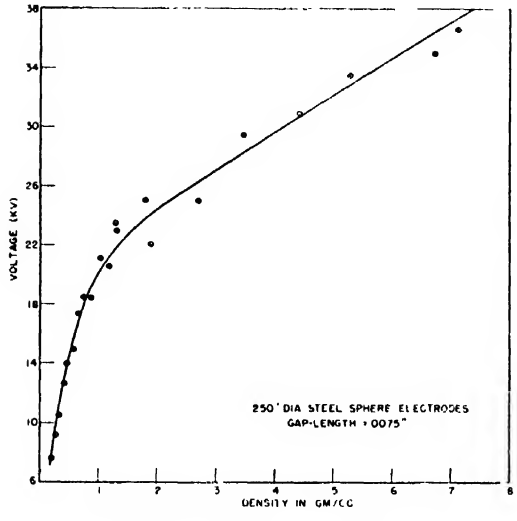

FIG. 25. Breakdown voltage *vs.* density.

α for different strengths from these lines. Then by extrapolation of the lines of constant E to zero voltage (which is the same as zero d) one obtains

$$i_0 = ae^{-b/E} = i_0(E) \quad \text{(cf. Eq. 3)}, \tag{4}$$

and a plot of i_0 as a function of $1/E$ gives the constants a and b (Figs. 20–22). Again a straight line results showing that also the exponential dependence on $1/E$ is fulfilled. Thus the current measurements demonstrate that field emission occurs under these high pressure conditions.

The values of a, b, and α obtained for these gas densities are given in Table I.

If the applied field strength is constant, the current increases with increasing density as shown by Fig. 23. Since α decreases, and b is constant, this is due to an increasing a, as already seen in Table I.

For small gap-spacings the current is larger than predicted by Eq. (3) as can be seen in Figs. 17 to 19, since the curves of constant field strength are no longer straight lines.

BREAKDOWN IN LIQUID CO_2

To make measurements in the liquid phase, a special compressor was constructed to compress the CO_2 gas which is delivered from the tank at saturation pressure. Alternatively, the breakdown vessel was cooled to about 1°C below the tank temperature, in order to condense the CO_2. This latter method is not as flexible as the first one mentioned for establishing a desired pressure above the liquid phase. A diagram of the experimental apparatus is shown in Fig. 24. To study the effect of pressure on the breakdown strength, a thermostat-controlled oil bath was constructed in which the breakdown vessel could be immersed. (No measurements were made in the liquid-vapor equilibrium region where two phases are present.) Measurements were made at the saturation pressure, heating from room temperature and with either gas or liquid CO_2 filling the breakdown vessel while the vessel was sealed off to prevent density change. In both cases there was no change in breakdown voltage with temperature. Therefore, if the density is constant for a given gap-length the breakdown voltage is independent of temperature in the range covered (for gas, 25°–55°C; for liquid, 25°–35°C).

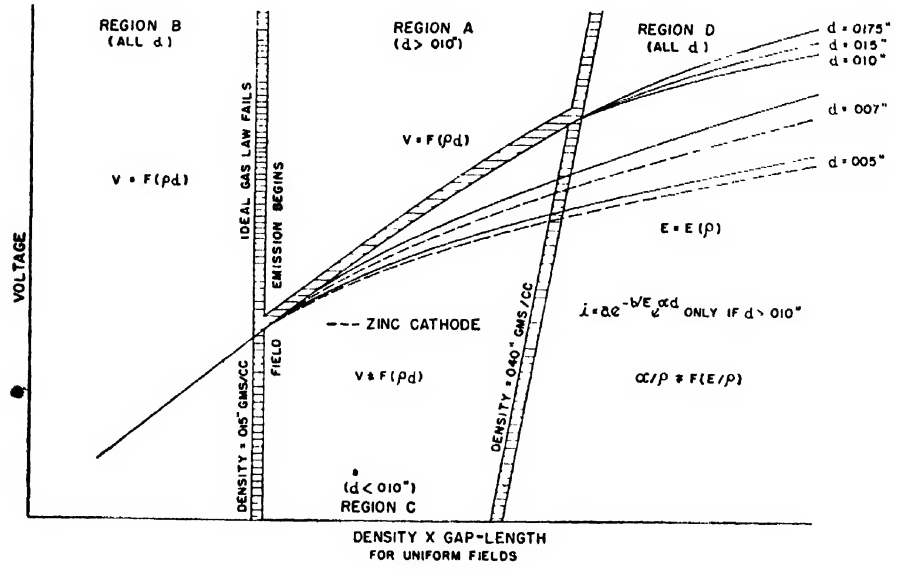

FIG. 26. Breakdown voltage *vs.* ρd (schematic).

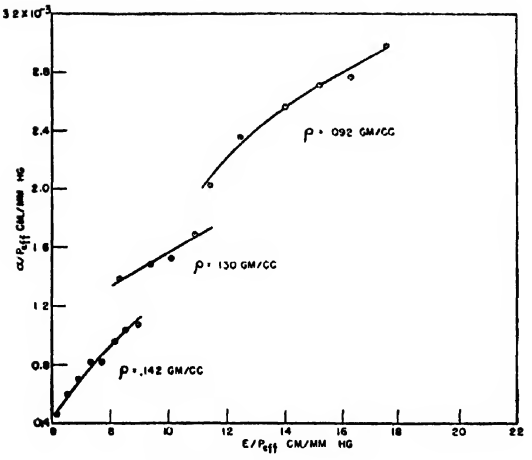

FIG. 27. α/P_{eff} *vs.* E/P_{eff}.

By heating the liquid to 33°C, that is, 2° above the critical temperature, it was possible to change the density continuously from that corresponding to the liquid to that of the vapor. A continuous variation in the breakdown voltage results (Fig. 25).

DISCUSSION

Breakdown Measurements

The most interesting result of these breakdown measurements is the discontinuity in the slope of the ρd curves (Fig. 8) which becomes pronounced above densities $\simeq$0.015 g/cc. This effect corresponds to the branching of the breakdown voltage characteristics plotted in Fig. 26 which occurs at $\rho=0.015$ g/cc. The large departures from Paschen's law for smaller gap-lengths indicate the importance of a new process that aids the breakdown but does not satisfy the similarity law requirements. The onset of this process is partially determined by the cathode material (cf. Fig. 8 with Fig. 13), and its presence is also revealed by the pre-breakdown current which was larger than predicted by Eq. (3) for d's $<$0.010 in. (Figs. 17 to 19).

The explanation of this effect is not obvious. One possibility is that space charge becomes important for small gap-lengths. This would increase the effective ionization coefficient and, in addition, raise the field at the cathode which increases the probability of secondary emission of electrons (γ-process) and the field emission. A solution of the field equation does not predict that an appreciable field distortion occurs for current densities averaged from the measured current; however, field emission does not occur uniformly, and therefore the current densities may be very much higher than assumed.

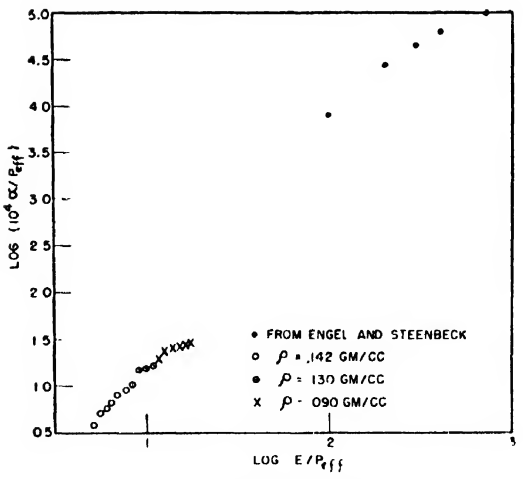

FIG. 28. Present data compared with that given by Engel and Steenbeck (see reference 10) for $\log_{10}(10^4\alpha/P_{eff})$ *vs.* $\log_{10}E/P_{eff}$.

Current Measurements

At low pressures the relation $\alpha/\rho=f(E/\rho)$ holds, but at high pressures, as Fig. 27 indicates, α/ρ is not uniquely determined by E/ρ. This might be expected because the interaction of the molecules will increase the energy loss suffered by the electrons through the excitation of vibrations.

In order to make comparisons with low pressure data, it is convenient to define an effective pressure as

$$P_{eff}=P_0\rho/\rho_0=3.87\times10^5\rho \quad [\text{mm Hg}] \qquad (5)$$

if P_0 and ρ_0 are measured at S.T.P., where the ideal gas law is valid. Low pressure data for α/P *vs.* E/P given by Engel and Steenbeck[10] are combined with the present data in Fig. 28.

The probability of impact ionization before breakdown decreases rapidly with increasing gas density at the highest density studied (Fig. 27).

The increase of the field emission constant a with increasing density may be due to the increasing dielectric constant and its effect on the image force field of the escaping electrons.

The author is grateful to Professor A. von Hippel for suggesting this problem and for constant advice and encouragement during the progress of the work. The many helpful suggestions given by members of the High Voltage Group of this laboratory are also appreciated.

A Method for the Numerical Calculation of Hydrodynamic Shocks

J. VonNeumann and R. D. Richtmyer
Institute for Advanced Study, Princeton, New Jersey
(Received September 26, 1949)

The equations of hydrodynamics are modified by the inclusion of additional terms which greatly simplify the procedures needed for stepwise numerical solution of the equations in problems involving shocks. The quantitative influence of these terms can be made as small as one wishes by choice of a sufficiently fine mesh for the numerical integrations. A set of difference equations suitable for the numerical work is given, and the condition that must be satisfied to insure their stability is derived

I. INTRODUCTION

In the investigation of phenomena arising in the flow of a compressible fluid, it is frequently desirable to solve the equations of fluid motion by stepwise numerical procedures, but the work is usually severely complicated by the presence of shocks. The shocks manifest themselves mathematically as surfaces on which density, fluid velocity, temperature, entropy and the like have discontinuities; and clearly the partial differential equations governing the motion require boundary conditions connecting the values of these quantities on the two sides of each such surface. The necessary boundary conditions are, of course, supplied by the Rankine-Hugoniot equations, but their application is complicated because the shock surfaces are in motion relative to the network of points in space-time used for the numerical work, and the differential equations and boundary conditions are non-linear. Furthermore, the motion of the surfaces is not known in advance but is governed by the differential equations and boundary conditions themselves. In consequence, the treatment of shocks requires lengthy computations (usually by trial and error) at each step, in time, of the calculation.

We describe here a method for automatic treatment of shocks which avoids the necessity for application of any such boundary conditions. The approximations in it can be rendered as accurate as one wishes, by suitable choice of interval sizes and other parameters occurring in the method. It treats all shocks, correctly and automatically, whenever and wherever they may arise.

The method utilizes the well-known effect on shocks of dissipative mechanisms, such as viscosity and heat conduction.[1] When viscosity is taken into account, for example, the shocks are seen to be smeared out, so that the mathematical surfaces of discontinuity are replaced by thin layers in which pressure, density, temperature, etc. vary rapidly but continuously. Our idea is to introduce (artificial) dissipative terms into the equations so as to give the shocks a thickness comparable to (but preferably somewhat larger than) the spacing of the points of the network. Then the differential equations (more accurately, the corresponding difference equations) may be used for the entire calculation, just as though there were no shocks at all. In the numerical results obtained, the shocks are immediately evident as near-discontinuities that move through the fluid with very nearly the correct speed and across which pressure, temperature, etc. have very nearly the correct jumps.

It will be seen that for the assumed form of dissipation (and, indeed, for many others as well), the Rankine-Hugoniot equations are satisfied, provided the thickness of the shock layers is small in comparison with other physically relevant dimensions of the system. We then consider one way in which the transition from differential to finite-difference equations can be made and we discuss the mathematical stability of these equations. It will be seen that the dissipative terms have the effect of making the stability condition more stringent than the familiar one of Courant, Friedrichs, and Lewy,[2] but not seriously so if the amount of dissipation introduced is only enough to produce a shock thickness comparable with the spatial interval length of the network used.

The method has been applied, so far, only to one-dimensional flows, but appears to be equally suited to the study of more complicated flows; where, indeed, shock calculations by direct application of the Hugoniot equations would ordinarily be prohibitively difficult, even for rapid, automatic computers.

The discussions which follow are primarily intended to give a complete picture of the ideas and mathematical procedures involved. In some places (Chapter VII, also the essential inferences from some of the material of Chapters IV, V) the mathematical discussions are, however, carried through only with a view to give a complete chain of the necessary procedure, but not with all the detail that rigorous proofs in a primarily mathematical paper would require. The reason for doing this was partly desire to avoid inconvenient length, partly that of not wishing to have to select now the precise degree of generality for the

[1] Lord Rayleigh (Proc. Roy. Soc. **A84**, 247 (1910)) and G. I. Taylor (Proc. Roy. Soc. **A84**, 371 (1910)) showed, on the basis of general thermodynamical considerations, that dissipation is necessarily present in shock waves. Later, R. Becker (Zeits. f. Physik **8**, 321 (1922)) gave a detailed discussion of the effects of heat conduction and viscosity. Recently, L. H. Thomas (J. Chem. Phys. **12**, 449 (1944)) has investigated these effects further in terms of the kinetic theory of gases.

[2] Courant, Friedrichs, and Lewy, Math. Ann. **100**, 32 (1928). It is in this important paper that these authors first published their discovery of the conditional stability of the difference-equation integration method for partial differential equations.

validity of the method. It seems preferable to reserve such discussions for later occasions.

The validity of our methods has been tested empirically on various computational applications. These are partly still under analysis, and will be published and discussed elsewhere.

II. THE BASIC EQUATIONS

Consider a one-dimensional fluid motion. Let x be the Lagrangean coordinate, and $X=X(x, t)$ be the Eulerian coordinate. That is, $X(x, t)$ gives the position, at time t, of a fluid element that was initially at position x. Let $\rho_0(x)$ be the initial density, so that V and U, given by

$$V(x, t)=(1/\rho_0(x))(\partial X/\partial x) \tag{1}$$

and

$$U(x, t)=\partial X/\partial t, \tag{2}$$

are the specific volume and fluid velocity, respectively. The equations of motion, of energy, and of continuity are:

$$\rho_0(\partial U/\partial t)=-(\partial/\partial x)(p+q), \tag{3}$$

$$(\partial \mathcal{E}/\partial t)+(p+q)(\partial V/\partial t)=0, \tag{4}$$

and

$$\rho_0(\partial V/\partial t)=(\partial U/\partial x). \tag{5}$$

In these equations, $p=p(x, t)$ is the ordinary (or static) fluid pressure and $\mathcal{E}=\mathcal{E}(x, t)$ is the internal energy per unit mass. A connection between $\mathcal{E}$, p, V is established by an equation of state, which will be assumed, for the purpose of illustration, to have the form

$$\mathcal{E}=(pV)/(\gamma-1) \tag{6}$$

which holds, for example, in the case of a perfect gas. γ is a constant >1. It is supposed that the dissipative mechanism can be represented by the additional term q in the pressure, which is assumed to be negligibly small, except in the neighborhood of the shock.

III. THE EXPRESSION FOR q

The dissipation is introduced for purely mathematical reasons. Therefore q may be taken as any convenient function of p, V, etc. and their derivatives, provided that the following requirements are met:

1. The Eqs. (3), (4), and (5) must possess solutions without discontinuities.
2. The thickness of the shock layers must be everywhere of the same order as the interval length Δx used in the numerical computation, independently of the strength of the shock and of the condition of the material into which it is running.
3. The effect of the terms containing q in (3) and (4) must be negligible outside of the shock layers.
4. The Hugoniot equations must hold when all other dimensions characterizing the flow are large compared to the shock thickness.

We shall show that the expression

$$q=-\frac{(\rho_0 c\Delta x)^2}{V}\frac{\partial V}{\partial t}\left|\frac{\partial V}{\partial t}\right| \tag{7}$$

meets the requirements. c is a dimensionless constant near unity. The dissipative mechanism is essentially a non-linear viscosity as can be seen more clearly if (7) is written equivalently (for the one-dimensional case) as

$$q=-\frac{(c\Delta x)^2}{V}\frac{\partial U}{\partial x}\left|\frac{\partial U}{\partial x}\right| \tag{8}$$

by use of (5). To show that the expression (7) meets the stated requirements, we consider a steady-state shock.

IV. STEADY-STATE PLANE SHOCK

Imagine a long pipe containing a fluid initially in equilibrium (thermally and mechanically), into which a piston is pushing from one end with constant speed, as shown in Fig. 1. In the absence of dissipation the specific volume, V, and the fluid velocity, U, are, at a given instant, as shown by the solid curves in the graphs, whereas in the presence of dissipation they are as shown by the dashed curves. In either case, the shock is steady, at least approximately, after it has gone to a sufficiently great distance from the initiating piston. Then U, V, $\mathcal{E}$, etc. depend on x and t only through the combination

$$w=x-st, \tag{9}$$

where s is the speed of the shock relative to the original, or Lagrangean, coordinates. We suppose that ρ_0 and Δx are constants (independent of x).

It is convenient to define

$$M=\rho_0 s \tag{10}$$

—in a co-moving coordinate system, M is the mass crossing unit area in unit time—whereupon Eqs. (3)–(5) become:

$$M(dU/dw)=(d/dw)(p+q), \tag{11}$$

$$(d\mathcal{E}/dw)+(p+q)(dV/dw)=0, \tag{12}$$

and

$$-M(dV/dw)=dU/dw. \tag{13}$$

Then, (11) and (13) give:

$$-M^2(dV/dw)=(d/dw)(p+q); \tag{14}$$

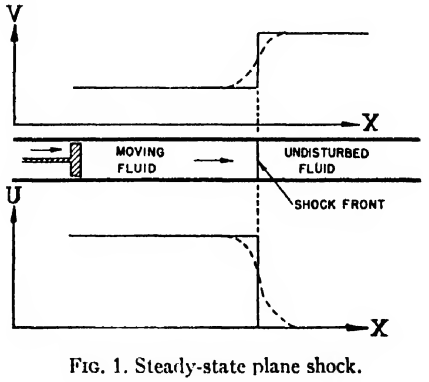

FIG. 1. Steady-state plane shock.

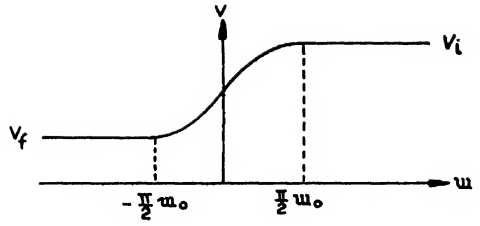

FIG. 2. Specific volume in steady shock.

and (12) and (14) give

$$\frac{d\mathcal{E}}{dw}+\frac{d}{dw}[(p+q)V]+M^2V\frac{dV}{dw}=0. \tag{15}$$

The solutions of (13), (14), (15) are:

$$MV+U=C_1 \tag{16}$$

$$M^2V+p+q=C_2 \tag{17}$$

$$\mathcal{E}+(p+q)V+\tfrac{1}{2}M^2V^2=C_3, \tag{18}$$

where C_1, C_2, and C_3 are constants.

Let the initial and final values be denoted by:

$$\text{As } w\to\infty;\quad V\to V_i,\quad p\to p_i,\quad \mathcal{E}\to\mathcal{E}_i,\quad q\to 0; \tag{19}$$

$$\text{As } w\to-\infty;\quad V\to V_f,\quad p\to p_f,\quad \mathcal{E}\to\mathcal{E}_f,\quad q\to 0. \tag{20}$$

Then (17) gives:

$$M^2(V_i-V_f)=P_f-P_i; \tag{21}$$

and (18) and (21) together give:

$$\mathcal{E}_f-\mathcal{E}_i=\tfrac{1}{2}(P_i+P_f)(V_i-V_f). \tag{22}$$

(21) and (22) are the equations of Hugoniot and are seen to be independent of the amount and form of the dissipation, provided that $q\to 0$ as $w\to\pm\infty$. The physical reason for this is that the Hugoniot equations are direct consequences of the conservation laws of mass, momentum and energy, and the form of dissipation assumed is such as top reserve the over-all conservation of these quantities. These laws require that in a shock a certain amount of mechanical energy be converted irreversibly into heat. In the steady state, the motion adjusts itself, in the shock layer, until precisely that amount of work is done against the pressure q according to Eq. (3) and is converted into heat according to Eq. (4).

To investigate the shape of the shock, we first look for solutions satisfying

$$(\partial V/\partial t)\leq 0 \quad \text{or} \quad (dV/dw)\geq 0. \tag{23}$$

This is normally the case for a shock moving to the right. Then (7) can be written:

$$qV=+(Mc\Delta x)^2(dV/dw)^2. \tag{24}$$

From (17) and (18)

$$\mathcal{E}-\tfrac{1}{2}M^2V^2=C_3-C_2V, \tag{25}$$

so that by (6),

$$pV=[(\gamma-1)/2]M^2V^2+C_4V+C_5, \tag{26}$$

whereupon (17) gives:

$$qV=C_2-[(\gamma+1)/2]M^2V^2-C_4V-C_5. \tag{27}$$

The right member of (27) is a quadratic in V that vanishes for $V=V_i$ and for $V=V_f$, so that, clearly,

$$(Mc\Delta x)^2\left(\frac{dV}{dw}\right)^2=qV=\frac{\gamma+1}{2}M^2(V_i-V)(V-V_f). \tag{28}$$

(Equation (28) can also be obtained from (27) by direct use of the Hugoniot equations and the equations that fix C_2, C_4, C_5.)

To solve (28), put:

$$\psi=V-\frac{V_i+V_f}{2},\quad \psi_0=\frac{V_i-V_f}{2},\quad \varphi=\frac{\psi}{\psi_0}, \tag{29}$$

so that

$$c\Delta x\frac{d\psi}{dw}=[(\gamma+1)/2]^{\frac{1}{2}}(\psi_0^2-\psi^2)^{\frac{1}{2}}, \tag{30}$$

or

$$c\Delta x\frac{d\varphi}{dw}=[(\gamma+1)/2]^{\frac{1}{2}}(1-\varphi^2)^{\frac{1}{2}}. \tag{31}$$

Therefore,

$$w=[2/(\gamma+1)]^{\frac{1}{2}}c\Delta x\int\frac{d\varphi}{(1-\varphi^2)^{\frac{1}{2}}}=w_0\arcsin\varphi \tag{32}$$

where

$$w_0=[2/(\gamma+1)]^{\frac{1}{2}}c\Delta x. \tag{33}$$

Finally,

$$\psi=V-\frac{V_i+V_f}{2}=\frac{V_i-V_f}{2}\sin\frac{w}{w_0}. \tag{34}$$

Because of our initial assumption (23) that $dV/dw\geq 0$, we can use only a half wave of the solution (34), but this half wave can be pieced together with two other particular solutions,

$$V\equiv V_i \quad \text{and} \quad V\equiv V_f \tag{35}$$

(they satisfy Eq. (28)), to make the composite continuous solution depicted in Fig. 2. w_0 is a measure of the thickness of the shock, and is of order Δx, provided c is of order unity, independently of the strength of the shock and conditions ahead of it, by Eq. (33). Throughout most of the system q is negligible in comparison with the ordinary pressure, p, because of the factor $(\Delta x)^2$ in (7); but in the shock layer q becomes comparable with p because of the abnormally large value of $\partial V/\partial t$ there.

Expression (7) thus meets all requirements.

It may be noted that if we had looked instead for solutions having $dV/dt>0$, no solution would have been found for which all quantities are continuous and bounded, because in that case the opposite sign would occur in (28), leading to the hyperbolic instead of ordi-

nary sine function. Therefore negative shocks do not exist in the steady state, for our equations. Negative shocks do not exist in the physical world, either, so that our expression (7) is satisfactory from this point of view.

V. STABILITY OF THE DIFFERENTIAL EQUATIONS

Suppose that at some instant there is superposed on a desired solution $U(x, t)$, $V(x, t)$, etc., a small perturbation δU, δV, etc. It is of interest to know whether the perturbation grows with increasing time. To investigate this we replace U, V, etc. by $U+\delta U$, $V+\delta V$, etc. in (3), (4), (5), (8), after first rewriting (4), by use of (6), in the form:

$$[\gamma p+(\gamma-1)q](\partial V/\partial t)+V(\partial p/\partial t)=0. \tag{36}$$

We obtain in this way the equations of first variation:

$$\rho_0(\partial/\partial t)\delta U=-(\partial/\partial x)(\delta p+\delta q), \tag{37}$$

$$\left.\begin{aligned}\frac{\partial V}{\partial t}[\gamma\delta p+(\gamma-1)\delta q]+[\gamma p+(\gamma-1)q]\frac{\partial}{\partial t}\delta V\\ +V\frac{\partial}{\partial t}\delta p+\frac{\partial p}{\partial t}\delta V=0,\end{aligned}\right\} \tag{38}$$

$$\delta q=\frac{(c\Delta x)^2}{V^2}\frac{\partial U}{\partial x}\cdot\left|\frac{\partial U}{\partial x}\right|\delta V-2\frac{(c\Delta x)^2}{V}\cdot\left|\frac{\partial U}{\partial x}\right|\frac{\partial}{\partial x}\delta U, \tag{39}$$

$$\rho_0\frac{\partial}{\partial t}\delta V=-\frac{\partial}{\partial x}\delta U. \tag{40}$$

In writing the last term of (39) we have assumed that the perturbation is not large enough to alter the sign of $\partial U/\partial x$. (37) to (40) are a set of simultaneous linear differential equations for δU, δV, δp, δq. Their coefficients depend on the desired solution U, V, p, q, and are thought of as smoothly varying functions of x, t. We shall be concerned with rapidly varying perturbations. We therefore treat the coefficients of (37) to (40) as constants in a small region and look for solutions having the form:

$$\delta U=\delta U_0e^{ikx+\alpha t},\quad \delta V=\delta V_0e^{ikx+\alpha t},\text{ etc.,} \tag{41}$$

where δU_0, δV_0, δp_0, δq_0, k, and α are constant and k is real. Substitution of (41) into (37) to (40) leads to four simultaneous homogeneous linear equations in δU_0, δV_0, δp_0, δq_0. The vanishing of the determinant of these equations establishes an equation connecting α and k. By solving this equation, for given k, and examining the real part of α, we can determine whether a given Fourier component (41) of the perturbation grows with increasing time. This program is readily carried out, but we omit the details in the interest of brevity. The determinantal equation is:

$$\begin{aligned}(\alpha\rho_0)^2\gamma\frac{\partial V}{\partial t}+2\frac{\rho_0\alpha}{V}\frac{\partial V}{\partial t}(kc\Delta x)^2\left|\frac{\partial U}{\partial x}\right|\\ -\frac{1}{V^2}\frac{\partial V}{\partial t}(kc\Delta x)^2\frac{\partial U}{\partial x}\cdot\left|\frac{\partial U}{\partial x}\right|+k^2\alpha[\gamma p+(\gamma-1)q]\\ +\rho_0^2\alpha^3V+2\rho_0\alpha^2(kc\Delta x)^2\left|\frac{\partial U}{\partial x}\right|\\ -\frac{\alpha}{V}(kc\Delta x)^2\frac{\partial U}{\partial x}\cdot\left|\frac{\partial U}{\partial x}\right|+k^2\frac{\partial p}{\partial t}=0.\end{aligned} \tag{42}$$

If we restrict our attention to Fourier components with very large k, only certain terms of (42) need be retained, the others being negligible either by viture of being of lower order in k or by virtue of being of lower order in α. Two cases are distinguished: in shock regions we retain all terms in (42); in normal regions we drop the dissipative terms (those containing Δx). In the two regions, the dominant terms, in the sense explained, give: shock regions:

$$\alpha=-2\frac{(kc\Delta x)^2}{\rho_0V}\left|\frac{\partial U}{\partial x}\right| \tag{43}$$

normal regions:

$$\alpha^2=-\frac{k^2}{\rho_0V}\frac{\gamma p}{\rho_0}. \tag{44}$$

It is seen that small disturbances are damped out in the shock layers but propagate without either growth or decay in normal regions. This corresponds to physical reality, so our expression (7) is satisfactory also as regards stability of the resulting differential equations.

We can furthermore identify the terms in the equations of variation that lead to the dominant terms in (42). They give:

shock regions:

$$\frac{\partial}{\partial t}\delta U\approx\sigma\frac{\partial^2}{\partial x^2}\delta U, \tag{45}$$

where

$$\sigma=\frac{2(c\Delta x)^2}{V\rho_0}\left|\frac{\partial U}{\partial x}\right|;$$

normal regions:

$$\frac{\partial^2}{\partial t^2}\delta U\approx s_0^2\frac{\partial^2}{\partial x^2}\delta U, \tag{46}$$

where

$$s_0^2=\frac{\gamma p}{\rho_0^2V}.$$

Thus our system has the character of a diffusion equation in the shock layers and of a sound equation elsewhere.

VI. FINITE DIFFERENCE EQUATIONS

There are many systems of finite difference equations equivalent to the differential equations, but we shall restrict the discussion to one of the simplest. Certain other systems are much superior from the point of view of stability but are more complicated from the point of view of numerical solution. Systems of the latter type will be discussed elsewhere.

Let the points of a rectangular network with spacings Δx and Δt be denoted by x_l, $t^n (l=0, 1, 2, \cdots, L; n=0, 1, 2, \cdots)$. We shall also have occasion to deal with intermediate points, having coordinates $x_{l+\frac{1}{2}} \overset{\text{def.}}{=} \frac{1}{2}(x_{l+1}+x_l)$ etc. To facilitate the writing, we introduce abbreviations such as:

$$V_{l+\frac{1}{2}}^{n} = V(x_{l+\frac{1}{2}}, t^n) \text{ etc.} \tag{47}$$

The difference equations corresponding to (3), (5), (8)' and (36) are:

$$\rho_0 \frac{U_l^{n+\frac{1}{2}} - U_l^{n-\frac{1}{2}}}{\Delta t} = \frac{p_{l+\frac{1}{2}}^{n} + q_{l+\frac{1}{2}}^{n-\frac{1}{2}} - p_{l-\frac{1}{2}}^{n} - q_{l-\frac{1}{2}}^{n-\frac{1}{2}}}{\Delta x}, \tag{48}$$

$$\rho_0 \frac{V_{l+\frac{1}{2}}^{n+1} - V_{l+\frac{1}{2}}^{n}}{\Delta t} = \frac{U_{l+1}^{n+\frac{1}{2}} - U_l^{n+\frac{1}{2}}}{\Delta x}, \tag{49}$$

$$q_{l+\frac{1}{2}}^{n+\frac{1}{2}} = \frac{2(c\Delta x)^2}{V_{l+\frac{1}{2}}^{n} + V_{l+\frac{1}{2}}^{n+1}} \cdot \frac{(U_{l+1}^{n+\frac{1}{2}} - U_l^{n+\frac{1}{2}}) \cdot |U_{l+1}^{n+\frac{1}{2}} - U_l^{n+\frac{1}{2}}|}{(\Delta x)^2}, \tag{50}$$

and

$$\left[\gamma \frac{p_{l+\frac{1}{2}}^{n+1} + p_{l+\frac{1}{2}}^{n}}{2} + (\gamma-1) q_{l+\frac{1}{2}}^{n+\frac{1}{2}}\right] \frac{V_{l+\frac{1}{2}}^{n+1} - V_{l+\frac{1}{2}}^{n}}{\Delta t} + \frac{V_{l+\frac{1}{2}}^{n+1} + V_{l+\frac{1}{2}}^{n}}{2} \frac{p_{l+\frac{1}{2}}^{n+1} - p_{l+\frac{1}{2}}^{n}}{\Delta t} = 0. \tag{51}$$

These equations are correct to second order of small quantities Δx and Δt, except for the terms containing q in (48) which are only correct to the first order; but these terms are negligible except in the shock layers and are physically artificial in any case.

For numerical solution, suppose that all quantities are known for superscript n or less. Compute $U_l^{n+\frac{1}{2}}$ from (48) for each l; compute $V_{l+\frac{1}{2}}^{n+1}$ from (49) for each l; compute $q_{l+\frac{1}{2}}^{n+\frac{1}{2}}$ from (50) for each l; compute $p_{l+\frac{1}{2}}^{n+\frac{1}{2}}$ from (51) for each l; this completes a cycle. Boundary conditions are needed, an example being (rigid walls at ends of a tube): $U_0^{n+\frac{1}{2}}=0$, $U_L^{n+\frac{1}{2}}=0$.

VII. STABILITY OF THE DIFFERENCE EQUATIONS

Equations (48) to (51), being only approximations to the differential equations, cannot be expected to give all features of the solution with precision. If U, V are thought of as being expanded in Fourier series with coefficients depending on t, the long-wave-length components are accurately given by (48) to (51), provided Δx and Δt are sufficiently small, but the components whose wave-lengths are of order Δx are always falsified somewhat. This falsification is harmless, provided that all physically relevant components are treated accurately; this requires not only that Δx and Δt be small but also that the physically insignificant components with wave-lengths of order Δx remain small during the entire calculation. It may happen not only that the short-wave-length components are falsified but also that their amplitudes increase with increasing n, in spite of the stability of the *differential* equations. This increase is generally exponential and, if it occurs, quickly makes gibberish of the entire calculation.

The avoidance of such catastrophes, when partial differential equations are approximated by difference equations, has been the subject of study by various investigators, beginning with the fundamental paper of Courant, Friedrichs, and Lewy referred to in reference 1. We shall give a somewhat heuristic discussion of the stability questions met in the present problem.

We again suppose a small perturbation δU, δV, etc., superposed on a smooth solution, and consider the equations of variation of (48) to (51). According to the analysis of Part V, the dominant terms are expected to be (see Eqs. (45) and (46)):

shock regions:

$$\frac{\delta U_l^{n+\frac{1}{2}} - \delta U_l^{n-\frac{1}{2}}}{\Delta t} \approx \sigma \frac{\delta U_{l+1}^{n-\frac{1}{2}} - 2\delta U_l^{n-\frac{1}{2}} + \delta U_{l-1}^{n-\frac{1}{2}}}{(\Delta x)^2}; \tag{52}$$

normal regions:

$$\frac{\delta U_l^{n+\frac{1}{2}} - 2\delta U_l^{n-\frac{1}{2}} + \delta U_l^{n-\frac{3}{2}}}{(\Delta t)^2} \approx s_0^2 \frac{\delta U_{l+1}^{n-\frac{1}{2}} - 2\delta U_l^{n-\frac{1}{2}} + \delta U_{l-1}^{n-\frac{1}{2}}}{(\Delta x)^2}; \tag{53}$$

and this can be verified by writing out the difference equations of variation in detail.

As before, we consider perturbations of the form:

$$\delta U = \delta U_0 e^{ikx+\alpha t}, \text{ etc.}, \tag{54}$$

so that:

$$\delta U_l^{n+\frac{1}{2}} = \delta U_0 \zeta^l \xi^{n+\frac{1}{2}}, \tag{55}$$

where:

$$\zeta = e^{ik\Delta x}, \quad \xi = e^{\alpha \Delta t}. \tag{56}$$

For stability we require that $|\xi| \leq 1$ for all real k.

We consider normal regions first. Substitution of (55) into (53) and cancellation of common factors gives:

$$\xi - 2 + \frac{1}{\xi} = 2\left(\frac{s_0 \Delta t}{\Delta x}\right)^2 (\cos k\Delta x - 1). \tag{57}$$

If we call

$$L=\frac{s_0\Delta t}{\Delta x}, \tag{58}$$

the solution of (57) is

$$\xi_{1,2}=b\pm(b^2-1)^{\frac{1}{2}} \tag{59}$$

where

$$b=1-L^2(1-\cos k\Delta x). \tag{60}$$

According to (60), b is always <1, so there are two cases:

$$-1<b<1, \quad |\xi_1|=|\xi_2|=1; \quad \text{stability}; \tag{61}$$

$$b<-1, \quad |\xi_1|<1<|\xi_2|; \quad \text{instability}. \tag{62}$$

From Eq. (60) it is seen that (61) will hold for all k if and only if

$$L\leq 1. \tag{63}$$

This is the familiar condition for stability of hydrodynamical equations of the form (53).

A similar treatment of Eq. (52) for the shock region yields directly:

$$\xi-1=2\frac{\sigma\Delta t}{(\Delta x)^2}(\cos k\Delta x-1), \tag{64}$$

and the stability condition is clearly that

$$\frac{2\sigma\Delta t}{(\Delta x)^2}\leq 1 \quad \text{or} \quad \Delta t\leq\frac{(\Delta x)^2}{2\sigma}. \tag{65}$$

To interpret this result, we calculate σ according to (45) for the steady shock discussed in Part IV. From (33), (34);

$$\left|\frac{\partial U}{\partial x}\right|=\rho_0\left|\frac{\partial V}{\partial t}\right|=\rho_0 s\left|\frac{\partial V}{\partial w}\right|$$

$$=\rho_0 s\frac{V_s-V_f}{2c\Delta x}((\gamma+1)/2)^{\frac{1}{2}}\cos\frac{w}{w_0}. \tag{66}$$

Therefore

$$\sigma=sc\Delta x\frac{V_s-V_f}{V}((\gamma+1)/2)^{\frac{1}{2}}\cos\frac{w}{w_0}, \tag{67}$$

and the stability condition (65) takes the form:

$$\Delta t\leq\frac{V\Delta x}{2sc(V_s-V_f)}\left(\frac{2}{\gamma+1}\right)^{\frac{1}{2}}\frac{1}{\cos(w/w_0)}, \tag{68}$$

or,

$$\Delta t\leq\frac{\Delta x}{4sc}\left(\frac{2}{\gamma+1}\right)^{\frac{1}{2}}\frac{(\eta+1)/(\eta-1)+\sin(w/w_0)}{\cos(w/w_0)}, \tag{69}$$

by further use of (34), where

$$\eta=V_i/V_f. \tag{70}$$

The quantity η is a measure of the shock strength. Equation (69) shows that different parts of the shock layer (i.e., different values of w) impose different restrictions on Δt. The effective restriction is obtained by replacing the right member of (69) by its minimum value for $-(\pi/2)w_0\leq w\leq(\pi/2)w_0$. The minimum of the last factor in (69) is found to be $2(\eta)^{\frac{1}{2}}/(\eta-1)$, and the stability condition is

$$\Delta t\leq\frac{\Delta x}{2sc}\left(\frac{2}{\gamma+1}\right)^{\frac{1}{2}}\frac{\eta^{\frac{1}{2}}}{\eta-1}. \tag{71}$$

For practical application, it is convenient to express (71) in terms of the quantity L appearing in the normal hydrodynamic stability condition (63). By elimination of p_i from the Hugoniot Eqs. (21), (22), and (8), the speed of the shock is found to be

$$\left.\begin{aligned}s=\frac{M}{\rho_0}=\frac{1}{\rho_0}\left(\frac{2}{(\gamma+1)\eta-(\gamma-1)}\right)^{\frac{1}{2}}\left(\gamma\frac{p_f}{V_f}\right)^{\frac{1}{2}}\\=\left(\frac{2}{(\gamma+1)\eta-(\gamma-1)}\right)^{\frac{1}{2}}s_{0f},\end{aligned}\right\} \tag{72}$$

where s_{0f} is the speed of sound, relative to Lagrangean coordinates, in the material behind the shock. By combining (71) and (72) and use of (58), the stability condition becomes:

$$L_f=\frac{s_{0f}\Delta t}{\Delta x}\leq\frac{1}{2c}\frac{\{[\eta-(\gamma-1)/(\gamma+1)]\eta\}^{\frac{1}{2}}}{\eta-1}. \tag{73}$$

Lastly, the shock strength, and hence η, is generally unknown until the calculation has been performed; it is therefore advisable to replace the right member of (73) by its minimum with respect to η. η can vary in the range $1\leq\eta\leq(\gamma+1)/(\gamma-1)$ (the latter value corresponding to an infinitely strong shock) and the minimum of (73) is attained at the upper end of this range, where the last factor in (73) has the value $\gamma^{\frac{1}{2}}$. Our final, sufficient condition for stability reads:

$$L_f\leq\gamma^{\frac{1}{2}}/2c. \tag{74}$$

This condition has been found to insure stability in test calculations, whereas a serious violation of it leads to trouble. The choice $c=1$ has been found to yield good results in practice for the representation of shocks, in which case the stability condition is at worst slightly more severe than the one that must be observed, anyway (compare Eq. (63)), to insure stability of the motion behind the shock.

Some Non-Linear Systems Permitting Simple Harmonic Motion

JOHN E. BROCK
Department of Mechanics, Washington University, St. Louis, Missouri
(Received October 24, 1949)

By elementary and obvious methods a differential equation is obtained, which in general is non-linear and usually affords a solution which is a simple sinusoidal function of the independent variable (i.e., simple harmonic motion). Two particular examples are studied briefly although no physical realizations are presented. One is led to speculate that new types of oscillators having a sinusoidal output are described by these equations, and that practical applications, such as to frequency metering, may eventually be evolved. However, the writer's speculations along these lines have as yet borne no fruit and his primary object in publishing this material is to bring to the attention of those interested in non-linear phenomena, about which our understanding is so essentially imperfect, an analysis which, though itself possibly trivial, conceivably may prove of service in setting someone else off on a productive investigation.

THE ordinary linear oscillator described by the equation

$$\ddot{x}+\omega^2 x=0, \tag{1}$$

in which $\omega^2>0$, permits simple harmonic motion given by

$$x=A\sin(\omega t+\phi), \tag{2}$$

in which A and ϕ are arbitrary constants, determined by the initial conditions of the motion and independent of ω^2.

This is a special case of the more general oscillator described by

$$F[-(\ddot{x}/x),\quad x^2-(x\dot{x}^2/\dot{x})]=0, \tag{3}$$

in which F represents an arbitrary function of two variables. Equation (3) possesses the solution given by Eq. (2) subject to the condition

$$F(\omega^2,A^2)=0. \tag{4}$$

That is, frequency ω and amplitude A are related as indicated by Eq. (4). Equation (3) may also possess solutions other than that given by Eq. (2).

Equation (3) is derived as follows. From Eq. (2) we also have

$$\dot{x}=A\omega\cos(\omega t+\phi), \tag{5}$$

$$\ddot{x}=-A\omega^2\sin(\omega t+\phi). \tag{6}$$

Eliminating A between Eqs. (2) and (6), we get

$$\omega^2=-\ddot{x}/x, \tag{7}$$

and eliminating ω between Eqs. (2), (5), and (6), we get

$$A^2=x^2-x\dot{x}^2/\ddot{x}. \tag{8}$$

If the solution, Eq. (2), is to be subject to the condition, Eq. (4), the desired differential equation clearly is given by Eq. (3).

The solutions to Eq. (3) given by Eq. (2) and subject to Eq. (4) represent conservative motions, for writing

$$T=\tfrac{1}{2}\dot{x}^2, \tag{9}$$

$$V=-\tfrac{1}{2}x\ddot{x}=\tfrac{1}{2}x^2\left(-\frac{\ddot{x}}{x}\right)=\tfrac{1}{2}\omega^2x^2, \tag{10}$$

we have, from Eq. (3),

$$F\left(\omega^2,\frac{T+V}{\tfrac{1}{2}\omega^2}\right)=0, \tag{11}$$

and, from Eq. (4), this yields

$$T+V=\tfrac{1}{2}\omega^2A^2=\text{const.} \tag{12}$$

From Eq. (10), it is seen that the systems under consideration involve what is essentially a non-linear spring in which the effective spring constant is ω^2, and thus generally a function of amplitude.

If the implicit function $F(\omega^2,A^2)=0$ may be written explicitly as

$$\omega^2=f(A^2) \tag{13}$$

or

$$A^2=g(\omega^2), \tag{14}$$

Eq. (3) takes the form

$$\ddot{x}+xf[x^2-(x\dot{x}^2/\dot{x})]=0 \tag{15}$$

or

$$(x\dot{x}^2/x)-x^2+g(-\ddot{x}/x)=0, \tag{16}$$

as the case may be.

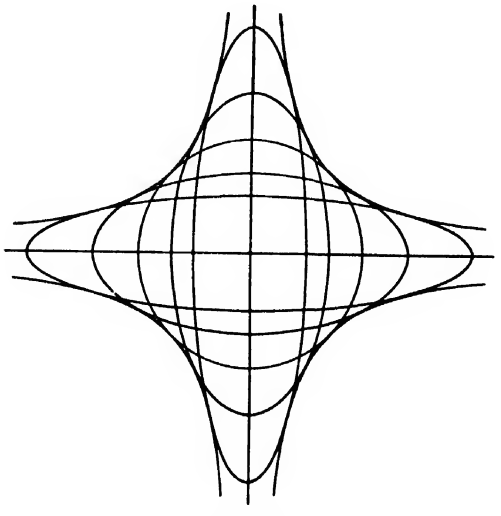

FIG. 1.

Defining the new function

$$h(z)=zg(z) \tag{17}$$

permits writing Eq. (16) in the more convenient form

$$x\ddot{x}-\dot{x}^2-h(\ddot{x}/x)=0. \tag{18}$$

From Eqs. (13) and (14), it is observed that f and g are non-negative functions which need be defined only for positive values of the argument. Thus, these remarks are also true of the function h.

Equation (3) as written may be of degree greater than one, and this leads to ambiguities in interpreting the physical motion. It is, in effect, equivalent to the product of one or more equations of the type

$$\dot{x}+x\psi_i(x,\dot{x})=0 \tag{19}$$

each of first degree and capable of physical interpretation.

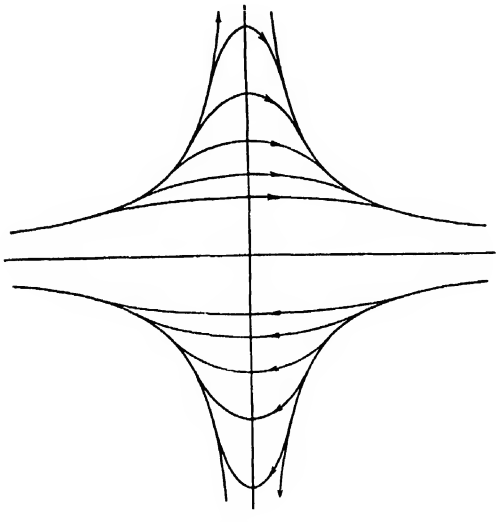

FIG. 2.

From Eq. (19), it is seen that

$$\psi=-\dot{x}/x \tag{20}$$

and

$$x^2+(\dot{x}^2/\psi)=x^2-(xx^2/x). \tag{21}$$

Thus,

$$F[\psi,x^2+(\dot{x}^2/\psi)]=0 \tag{22}$$

can be solved for

$$\psi=\psi_i(x,\dot{x}), \tag{23}$$

where the subscript i indicates that there may be several solutions.

Further points of interest will be forthcoming from examination of two simple examples. For convenience, the possible physical motions are discussed by reference to their trajectories in the displacement-velocity

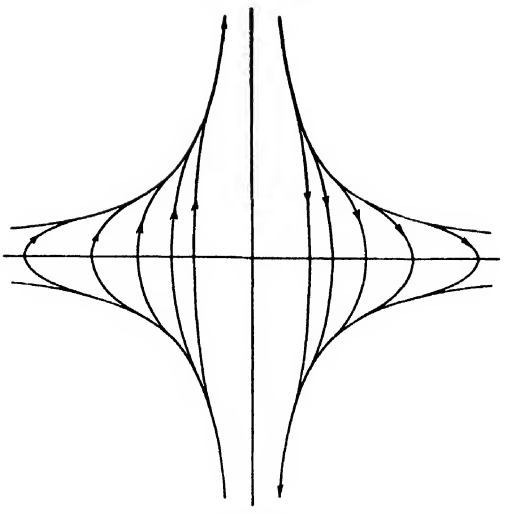

FIG. 3.

"phase" plane.[1] In these discussions, the notation

$$y=\dot{x} \tag{24}$$

will be used.

EXAMPLE 1

Let the relation between frequency and amplitude be given by

$$\omega^2=M^2/A^4, \quad (M>0). \tag{25}$$

Equation (3) becomes

$$\frac{\dot{x}}{x}+\frac{M^2}{(x^2-x\dot{x}^2/x)^2}=0, \tag{26}$$

with a solution

$$x=A\sin[(Mt/A^2)+\phi] \tag{27}$$

for which the phase trajectories are given by

$$(x^2/A^2)+(A^2y^2/M^2)=1. \tag{28}$$

The solution represents simple harmonic motion and the trajectories are concentric ellipses each of area πM. The trajectories are shown in Fig. 1. These ellipses are tangent to the equilateral hyperbolas

$$4x^2y^2=M^2 \tag{29}$$

at the points

$$\left.\begin{matrix}x=\pm(A\sqrt{2})/2\\ y=\pm(M\sqrt{2})/2A\end{matrix}\right\}. \tag{30}$$

Through every point for which $4x^2y^2<M^2$ there pass two ellipses and there are obvious difficulties in attempting to interpret the physical motion.

[1] For a discussion of and examples illustrating this type of representation, cf., N. Minorski, *Introduction to Non-Linear Mechanics* (J. W. Edwards, Ann Arbor, Michigan, 1947), especially Chapters 1–3.

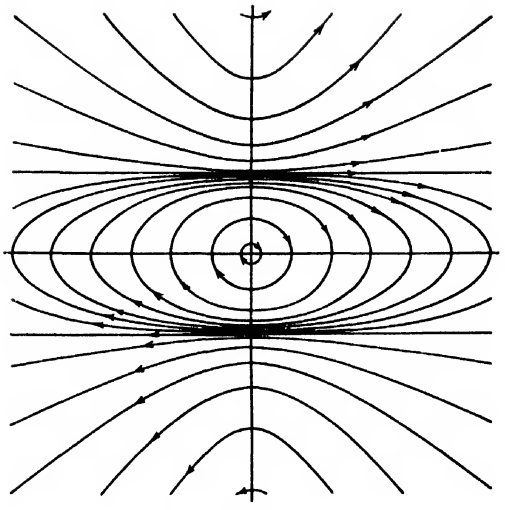

FIG. 4.

In this case, Eq. (22) becomes

$$\psi=\frac{M^2}{(x^2+y^2/\psi)^2} \tag{31}$$

from which we obtain the following two equations in the form of Eq. (19):

$$\ddot{x}+\frac{1}{x^3}\left\{\frac{M^2}{2}-x^2\dot{x}^2-M\left(\frac{M^2}{4}-x^2\dot{x}^2\right)^{\frac{1}{2}}\right\}=0 \tag{32}$$

$$\ddot{x}+\frac{1}{x^3}\left\{\frac{M^2}{2}-x^2\dot{x}^2+M\left(\frac{M^2}{4}-x^2\dot{x}^2\right)^{\frac{1}{2}}\right\}=0. \tag{33}$$

These two equations are, of course, also obtained by solving Eq. (26) for $\ddot{x}$. In each case the accelerations are real only if

$$4x^2y^2\leqq M^2, \tag{34}$$

which explains why no trajectories are found outside the region bounded by the hyperbolas of Eq. (29).

In the case of Eq. (32), a solution is given by Eq. (27), and this solution is valid only for

$$x^2\leqq A^2/2, \tag{35}$$

in other words, only for those values of x between the points where the elliptical trajectory (given by Eq. (28)) becomes tangent to the hyperbolas of Eq. (29), (cf. Eq. (30)).

In the case of Eq. (33), the solution afforded by Eq. (27) is valid only for

$$x^2\geqq A^2/2. \tag{36}$$

In both cases, the hyperbolic envelope also represents a solution valid for all x, the solution being

$$x^2=C\pm Mt, \tag{37}$$

the corresponding trajectories being the hyperbolas themselves (Eq. (29)).

Figures 2 and 3 show the trajectories corresponding to Eq. (32) and Eq. (33), respectively. It is seen that Fig. 1 represents a superposition of these.

In the cases of Eq. (32), by writing

$$\begin{cases} y=\dot{x}=F_1(t;x,y) \\ \dot{y}=-(1/x^3)\{(M^2/2)-x^2y^2 \\ \qquad -M[(M^2/4)-x^2y^2]^{\frac{1}{2}}\}=F_2(t;x,y) \end{cases} \tag{38}$$

we have a system of two first-order equations to which the ordinary test for uniqueness applies.[2] It is clear that both functions F_1 and F_2 satisfy Lipschitz conditions

$$|F_i(t;x_1,y_1)-F_i(t;x_2,y_2)|<k(|x_1-x_2|+|y_1-y_2|) \tag{39}$$

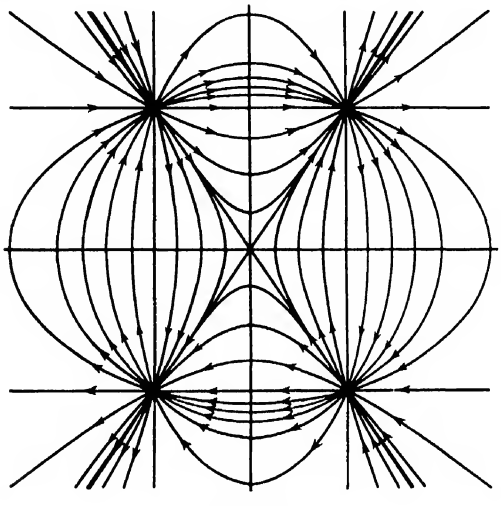

FIG. 5.

in any domain D which does not include any part of the y axis or any part of the hyperbolas of Eq. (29). Since (real) solutions are defined only for $4x^2y^2\leqq M^2$, we can assert their uniqueness except possibly for $x=0$, and upon the hyperbolas.

The trajectories of Fig. 2 show that indeed the solution is not unique on the hyperbolas. However, a unique solution does exist for any set of initial conditions corresponding to a point on the interior of the region bounded by the hyperbolas. For representative points on the y-axis, the situation must be investigated by the following limiting process:

$$\begin{aligned} \lim_{x\to 0}\dot{x}&=\lim_{x\to 0}\left[-\frac{1}{x^3}\left\{(M^2/2)-x^2y^2 \right.\right. \\ &\qquad \left.\left. -M[(M^2/4)-x^2y^2]^{\frac{1}{2}}\right\}\right] \\ &=\lim_{x\to 0}\left[-(xy^4/M^2)+0(x^3y^6/M^4)\right]=0. \end{aligned} \tag{40}$$

(This result holds regardless of the value of y.) Thus, a particle starting with any velocity and zero displace-

[2] Cf. E. L. Ince, *Ordinary Differential Equations* (Dover Publications, New York, 1944), p. 71.

ment continues with the same velocity until the representative point moves off the y-axis into the region to which the preceding uniqueness test applies. The origin provides an exception to this statement, but it is clear that in this case the particle will remain with zero velocity and zero displacement.

The trajectories of Fig. 2 do not clearly show the behavior if the initial conditions involve $y_0=0$. In such a case, the acceleration vanishes identically and the solutions is $x\equiv x_0$; such a state of equilibrium is evidently unstable since if any positive (negative) velocity is given to the particle, its displacement will tend to positive (negative) infinity.

A somewhat similar analysis may be applied to Eq. (33). This will not be given here in full detail, but it may be remarked that the motion is not defined if the initial conditions involve zero displacement, i.e., the representative point on the y-axis.

Subject to the exceptions noted in the two preceding paragraphs, it is seen that, if the initial conditions are such that

$$4x_0^2\dot{x}_0^2<M^2, \tag{41}$$

the motion will be simple harmonic until the repre-

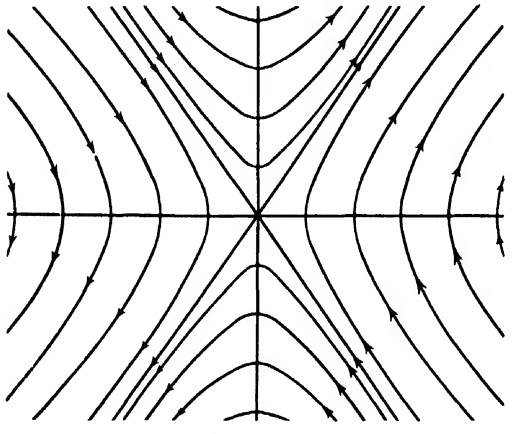

Fig. 6.

sentative point in the phase plane, moving along an elliptical path, touches one of the bounding hyperbolas. From this time on, the point follows the hyperbola and the motion is described by Eq. (37). There is no ambiguity unless the representative point for the initial conditions lies upon the bounding hyperbola in either the second or fourth quadrants. In such a case there is an instability and the representative point may follow a hyperbola or break away and follow an ellipse at any time. It may be remarked that hyperbolic trajectories have some properties similar to those of "limit cycles."

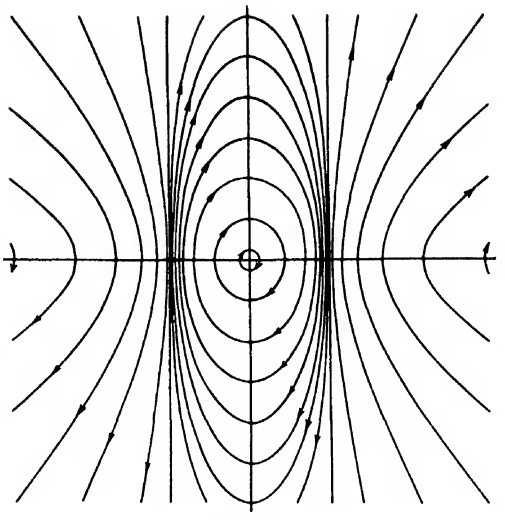

Fig. 7.

EXAMPLE 2

A fairly general case is represented by the condition

$$\omega^2=\frac{aA^2+b}{cA^2+d}, \tag{42}$$

where a, b, c, and d are constants such that $ad\neq bc$. We are led to the equations

$$\ddot{x}+x\left\{\frac{(ax^2+b-c\dot{x}^2)\pm[(ax^2+b-cx^2)^2+4a\dot{x}^2(cx^2+d)]^{\frac{1}{2}}}{2(cx^2+d)}\right\}. \tag{43}$$

The function

$$x=A\sin\left[\left(\frac{aA^2+b}{cA^2+d}\right)^{\frac{1}{2}}t+\omega\right] \tag{44}$$

is a solution to Eq. (43) with the plus sign if and only if

$$\frac{acA^4+[bc\sin^2\theta+ad(1+\cos^2\theta)]A^2+bd}{(cA^2+d)}<0, \tag{45}$$

where

$$\theta=\left(\frac{aA^2+b}{cA^2+d}\right)^{\frac{1}{2}}t+\phi. \tag{46}$$

Similarly, Eq. (44) is a solution to Eq. (43) with the minus sign if and only if the inequality opposite to that of condition (45) is satisfied.

This example is too involved to work out in full detail here, so we consider the special case where $a=0$. With this simplification we are led to:

$$[x^2+(d/c)]\ddot{x}/x=\dot{x}^2-(b/c). \tag{47}$$

In this case the investigation naturally divides itself into four cases.

Case (1). $(d/c)>0$; $(b/c)>0$

If $\dot{x}^2<(b/c)$, a solution is

$$x=A\sin\left[\left(\frac{b}{cA^2+d}\right)^{\frac{1}{2}}t+\phi\right] \tag{48}$$

with trajectories

$$x^2/A^2+[(cA^2+d)/(bA^2)]y^2=1. \tag{49}$$

If $\dot{x}^2>(b/c)$, a solution is

$$x=A\sinh\left[\left(\frac{b}{cA^2-d}\right)^{\frac{1}{2}}t+\phi\right] \tag{50}$$

with trajectories

$$[y^2(cA^2-d)/bA^2]-(x^2/A^2)=1. \tag{51}$$

For the whole phase plane the trajectories are shown in Fig. 4.

Case (2). $(d/c)<0$; $(b/c)>0$

In this case if $A^2<-(d/c)$, the frequency becomes imaginary and we cannot expect simple harmonic motion. The solution and trajectories given by Eqs. (48) and (49) hold for $-(d/c)<A^2<\infty$. For $A^2<-(d/c)$, the solutions and trajectories of Eqs. (50) and (51) hold as well as those given by

$$x=A\cosh\left[\left(\frac{-b}{cA^2+d}\right)^{\frac{1}{2}}t+\phi\right] \tag{52}$$

and

$$(x^2/A^2)+(y^2(cA^2+d)/A^2b)=1. \tag{53}$$

All the trajectories pass through the points $x=\pm(-d/c)^{\frac{1}{2}}$, $y=\pm(b/c)^{\frac{1}{2}}$, which represent instability in the sense that many motions of the representative point are possible at these points. The trajectories are shown in Fig. 5.

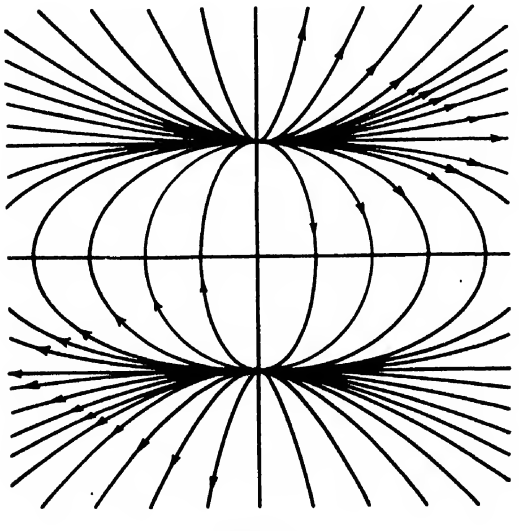

FIG. 8.

Case (3). $(d/c)>0$; $(b/c)<0$

In this case the frequency is imaginary and there can be no periodic motions as may be seen directly from Eq. (47). The singularity at $x=\dot{x}=0$ is an ordinary saddle point. The solutions and corresponding trajectories are given by Eqs. (50), (51), (52), and (53). The trajectories are shown in Fig. 6.

Case (4). $(d/c)<0$; $(b/c)<0$

If $A^2<-(d/c)$, Eqs. (48) and (49) give the solution and trajectories respectively. If $A^2>-(d/c)$, Eqs. (52) and (53) give these results. The trajectories are shown in Fig. 7.

Two interesting special cases are obtainable from this analysis. If $b=c$, and $d=0$, we have the equation

$$\dot{x}^2-x\ddot{x}=1 \tag{54}$$

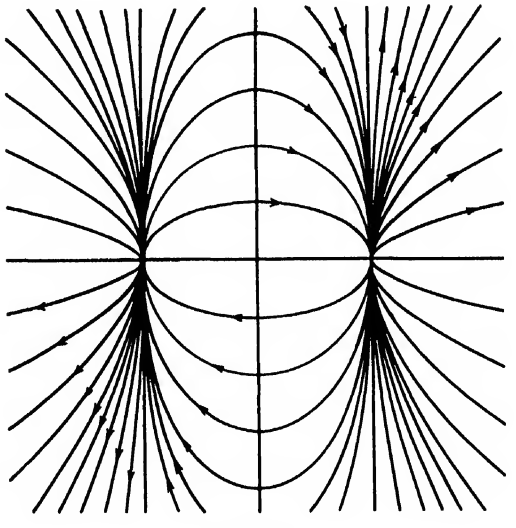

FIG. 9.

for which, if $x^2\gtrless 1$, the solution is

$$x=A\sin[(t/A)+\phi] \tag{55}$$

and the trajectories are

$$(x^2/A^2)+y^2=1. \tag{56}$$

If $\dot{x}^2\gtrless 1$, the solution is

$$x=A\sinh[(t/A)+\phi] \tag{57}$$

and the trajectories are

$$y^2-(x^2/A^2)=1. \tag{58}$$

All trajectories pass through the points $x=0$; $y=\pm 1$. (Fig. 8).

If $b=0$, and $d=-c$, we have the equation

$$\ddot{x}(1-x^2)+x\dot{x}^2=0. \tag{59}$$

If $x^2 \leqq 1$, the solution is given by

$$x = \sin[(t/A)+\phi] \tag{60}$$

and the trajectories by

$$x^2 + A^2y^2 = 1. \tag{61}$$

If $x^2 \geqq 1$, the solution is given by

$$x = \cosh[(t/A)+\phi] \tag{62}$$

and the trajectories by

$$x^2 - A^2y^2 = 1. \tag{63}$$

The trajectories are shown in Fig. 9.

The ordinary Lipschitz condition[2] for (existence and) uniqueness of the solutions suffices to demonstrate uniqueness for solutions to Eq. (47) except for $x = \pm(-d/c)^{\frac{1}{2}}$. The implications of this are apparent in Cases (2) and (4). In Cases (1) and (3) there is no exception to uniqueness.

The Analogy between Hydraulic Jumps in Liquids and Shock Waves in Gases*

F. R. Gilmore, M. S. Plesset, and H. E Crossley, Jr.
Hydrodynamics Laboratory, California Institute of Technology, Pasadena, California
(Received September 30, 1949)

The theory of the hydraulic jump is presented briefly, and the analogy between this phenomenon and the compression shock wave in gases is pointed out. The results of experimental measurements of hydraulic-jump intersections on a water table are reported. Considerable disagreement between theory and experiment is found. Other investigators have noted a disagreement between theory and experiment for compression shock intersections in gases. The discrepancy in the aerodynamic case appears unlike that found in the hydraulic case. Possible reasons for the discrepancy in the hydraulic case are discussed; some sources of error are peculiar to hydraulic jumps and do not apply to compression shocks. Such factors limit the utility of the water table as an analog device.

INTRODUCTION

IT has been known for a long time that liquid flow in open channels is of two different types: relatively smooth "streaming" flow at low speeds, and high speed "shooting" flow characterized by standing waves and frequently by sudden changes in depth known as hydraulic jumps. More recently, the increased study of compressible-flow phenomena has led investigators to note the resemblances between streaming channel flow and subsonic compressible flow, and between shooting channel flow and supersonic compressible flow. This similarity was put on a mathematical basis by Jouguet[1] and Riabouchinsky.[2] Further theoretical investigations have been carried out by von Kármán[3] and by Preiswerk[4]; experimental studies have been made by Ippen[5] and by Binnie and Hooker.[6] Later work[7] has been concerned with the application of the theory to model testing, except for a recent theoretical paper by Stoker.[8]

The analogy between liquid flow with a free surface and two-dimensional gas flow has been found useful for qualitative investigations of high speed gas flow by means of relatively simple water-table installations. However, recent advances in aerodynamics have brought many problems to the point where more accurate information is required than can be obtained from the hydraulic analogy. The present utility of the water table as an analog device is limited to special problems in aerodynamics, such as transient phenomena in high speed flow, and shock-wave intersection phenomena, particularly of the Mach type.

The discussion here is concerned with the analogy between hydraulic-jump intersections on a water table and shock-wave intersections in gases.

THEORY

Shock Waves in Compressible Gas Flow

As is well known, a compression wave of finite amplitude in a gas grows continually steeper as the wave progresses until a finite limiting steepness determined by viscous and heat-conduction effects is attained. The limiting thickness of the shock in the usual situation is negligible compared with the other dimensions in the flow field. The flow relations across a straight compression shock are determined by the conservation laws for mass, momentum, and energy without consideration of the conditions inside the shock. The results are the

familiar Rankine-Hugoniot equations.[9] Figure 1 shows curves of the density ratio, temperature ratio, and the square root of the pressure ratio across a normal shock as functions of the initial Mach number for perfect gases having specific-heat ratios of $\gamma=1.4$ and $\gamma=2$.

The flow relations across a straight shock which is oblique to the flow may be obtained by superimposing on the normal velocity an additional velocity tangential to the shock which remains unchanged across the shock. For a curved shock, if the radius of curvature is much larger than the shock thickness, the flow relations may be obtained by approximating the curved shock with a number of straight segments.

Hydraulic Jumps in Liquid Flow with a Free Surface

If an elevation wave of finite amplitude is produced on the surface of a liquid, Stoker[9] has shown from the equations of motion that the wave front will grow continually steeper as it progresses, until finally the wave leans forward. At this point experiments show that the wave form deviates from the theoretical form, with the formation of a breaker or "roller" and the establishment of a turbulent wave of constant shape (except for minor fluctuations of short period). Such a steady finite wave is called a hydraulic jump. Bakhmeteff and Matzke[10] have found experimentally that

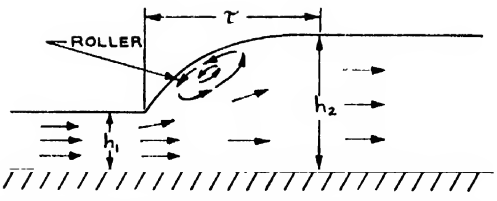

FIG. 2. Typical profile of a strong hydraulic jump ($h_2/h_1>2$).

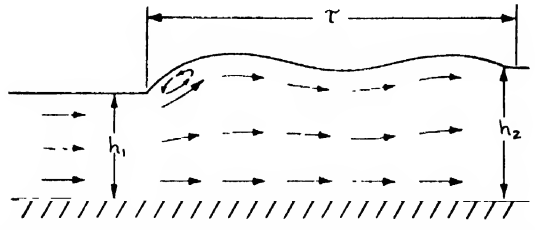

FIG. 3. Typical profile of a weak hydraulic jump ($h_2/h_1<2$).

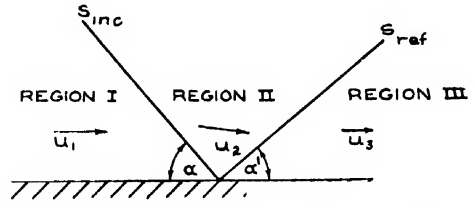

FIG. 4. Regular reflection of a shock from a rigid wall.

strong hydraulic jumps with a height ratio, h_2/h_1, greater than 2 have the simple profile shown in Fig. 2; in these strong hydraulic jumps, the thickness, τ, of the jump is four to six times the height of the jump, h_2-h_1. Weaker jumps generally have the undulatory form shown in Fig. 3. The surface first rises above the final level and then oscillates with diminishing amplitude about the final level. The thickness of the undulatory jump is not well defined, but the undulations generally die out at distances of three to ten times the initial water height, h_1, the distance being greater for the smaller jumps. A theoretical explanation of this general behavior has not as yet been given.

As in the case of compression shocks in gases, flow relations across straight hydraulic jumps are determined by the conservation laws for mass, momentum, and energy without consideration of the conditions inside the jump. The result for the height and velocity ratio of a jump normal to the flow is

$$h_2/h_1=u_1/u_2=(2u_1^2/gh_1+\tfrac{1}{4})^{\frac{1}{2}}-\tfrac{1}{2}. \qquad (1)$$

The height ratio given by Eq. (1) is plotted against initial Mach number as the solid curve in Fig. 1. "Mach number" in this case is defined as $u/(gh)^{\frac{1}{2}}$, since $(gh)^{\frac{1}{2}}$ is the velocity of infinitesimal surface waves.

Flow relations across oblique hydraulic jumps may be calculated in the same way as for oblique compression shocks. Similarly, flow relations across curved jumps can be found, provided the radius of curvature is much larger than the jump thickness. In many experi-

mental situations, however, the thickness of the jump may be of the same order of magnitude as the radius of curvature. Existing theory does not cover this case.

The Analogy between Shocks and Jumps

It may be shown[1–4] that the smooth free-surface flow of a liquid over a horizontal bed obeys equations of motion similar to those for the isentropic two-dimensional flow of a hypothetical gas with specific heat ratio $\gamma=2$. The mathematical correspondence is between the following quantities: the liquid velocity ratio and the gas velocity ratio; and the liquid depth ratio on the one hand and the gas density ratio, the gas temperature ratio, and the square root of the gas pressure ratio, on the other hand. It is to be noted that the isentropic condition makes the gas density ratio, the gas temperature ratio and the square root of the gas pressure ratio all equal when $\gamma=2$.

Flows with shocks or jumps are not isentropic and it might be expected that the quantitative correspondence breaks down. The entropy change, however, is of the third order in the shock strength so that weak shocks are very nearly isentropic; and the quantitative similarity should then hold to a good approximation. This situation is demonstrated in Fig. 1, which compares values of analogous quantities for the compression shock and the hydraulic jump. The curves for a gas with $\gamma=2$ approach the liquid curve asymptotically as the shock becomes weaker.

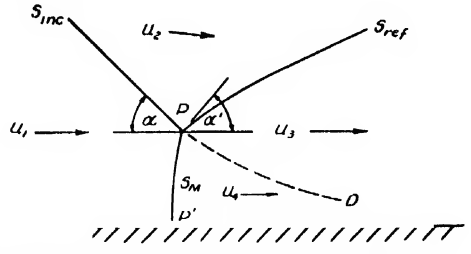

FIG. 5. Mach reflection of a shock from a rigid wall.

An analogy based on a hypothetical gas with $\gamma=2$ is somewhat unrealistic since kinetic theory shows that gases must have specific-heat ratios in the range $1<\gamma\leqslant 5/3$. Figure 1 includes curves for a gas with $\gamma=1.4$, which is the value for air. Although these curves do not have an asymptotic approach to the liquid curve as the shock strength is decreased, some of the flow parameters, e.g., u_1/u_2, have a smaller deviation over a range of strong shocks than the corresponding parameters for $\gamma=2$.

Intersections and Reflections of Hydraulic Jumps and Shock Waves

The following discussion will apply both to hydraulic jumps and compression shock waves, and the term "shock" will be used to signify either phenomenon.

Figure 4 shows the reflection of a straight shock from a plane rigid wall; it could as well refer to the intersection of two equal straight shocks where the wall becomes the plane of symmetry. The fluid in Region I, ahead of the shocks, is assumed to be either at rest or in a state of uniform motion. It is convenient to introduce a coordinate system relative to which the shocks and their intersection are stationary; in this coordinate system let u_1 be the velocity with which the fluid in Region I approaches the incident shock, S_{inc}. As the flow passes through this shock, it is slowed down and deflected to a velocity u_2 in Region II. The reflected shock, S_{ref}, must deflect the flow from the velocity u_2 to a velocity u_3 in Region III which, like u_1, must be parallel to the boundary wall or to the plane of symmetry. This condition is sufficient to determine the angle and strength of the reflected shock.[11]

When the incident shock is too strong, and when it makes too large an angle α with the wall, there is no real solution for the angle and strength of the reflected

shock so that the "regular" reflection scheme shown in Fig. 4 becomes impossible. In this situation the actual flow is found experimentally to follow the scheme shown in Fig. 5. A third shock, the "Mach," S_M, appears, and its length, i.e., the distance PP', increases with time at a fairly constant rate. The Mach, S_M, is frequently curved, and also the reflected shock, S_{ref}, is often curved near the triple-shock intersection.

The simplest theory of the Mach reflection assumes that all three shocks are straight.[11] Coordinates are chosen fixed with respect to the shock intersection P so that the problem is one of steady flow. In these coordinates, the wall (or plane of symmetry) is moving downward at a constant velocity equal to the component of u_1 or u_4 tangential to S_M. A line PD can be drawn separating the fluid which has passed through S_{inc} and S_{ref} from that which has passed through S_M. The gas pressure (or liquid height) must be continuous across PD since it is not a shock. However, fluid which has passed through a single large shock has lost more flow energy than that which has passed through two smaller shocks with the same total change in pressure (or height); hence the velocity and density of a gas (or the velocity of a liquid) will be less below PD than above it. Thus, PD is a slip-stream. Schlieren photographs of gas flows have shown such a density discontinuity at PD.

Quantitative relations for such three-shock intersections can be obtained by applying the oblique shock equations to each of the shocks. The results for some ranges of interest have been tabulated by Polachek and Seeger both for compression shocks[12] and for hydraulic jumps.[13]

EXPERIMENTAL MEASUREMENTS

The purpose of the present experimental study was the investigation of regular and Mach intersections in hydraulic jumps. The apparatus used in the experiments was essentially that used by Einstein and Baird[14]

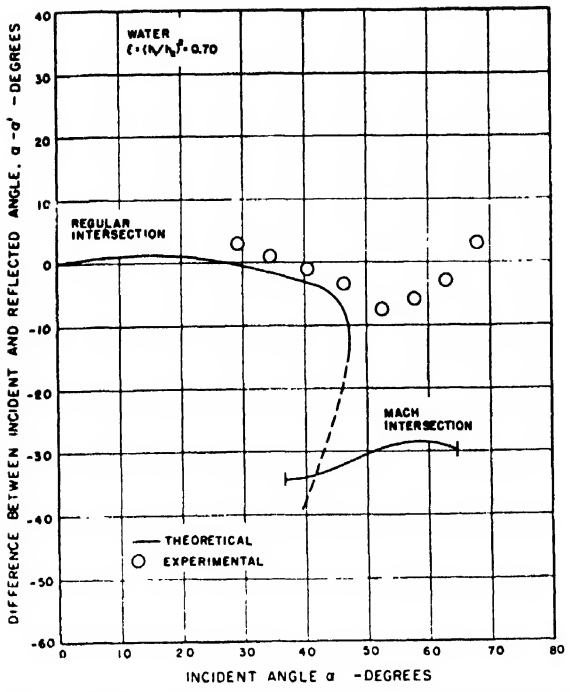

FIG. 11. Relationship between incidence and reflection angles for the intersection of weak hydraulic jumps ($\xi=0.70$).

in earlier investigations and is shown schematically in Fig. 6. The water table was approximately 5 ft. long, 4 ft. wide, and 2 in. deep. The liquid used in the tank was a 0.001 to 0.002 normal solution of manganous chloride in distilled water; the manganous chloride was added to the water so that the electrical conductivity of the solution would be more uniform. The hydraulic jumps were produced by two wave generators which were reservoirs into which a volume of water could be raised above the free surface; this volume of water could be discharged quickly through an adjustable horizontal slot 24 in. long located just below the free surface. Instantaneous water depths at any point on the water table could be determined by measuring the resistance between a pair of partially immersed platinum electrodes. A 1000-cycle alternating voltage was applied across the electrodes and the current which flowed was recorded by an oscillograph with an upper limit of about 100 cycles on its frequency response.

Typical wave depth records are shown in Fig. 7; the record is interrupted at intervals to give a zero reference line. The horizontal coordinate in these records is a time scale not a spatial scale, but a good estimate of the instantaneous wave form in space may be obtained by multiplying this time scale by the wave velocity.

In addition to a continuous record of the water depth at a point, an instantaneous refraction photogram of the entire field could be made. The bottom of the water tank was made of glass so that the light flash from a spark discharge across a $\frac{1}{8}$-in. gap could be transmitted upward through the water and the resulting refraction pattern could be recorded on photographic paper placed above the water surface.

RESULTS AND DISCUSSION

Measurements were first made to determine the shape and velocity of single hydraulic jumps produced with one wave generator alone; depths were determined with three pairs of electrodes. The initial water depth, h_1, ranged from about 0.5 cm for strong jumps to about 2 cm for weak jumps. Weak jumps were found to have an undulatory profile, stronger jumps had a smoother profile, and very strong jumps showed appreciable irregular roughness (cf. Fig. 7). These observations agree qualitatively with those of Bahkmeteff and Matzke[10] on hydraulic jumps larger by an order of magnitude than those reported here. The velocities of the hydraulic jumps were also measured and compared with the usual formula

$$u_1=\{g(h_1+h_2)h_2/(2h_1)\}^{\frac{1}{2}}, \qquad (2)$$

where h_1 is the water depth ahead of the jump and h_2 is the water depth behind the jump. The measured velocities of weak jumps agreed with the theoretical values within the experimental error of approximately two percent, but the measured velocities of the stronger jumps were up to five percent larger than the theoretical values. A possible explanation of this discrepancy is that the water released from the wave generator may tend to override the surface of the still water. The water

in the jump would then have a higher velocity at the free surface than at the bed so that the simple theory would not apply.

A study was also made of the effect of the addition of surface-tension reducing agents to the water. When 0.1 percent by volume of lauryl isoquinolinium bromide was added to the water, the wave fronts formed became steeper, and the strong jumps became smoother. However, an appreciable amount of foam was produced which interfered with the photographic procedure. It was noted, moreover, that the amplitude of the undulations in the weaker jumps was increased. A weaker detergent solution, which consisted of 0.5 percent by volume of Kodak Photo-Flo (an aerosol solution), was found to give an intermediate effect: the undulations were enhanced only in the weakest waves, while the wave form of the strong waves was smoothed and steepened. The effect of these detergent solutions is shown in Fig. 8.

Measurements were made on the hydraulic jump intersections produced by two wave generators set at various angles. The jump strengths were determined by the resistance depth gauges while the general flow pattern was recorded on the refraction photograms (cf. Figs. 9 and 10).

Most of the measurements were made with jump strengths, $\xi\equiv(h_1/h_2)^2$, of 0.28, 0.45, and 0.70. For the medium and strong jumps ($\xi=0.45$ and 0.28), the aerosol solution was used, while for the weak jumps ($\xi=0.70$) detergent-free water was used, since this gave the best wave form. Figures 11 and 12 show the experimentally measured differences between the angle of incidence, α, and the angle of reflection, α', plotted against α for weak and strong jumps, respectively. Theoretical curves for the regular and Mach intersections are also shown. The agreement between theory and experiment is fair for the limited number of regular intersections investigated, but is definitely poor for the Mach intersections. There is little evidence of the sudden change in reflection angle which is predicted by the theory in passing from regular to Mach intersections.

These figures may be compared with Figs. 13 and 14, which give the corresponding data for intersections of compression shocks in air. The experimental points are taken from a report by Harrison and Bleakney.[15] The agreement between theory and experiment is seen to be better here, but an appreciable discrepancy remains, especially for the weaker shocks. There appears to be little resemblance between the trend of the disagreement in the liquid and gas cases.

One possible error in the use of the simple theory in the above comparisons is the neglect of the curvature of the Mach jump. The geometric effect of this curvature can be eliminated by considering only a small region about the triple jump intersection. Such a presentation of the data is shown in Figs. 15 and 16 where ω and ω' are the local angles which the incident and

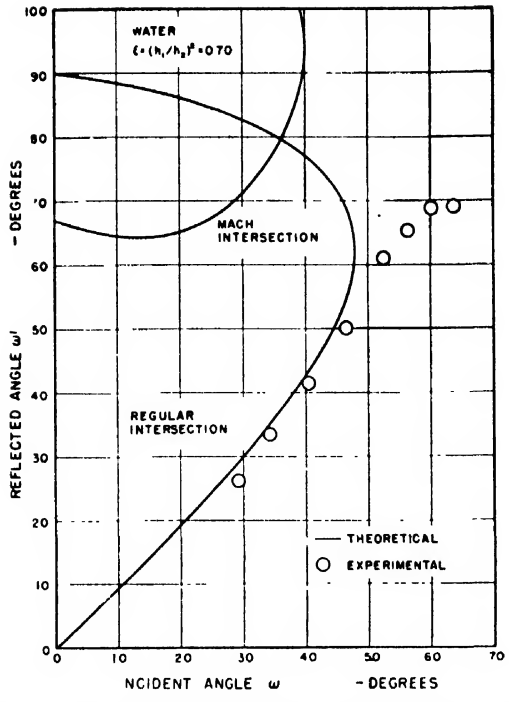

FIG. 15. Relationship between incidence and reflection angles, measured with respect to the direction of motion of the triple intersection, for the intersection of weak hydraulic jumps ($\xi=0.70$).

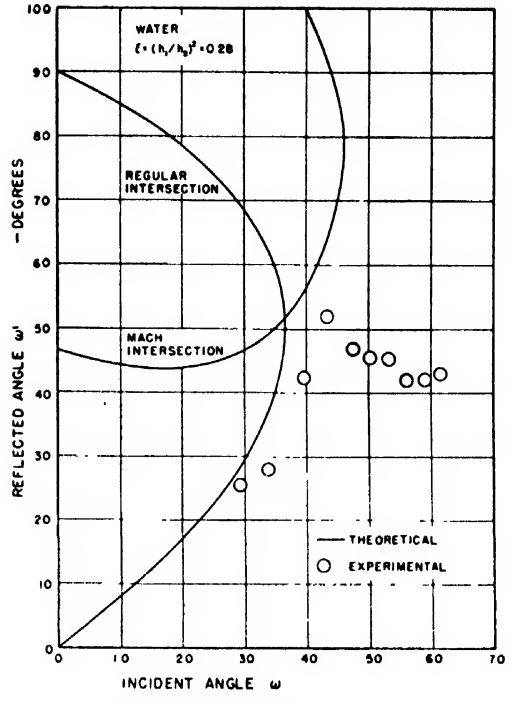

FIG. 16. Relationship between incidence and reflection angles, measured with respect to the direction of motion of the triple intersection, for the intersection of strong hydraulic jumps ($\xi=0.28$).

reflected jumps make with the direction of motion of the triple point. The weak-jump data shown in Fig. 15 show a disagreement with theory similar to that found by Harrison and Bleakney for air, although the discrepancy is somewhat greater for the hydraulic case. The strong-jump data shown in Fig. 16 show similar disagreement with theory, whereas Harrison and Bleakney found very little discrepancy in air.

Examination of the photograms indicates that the thickness of the Mach jump is not negligible compared with the radius of curvature of the Mach. The present theory does not take account of this possibility so that an error of unknown magnitude has been introduced. This difficulty does not arise in the aerodynamic case. The experimental observotions indicate an additional source of error in the simple theory: the liquid depth behind the reflected jump and the Mach jump is not uniform; in fact, there sometimes appears to be an additional hydraulic jump approximately parallel to, but behind, the reflected jump. Corresponding sources of error may exist in the aerodynamic case although direct observations on this possibility are not available.

One may conclude from the experimental observations discussed here that the deviations from the simple theory of hydraulic-jump intersections limit the use and validity of the hydraulic analog as a means for studying compression-shock intersections in gases.

An Optical Method for Measuring the Stress in Glass Bulbs

W. T. READ
Bell Telephone Laboratories, Inc., Murray Hill, New Jersey
(Received October 6, 1949)

In the sealing and processing of electron tubes residual stresses are introduced into the glass parts. This paper formulates a practical optical method for locating and measuring the maximum tension in the walls of glass bulbs.

The basic principles of photoelasticity in three dimensions are applied to the case of a cylindrical shell. Theoretical results are verified experimentally for a tube in which the stress distribution is axially symmetrical.

Experimental results on tubes in which the stress distribution was unsymmetrical lead to the conclusion that the maximum tensile stress is proportional to the maximum retardation, the factor of proportionality being simply related to the form of the fringe pattern.

A quick and simple technique is described for making the necessary optical measurements.

The method presented herein has been used and found to be practical for routine laboratory testing of tubes in quantity.

I. INTRODUCTION

IN the sealing and processing of electron tubes, residual stresses are introduced in the bulb walls due to non-uniform heating and mismatch of thermal expansion coefficients. Failures resulting from these stresses constitute a serious problem especially in glass walled tubes. A quick and reasonably accurate method of determining the maximum stress in the bulb would permit the detection and rejection of overstressed tubes at the factory and aid in the improvement of sealing techniques.

The usual procedure is to examine the tube in a polariscope and judge the stress magnitude by observation of relative phase retardation. Because of the three-dimensional state of stress in the tube wall the quantitative conversion of the observed retardation to stress magnitude involves considerations beyond those commonly employed. It was the purpose of this investigation to discover the relation between the observed retardation and the maximum stress in the cylindrical portion of the bulb and to develop a simple laboratory procedure for making the necessary measurements.

We begin with a brief review of the stress optical relations in the general three-dimensional case.

Upon entering a doubly refracting material such as stressed glass, the incident light is resolved into two waves, plane polarized at right angles to one another and traveling with different velocities. In a material as weakly birefringent as glass the two waves may be assumed to travel in the same direction and to have the same wave normal. In Fig. 1 let the wave normal be parallel to the y axis so that the wave front is parallel to the xz plane, f being the direction of polarization of the faster moving wave and s, of the slower moving wave. We designate φ as the (variable) angle between f and the x axis. The angle φ and the relative velocities of the two waves are determined by the directions and magnitudes of the secondary principal stresses in the plane of the wave front. The axes of secondary principal stress are the normals to the two perpendicular planes through the y axis on which the shearing stress vanishes, and the normal stress is stationary. The secondary principal stresses, p and q, are respectively the maximum and minimum values of the normal stress in the xz plane.

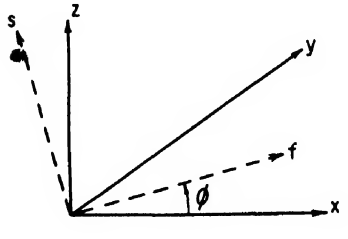

FIG. 1. Directions of polarization in plane of wave front.

We shall use the following two stress-optical laws which apply to weakly birefringent materials such as glass: (1) at each point in the stressed material the polarizing axes f and s in the plane of the wave front are along the axes of secondary principal stress, and (2) the difference between the reciprocals of the velocities of the two waves is proportional to the difference between the secondary principal stresses, i.e., to $p-q$. For most materials the direction of the maximum normal stress p is along the f axis.

The angle φ (Fig. 1) is, therefore, the angle between the direction of maximum normal stress and the x axis. Letting σ_x and σ_z be the normal components of stress in the x and z directions and τ_{xz} be the shearing component we have the relations[1]

$$\tan 2\varphi = (2\tau_{xz})/(\sigma_x - \sigma_z) \tag{1}$$

$$p - q = [(\sigma_x - \sigma_z)^2 + 4\tau_{xz}^2]^{\frac{1}{2}}. \tag{2}$$

If the light is monochromatic the vibration at any point in the glass is defined by the difference in phase ψ between the components along the f and s axes and by the ratio of amplitudes, $\tan\omega$. The two functions of y, ω and ψ, are given in terms of the functions φ and

[1] R. D. Mindlin, J. App. Phys. **10**, No. 4, 229 (April, 1939).

$p-q$ by the following two simultaneous first-order differential equations with variable coefficients:[2]

$$(d\omega/dy)+(d\varphi/dy)\cos\psi=0$$

$$\frac{\tan 2\omega}{2}\left[\frac{d\psi}{dy}+\frac{2\pi C}{\lambda}(p-q)\right]-\frac{d\varphi}{dy}\sin\psi=0, \qquad (3)$$

where λ is the wave-length of the incident light and C is the relative stress optical coefficient.

These equations were derived by F. Neumann from simple kinematical considerations involving approximations which are valid for photoelastic studies.[3] In the standard two-dimensional case the stress distribution is nearly constant through the thickness of the model so that rotation of the polarizing axes along the path of the ray may be neglected and Neumann's equations may be easily integrated to give $\omega=$ const and the standard two dimensional formula

$$\psi/2\pi=C/\lambda(p-q)d,$$

where d is the thickness of the model. In the general three-dimensional case there is rotation of the secondary principal axes and the exact solution is impractical. However, in some cases the equations can be considerably simplified subject to certain limitations on the quantities involved. Denoting by $R/2$ the ratio of rate of rotation of polarizing axes to rate of relative phase retardation referred to stationary axes and substituting into Neumann's first equation gives

$$d\psi/dy=-(2\pi C)/\lambda(p-q)[1+R\cot 2\omega\sin\psi]. \qquad (4)$$

If the rate of rotation of the secondary principal axes is small compared to the rate of relative phase retardation and if the amplitudes of the two components are equal on entry and remain approximately equal (so that ω remains close to $\pi/4$ radians) then $R\cot 2\omega$ is negligibly small compared to unity and we may use the simple formula

$$d\psi/dy=-(2\pi C)/\lambda(p-q). \qquad (5)$$

However here $p-q$ is in general an unknown function of y so that we shall leave the equation in differential form. Thus subject to the conditions on R and ω the rate of relative phase retardation depends only on the secondary principal stress difference, and not on the rotation of the polarizing axes. The exact form of the equations and the effect of large $R\cot 2\omega$ are discussed for simple states of stress in Appendix I.

II. PHOTOELASTIC THEORY OF SHELLS

In this section we shall regard the bulb as a cylindrical shell and use the concepts and approximations of shell theory. Figure 2 shows a cross section of the

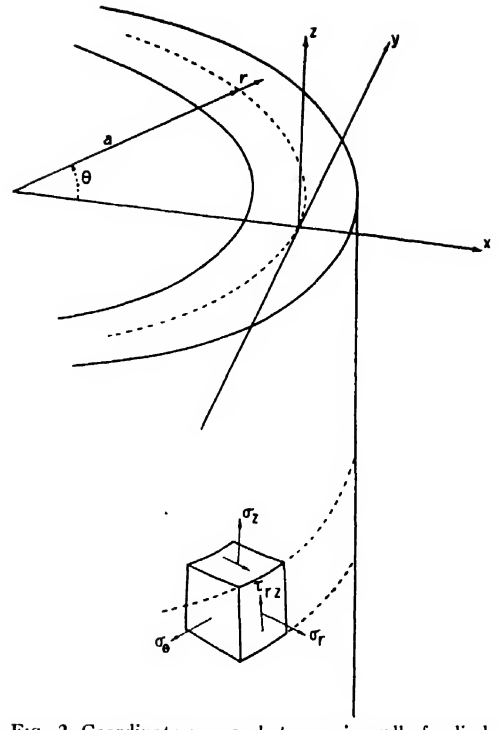

FIG. 2. Coordinate axes and stresses in wall of cylinder. Light rays are parallel to y axis.

cylinder perpendicular to the axis and a typical element of volume cut out of the tube wall. The tube is in a field of parallel rays and is surrounded by a liquid medium having the same index of refraction as the glass of the tube wall so that the light rays are not refracted on entry and exit. We designate a as the radius of the middle surface of the shell and h as the half-thickness. As before we take the y axis parallel to the light rays so that the xz plane is parallel to the wave front. We shall also use a cylindrical coordinate system constructed in the usual way with respect to the cylinder, except that the radial coordinate is measured from the middle surface of the shell.

The lower part of Fig. 3 shows the stress components in cylindrical coordinates. In shell theory the following assumptions are made regarding the stresses: the radial stress, σ_r, is identically zero, the circumferential stress, σ_θ, is constant, the axial stress, σ_z, is a linear function of r which vanishes on the middle surface, and the shearing stress τ_{rz} is a parabolic function vanishing on the inner and outer surfaces as required by the boundary conditions. The relations between the stresses σ_θ and τ_{rz} and the stresses σ_x and τ_{xz} in the plane of the wave front are

$$\tau_{xz}=\tau_{rz}\cos\theta$$
$$\sigma_x=\sigma_\theta\sin^2\theta.$$

Substituting into the formula for φ (Eq. (1))

$$\tan 2\varphi=\frac{2\tau_{rz}\cos\theta}{\sigma_\theta\sin^2\theta-\sigma_z}. \qquad (6)$$

[2] E. G. Coker and L. N. G. Filon, *Photo-Elasticity* (Cambridge University Press, London, 1931), p. 256.

[3] For the relation between Neumann's equations and Maxwell's electromagnetic equations see R. D. Mindlin and L. E. Goodman, "The optical equations of three-dimensional photoelasticity," J. App. Phys. 20, No. 1, 89–94 (January, 1949).

Since τ_{rz} must be zero on the inner and outer surfaces the angle φ between the polarizing axis of the faster moving wave and the x axis will be zero on exit and entry. Thus at the beginning and end of the path of a ray through the wall of a tube in an axially symmetrical state of stress the two polarizing axes are respectively along and perpendicular to the axis of the cylinder.

Inside the tube wall τ_{rz} will in general be non-vanishing and there will be some rotation of the secondary principal axes along the path of the ray. However, in the photoelastic study of stresses in electron tube bulbs we are interested only in the stresses at the point where failure is most likely to occur. Hence we wish to investigate the stress distribution where σ_z is a maximum and in particular to measure the maximum. Since glass is weak in tension, breakage will result from either excessive positive axial or circumferential stress. In the tubes considered here the axial stress was the critical

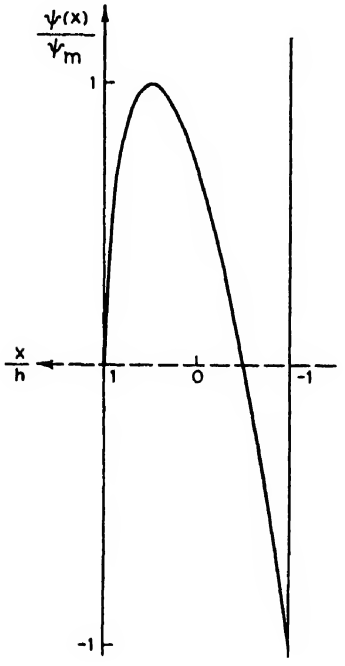

FIG. 3. Theoretical fringe pattern in bulb wall for symmetrical stress. Fringe displacement is proportional to phase difference.

one, as indicated by breakage results and by independent measurements of circumferential stress. The method of measuring σ_θ is described in Appendix II.

The axial stress is given by

$$\sigma_z=\sigma(r/h),$$

where σ is a function of z and is the maximum of σ_z for a given cross section. The absolute maximum of σ_z occurs where σ has its maximum value, and therefore where $d\sigma/dz=0$. Using this condition and the equation of equilibrium in the axial direction,[4]

$$\frac{\partial\sigma_z}{\partial z}+\frac{1}{r+a}\frac{\partial}{\partial r}(r+a)\tau_{rz}=0 \qquad (7)$$

[4] S. Timoshenko, *Theory of Elasticity* (McGraw-Hill Book Company, Inc., New York), p. 309. (Timoshenko's r is our $r+a$.)

we have $(r+a)\tau_{rz}=$constant. However, from the boundary conditions, τ_{rz} is zero at the inner and outer surfaces, so that $\tau_{rz}=0$ throughout the thickness of the wall, and from (6) $\varphi=0$ or $\pi/2$ over the cross section. We have now established the following useful result: in a cylindrical shell there is no rotation of the polarizing axes along the path of a ray lying in the cross section where the axial stress reaches its maximum value. Therefore Eq. (5) applies exactly and ω is constant and equal to the angle between the x axis and the plane of polarization of the incident light.

To discover the meaning of the observed retardation in terms of stress we use (5). In the cross section of maximum axial stress $\tau_{rz}=0$ so that (2) simplifies to

$$p-q=\sigma_x-\sigma_z=\sigma_\theta\sin^2\theta-\sigma_z.$$

Letting σ_m be the maximum value of σ_z we have

$$d\psi/dy=2\pi C/\lambda[(\sigma_m/h)r-\sigma_\theta\sin^2\theta]. \qquad (8)$$

To integrate this equation we express r and θ in terms of the variable y and the parameter x which is constant for a given ray and is equal to the minimum distance between the ray and the middle surface. When a is large compared to r and x we have the approximations:

$$y^2/2a=r-x \quad \sin\theta=y/a.$$

As the ray passes through the tube wall y varies between $-[2a(h-x)]^{\frac{1}{2}}$ and $+[2a(h-x)]^{\frac{1}{2}}$. Since the incident light is monochromatic and plane polarized there is a single λ and the phase difference on entry is zero. The phase difference on exit $\psi(x)$ is a function of the parameter x given by the integral of Eq. (8)

$$\frac{\psi(x)}{2\pi}=\frac{CL\sigma_m}{\sqrt{2}\lambda}\left[\frac{x}{h}+\frac{1}{3}\left(1-2\frac{\sigma_\theta}{\sigma_m}\frac{h}{a}\right)\left(1-\frac{x}{h}\right)\right][1-(x/h)]^{\frac{1}{2}},$$

where $L=2(4ah)^{\frac{1}{2}}=2[(\text{diameter})\times(\text{wall thickness})]^{\frac{1}{2}}$ is the length of the path of a ray tangent to the inner surface of the bulb.

In all of the tubes observed σ_θ was of the same order of magnitude as or less than σ_m, and in electron tubes $h\ll a$ so that we can neglect $2(\sigma_\theta/\sigma_m)(h/a)$ in comparison with unity. Then

$$\frac{\psi(x)}{2\pi}=\frac{CL\sigma_m}{3\sqrt{2}\lambda}\left(1+2\frac{x}{h}\right)[1-(x/h)]^{\frac{1}{2}}. \qquad (9)$$

We now have another useful result concerning cylindrical shells; namely, that in the cross section where the axial stress is a maximum the relative phase retardation depends on only the axial stress provided that the maximum axial stress is of the same order of magnitude as or greater than the circumferential stress. If σ_θ is much greater than σ_z the technique described in Appendix II should be used to measure σ_θ and the formula for σ_m connected accordingly.

Figure 3 is a plot of $[\psi(x)]/\psi_m$ as given by Eq. (9), where ψ_m is the maximum of $\psi(x)$.

Since we have assumed an axially symmetrical distribution of stress the first experiments to check the theory were made on a type of tube in which the fringe pattern remained constant as the tube was rotated about its axis. The phase difference in the cross section of maximum axial stress was measured using polarized light and a quartz wedge. Figure 4 (center fringe) shows the fringe pattern and tube wall focused in the same plane. The retardation caused by passage through the tube wall is proportional to the displacement of the fringe in the vertical direction, the distance between fringes corresponding to a retardation of 2π radians or one wave-length. Since the stress does not vary appreciably in the vertical direction in a distance equal to the maximum fringe displacement the fringe pattern itself is approximately a plot of the measured $\psi(x)$ *vs.* x.

Comparison of Figs. 3 and 4 shows that the theoretical curve of Fig. 3 derived from shell theory agrees very well with the pattern actually observed.

The formula for $\psi(x)$ Eq. (9) may be used to relate the measured maximum phase difference ψ_m to the maximum axial stress σ_m. Letting $\sigma_0=\lambda/CL$ be the stress which would produce a relative retardation of one wave-length, that is a phase difference of 2π radians, in the distance, L, traveled by the innermost ray of the tube wall, and letting $R_m=\psi_m/2\pi$ be the relative retardation in wave-lengths we have

$$\sigma_m=3\sigma_0 R_m. \tag{10}$$

If λ is expressed in angström units, L in millimeters and C in 10^{-2} brewsters than σ_0 and σ_m will be in kilograms per square millimeter.

III. ROTATION OF POLARIZING AXES — UNSYMMETRICAL STRESSES

We shall now consider in more detail the formation of the fringe pattern in Fig. 4. After emergence from the tube the originally plane polarized light is elliptically polarized. Since the f and s axes on exit are parallel to the z and x axes which in these experiments are vertical and horizontal respectively, the quartz wedge is oriented with its axes also vertical and horizontal. The relative retardation produced by the wedge varies linearly in the vertical direction so that for any value of x there is always a point on the wedge where the relative retardation caused by the tube $\psi(x)$ is equal and opposite to that caused by the wedge. At this point the light reaching the analyzer will be plane polarized at an angle $\omega(x)$ to the x axis. If the analyzer is set at an angle of $\omega(x)+(\pi/2)$ radians the light will be extinguished and the point will appear as a dark spot in the observed fringe pattern, the displacement of the point being proportional to $\psi(x)$. However this condition cannot be simultaneously satisfied for all x unless $\omega(x)$ is constant. For a variable $\omega(x)$ we would observe not a continuous fringe in the tube wall but an isolated dark spot which would move across the thickness of the tube wall as the analyzer was rotated.

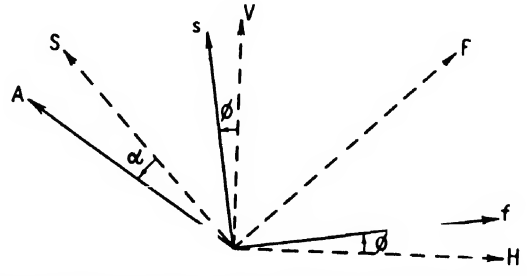

FIG. 5. Optical axes of specimen, quarter wave plate and analyzer.

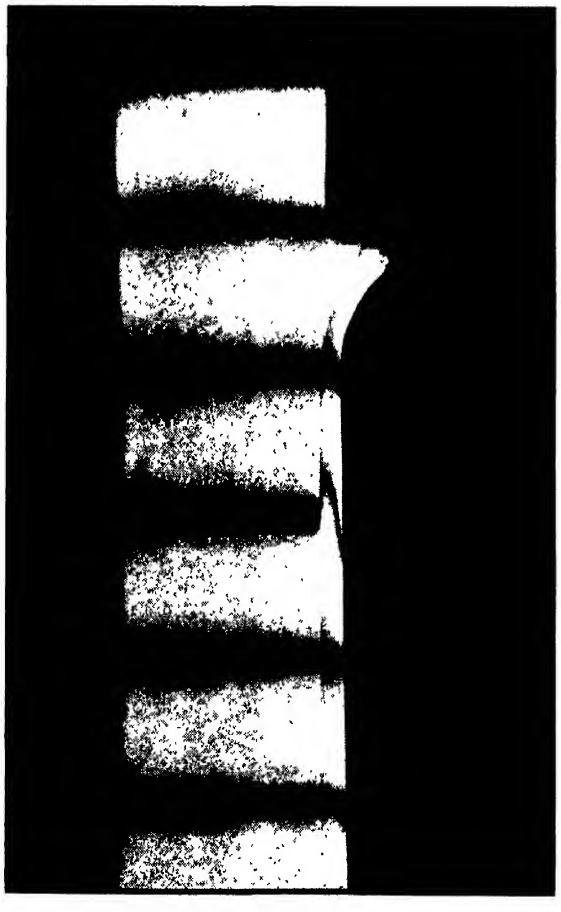

FIG. 4. Actual fringe pattern in bulb wall for symmetrical stress.

The theory of cylindrical shells predicts that where the axial stress is a maximum $\omega(x)$ will be constant and there we would expect to observe a continuous fringe. Actually, however, continuous fringes could be observed at every cross section indicating that throughout the bulb the deviation of ω from the initial value of $\pi/4$ radians is small enough to remain within the band largely extinguished by the analyzer. Rotating the analyzer obscured rather than improved the fringe pattern as a whole. Also the intensity at any point on the fringe was increased by rotating the analyzer by more than $\pm 5°$, indicating that the variation in ω is

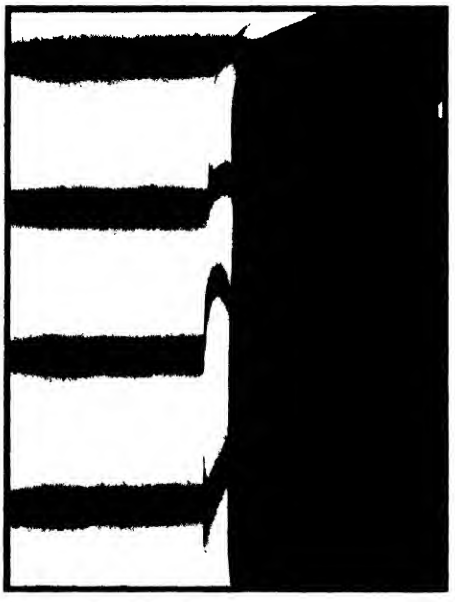

FIG. 6. Fringe pattern in wall of unsymmetrically stressed bulb. Maximum fringe displacement indicates maximum stress.

within these limits. From Eq. (3) the small variation in ω implies that the rotation of the polarizing axes is small which in turn implies that the shearing stress τ_{rz} is small compared with the axial stress σ_z. Thus the results obtained for the cross section of maximum axial stress apply approximately to every cross section and the phase difference at every level may be regarded as a function of the axial stress.

Where the stress distribution is not axially symmetrical the problem is considerably more complicated and we have the stress components $\tau_{r\theta}$ and $\tau_{\theta z}$ in addition to those shown in Fig. 2. However, even in a type of tube in which the stress distribution arose from local thermal effects and varied rapidly and erratically in both the axial and circumferential directions, continuous fringes could be observed at every level with the quartz wedge and cross polaroids. Again rotating the analyzer obscured the fringes. Thus even for this extreme case it was possible to neglect the effects of the shearing stresses and regard the observed retardation as a function of axial stress.

In the general case the maximum tension σ_m is related to the maximum relative phase retardation R_m by $\sigma_m = W\sigma_0 R_m$, where σ_0 is defined as in the preceding section and W is a dimensionless weighting factor depending on the form of the fringe pattern, that is on the variation of ψ on exit with x. As we have seen (Eq. (10)) the stress distribution assumed in shell theory gives $W=3$. The minimum value of W is unity and occurs when the axial stress is constant over the cross section. If we make the approximation that over the path of a ray in the bulb wall the stress depends only on r we can calculate the fringe patterns corresponding to different simple variations of σ_z with r. Comparing the calculated patterns with those observed we determine the range of variation of W and its dependence on obvious features of the fringe pattern. In the tubes tested at the Bell Laboratories W was found to vary from 1 to 3 and to depend mostly on the position of the observed maximum phase difference between the outer and inner surfaces of the bulb wall. For routine testing W was taken as 3 when the maximum was observed in the outer part of the bulb wall, as in Fig. 4, and as 2 for a maximum appearing in the center or inner half of the wall, as in Figs. 6 and 7. If the fringe displacement had no maximum but increased monatonically from the outer to inner surface of the wall as in Fig. 6 (bottom fringe) then W could safely be taken as unity.

Although the quartz wedge gives the most information for experimental studies, we shall see in the following section that the most practical routine method of identifying overstressed bulbs involves the use of a quarter wave plate or de Sénarment compensator. The quarter wave plate is first oriented to give minimum intensity with crossed polaroids at 45° to the vertical. The tube is then inserted with axis vertical between the polarizer and quarter wave plate and the analyzer rotated to give minimum intensity at a specified point. If $\varphi=0$ and $\omega=\pi/4$ on exit from the tube the rotation of the analyzer in radians will be equal to one-half the phase difference for the corresponding ray. By this method it is possible to obtain measurements of phase difference accurate to a few degrees. Since the deviations in ω and φ are also of the order of a few degrees it is interesting to ask whether the deviations in ω and φ are augmented or diminished in their effect on the accuracy of the measurement of phase difference.

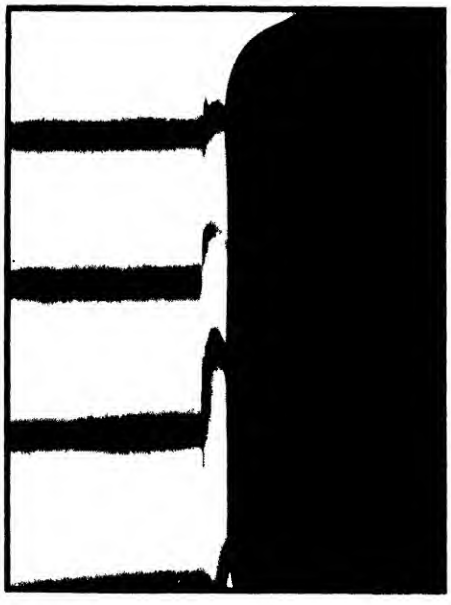

FIG. 7. Same as Fig. 6 except quartz wedge is raised to show fringes at different levels.

First we shall consider the case where $\varphi=0$ on exit and investigate the effect of taking $\omega\neq\pi/4$.

In Fig. 5 F and S are the fast and slow polarizing axes of the quarter wave plate which for $\varphi=0$ are at 45° to the f and s axes on exit. If α is the angle between the axis of the analyzer A and the S axis then it follows from simple trigonometry that the intensity of the light transmitted by the analyzer is proportional to

$$1-\cos 2[\omega-(\pi/4)]\cos(2\alpha-\psi).$$

If $\omega=\pi/4$, the light is extinguished when $2\alpha=\psi$. If $\omega\neq\pi/4$ it is impossible to obtain extinction. However, we do not set for absolute extinction but for minimum intensity which for low intensities is indistinguishable by eye from absolute extinction. It is evident from the above formula that the intensity of the light observed through the analyzer will always be a minimum when $\alpha=\frac{1}{2}\psi$ independently of the value of ω. We thus have the result that if the quarter wave plate is oriented

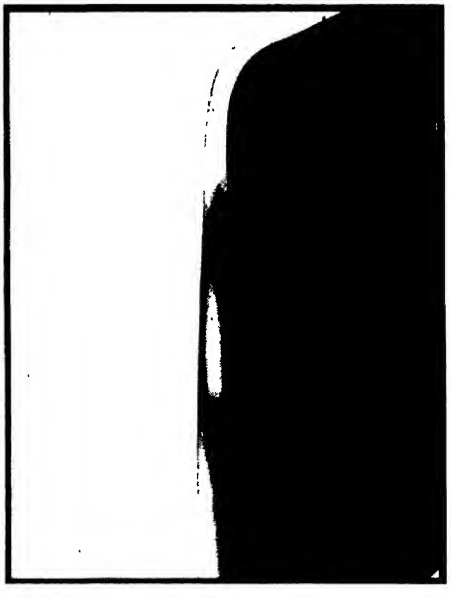

FIG. 8. Fringe pattern with quarter wave plate. Ring in bulb wall encloses region of critical stress.

with its axes at 45° to the polarizing axes of the tube on exit then the formula $\psi=2\alpha$ will be correct independently of the rotation of the polarizing axes along the path of the ray inside the tube wall.

Now consider the case where φ is not zero on exit. If we denote by ψ' the difference in phase between the H and V components we have from the preceding result that $\psi'=2\alpha$ for minimum intensity. That is, the de Sénarment compensator correctly measures the difference in phase between the H and V components. The error in the measurement of ψ is therefore $\psi'-\psi=2\alpha-\psi$. After considerable trigonometric manipulation we derive for the first-order term in $\psi'-\psi$

$$\psi'-\psi=2\sin\psi\sin\varphi\frac{\sin(\varphi+2\omega-\pi/2)}{\cos 2(\varphi+\omega-\pi/4)}$$

or neglecting second-order terms in φ and $\omega-\pi/4$ in comparison with unity we have for the upper limit of the absolute error

$$|\psi'-\psi|\leq|2\varphi^2+4\varphi(\omega-\pi/4)|.$$

Thus the error in the measurement of relative phase retardation is of second order in the deviations in ω and φ on exit and may therefore be considered negligible.

IV. TECHNIQUE OF MEASUREMENT

The de Sénarment compensator or quarter wave plate is free from a serious limitation of the quartz wedge, which gives fringes at only three or four levels in the tube wall. With the rapid and erratic variation of stress in the axial direction there is a high probability that maxima may fall between the fringes and consequently not be recorded. The de Sénarment compensator not only covers the whole extent of the tube in the axial direction but also provides the basis for a simple and practical technique for routine testing.

We have seen that when the analyzer is set at an angle α (to the S axis of the quarter wave plate—Fig. 5) a dark spot is observed in the resulting fringe pattern wherever the phase difference is 2α.

Consider the case where the analyzer is set so that 2α is equal to the maximum phase difference in the whole bulb. Then a single dark spot or fringe will be observed at the maximum and the rest of the bulb wall will

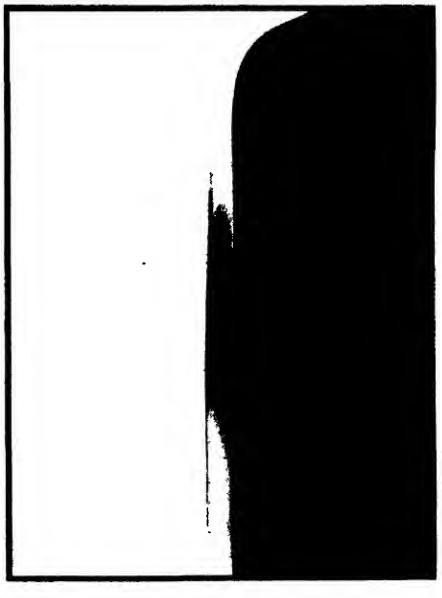

FIG. 9. Shrinking of ring about critically stressed region as analyzer is rotated.

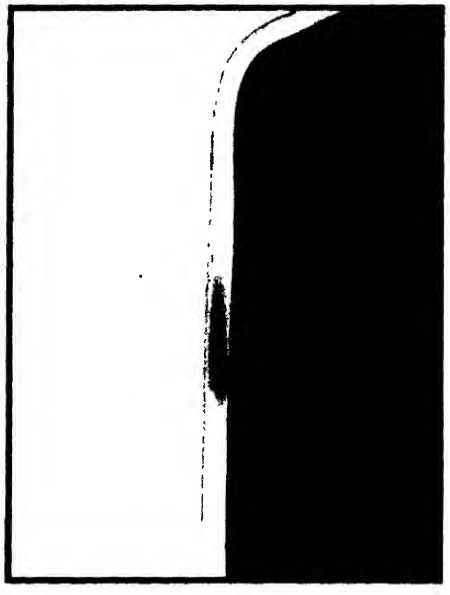

FIG. 10. Ring shrunk to single dark spot at level of maximum stress. Rotation of analyzer gives magnitude of maximum stress.

appear light as in Fig. 10. When the analyzer is set so that 2α is slightly less than the maximum phase difference the maximum will appear as a light spot enclosed by a closed dark fringe or ring on which the phase difference is 2α, Figs. 8 and 9. By rotating the analyzer so that α increases, the ring is caused to shrink to a single dark spot. The setting of the analyzer then gives the maximum phase difference.

Figures 6 and 7 are taken with a quartz wedge and illustrate a fringe pattern of typical form but somewhat larger than average amplitude. The maximum phase difference is seen to be approximately $\frac{2}{3}$ of a wavelength or $4\pi/3$ radians. This corresponds to a setting of $\alpha=120°$ for the de Sénarment compensator.

Figures 8 to 10 are taken with the de Sénarment compensator with $\alpha=60°$ in Fig. 8 $\alpha=85°$ in Fig. 9 and ending with the final setting of 120° in Fig. 10, which gives a single dark spot indicating a maximum phase retardation of 240° or $4\pi/3$ radians in agreement with the quartz wedge. The progressive shrinking of the dark ring can be clearly seen as the analyzer is rotated to approach the setting corresponding to the maximum retardation.

We now have established the following method for locating overstressed regions in the walls of glass bulbs with a de Sénarment compensator. When a limit on allowable stress has been set, the corresponding limit on phase difference is calculated (from σ_0) for the outer part of the tube wall where the weighting factor is 3. With the analyzer set for this phase difference the bulb is rotated once around its axis and the fringe pattern observed. If a dark ring appears in the outer part of the wall then the tube is rejected since the ring must enclose a maximum phase difference corresponding to a tensile stress above the allowable limit. If a dark ring appears in the center or the inside of the center of the tube wall, where the weighting factor is 2, then the analyzer setting is increased by a factor of $\frac{3}{2}$. If this causes the dark ring to shrink to a point and disappear then the tube is safe, but if a light spot still remains in the shrunken ring then the tube is rejected.

This procedure has been found to be practical for routine testing of tubes in quantity and is now in use at the Bell Telephone Laboratories at Allentown, Pennsylvania.

The experimental work involved in this investigation was carried out jointly by the author and Mr. J. E. Clark of the Electronic Apparatus Development Department of the Bell Laboratories. The photographs shown in Figs. 6 to 10 were made by R. D. Mindlin.

APPENDIX I

We shall now consider the case where both $d\varphi/dy$ and $p-q$ in Eq. (3) are constant. The exact solution for this case has been obtained by D. C. Drucker and R. D. Mindlin[5] using a dynamical theory of light.

We wish to study the dependence of the relative phase retardation ψ on the magnitude of R and the direction of polarization of the incident light. For this purpose we shall use Eqs. (12)

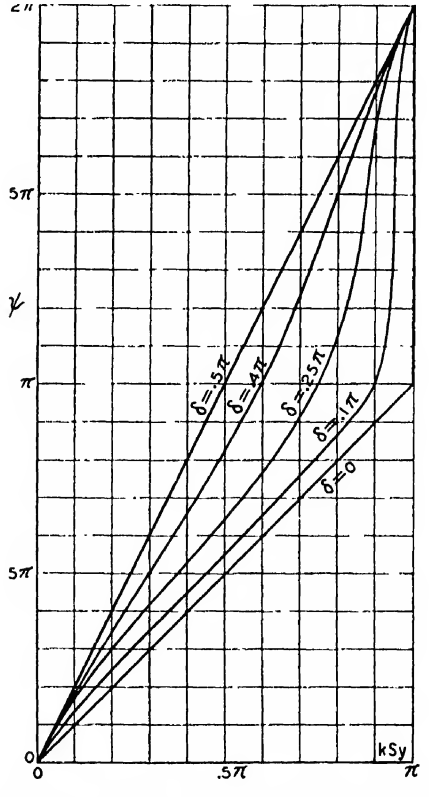

FIG. 11. Variation of phase difference with distance for several simple cases of constant principal stress difference.

[5] D. C. Drucker and R. D. Mindlin, "Stress analysis by three-dimensional photoelastic methods," J. App. Phys. 11, 724 (November, 1940).

of Drucker and Mindlin. These equations were obtained by Drucker and Mindlin upon inserting the assumption of weak birefringence in their exact solution. It can be shown that the identical formulas can be obtained by a direct solution of Neumann's equations. From these equations the difference in phase of the two waves (our ψ) is related to the distance along the path of the ray (our y) by

$$\tan\psi = \frac{\tan 2kSy}{S}\left[\frac{\tan\delta+\tan kSy}{\tan\delta+\tan 2kSy}\right], \tag{11}$$

where

$$k=\pi C/\lambda(p-q)$$
$$S=(1+R^2)^{\frac{1}{2}}$$
$$\tan\delta=\frac{S}{R\cot 2\omega_0}$$

and ω_0 is the angle between the direction of polarization of the incident light and the f axis on entry. Here we shall consider that $R^2\ll 1$ so that we may take $S=1$.

When the incident light is plane polarized at 45° to the f axis on entry, $R\cot 2\omega_0=0$ as in the simple two-dimensional case (Eq. (3)). However, as the direction of polarization of the incident light approaches the direction of one of the secondary principal axes on entry, then $\cot 2\omega_0$ becomes infinitely large, and since there is always some rotation of the secondary axes, δ approaches 0. In this case the slope of the ψ *vs.* kSy curve approaches infinity in the range $\pi\leqq\psi\leqq 2\pi$ while in the range $0\leqq\psi\leqq\pi$ the average slope is just one-half the average slope in the previous case. Figure 11 shows plots of ψ *vs.* kSy for several values of the parameter δ. In each case we take $S=1$.

Thus in this simple example where $p-q$ and R are constant and $R^2\ll 1$ the simple two-dimensional formula gives accurate results for the relative phase retardation when the incident light is polarized at 45° to the secondary principal axes on entry. However, when the direction of polarization of the incident light coincides with one of the secondary principal axes then the simple two-dimensional formula gives values of ψ which may be in error by a factor of 2.

If $S\neq 1$ then the form of the curves in Fig. 11 will be altered somewhat but the curves will still cut the lines $\psi=0$, $\psi=\pi/2$, $\psi=\pi$, $\psi=3\pi/2$, and $\psi=2\pi$ at the same values of kSy.

It should be noted that the points of equal phase will occur at intervals of π/kS independently of the direction of polarization of the incident light. If $p-q$ is calculated from measurements of the distances between points where the light is plane polarized (as in Weller's method) then the simple two-dimensional formula is correct within a factor of S (see reference 5, p. 729).

APPENDIX II

Measurement of Circumferential Stress

In this section we shall describe the method of measuring σ_θ. This method was suggested by R. D. Mindlin.

For this measurement the tube was oriented with its axis vertical, as before, but was not immersed in the liquid. Fig. 12 shows part of the tube wall bounded by sections of the outer surface A and the inner surface B. The two sets of reflected rays have approximately the same intensity since each represents the result of one reflection, and little energy is lost on refraction.

From the laws of geometrical optics it follows that the two

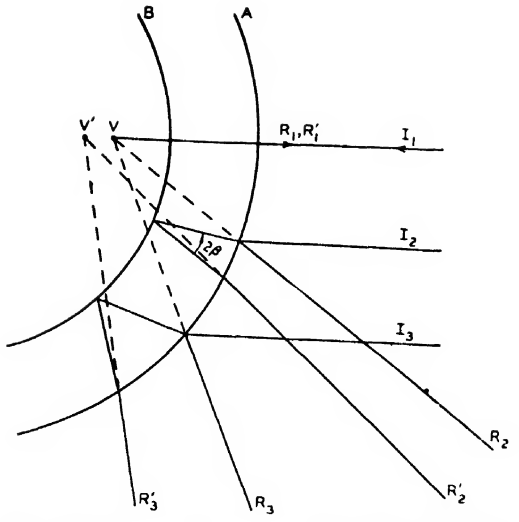

FIG. 12. Technique of measuring circumferential stress.

virtual sources V and V' are separated by a distance of $1/2n$ times the thickness of the wall where n is the index of refraction, that is the inner and outer surfaces of the tube are effectively cylindrical mirrors and the two virtual sources appear as lines parallel to the axis of the tube.

The light reflected from the outer surface of the tube remains plane polarized. However, the light reflected from the inner surface of the tube has twice passed through the tube wall and has been resolved into components which emerge out of phase.

The angle of incidence and index of refraction determine the angle β between the rays traveling inside the tube wall and the radial direction. The secondary principal stress difference in the plane of the wave front is therefore $\sigma_\theta\cos^2\beta-\sigma_z$. This gives for the phase difference ψ

$$\psi/2\pi=2\int_{-h}^{h}\frac{C}{\lambda}(\sigma_\theta\cos^2\beta-\sigma_z)\frac{dr}{\cos\beta}.$$

Since σ_z is an odd function of r it disappears in the integration and we have for the constant circumferential stress σ_θ

$$\sigma_\theta=\frac{\lambda}{4hC\cos\beta}\frac{\psi}{2\pi},$$

where as before h is the half-thickness of the tube wall. The phase difference can be measured with a quarter wave plate and analyzer inserted in the path of the reflected rays. This technique may be used for routine testing of tubes in quantity since it is only necessary to set the analyzer for the retardation corresponding to the critical circumferential stress, rotate the tube once around its axis and observe whether the virtual line source is extinguished at any point.

However, this technique cannot be used to measure the circumferential stress in any tube where the average axial stress over the thickness is not zero. However, by this technique it was shown that there was no rotation of the polarizing axes in the plane of the wave front thus indicating that the shearing stress $\tau_{\theta z}$ is negligible.

Letters to the Editor

Note on the Frictionless Bearing for Small Angular Deflections

J. A. Haringx
Philips Research Laboratories, Eindhoven, Netherlands
October 21, 1949

In the paper by Helmut Schlitt,[1] I found an interesting description of a new type of bearing for small angular deflections consisting of two concentric rings connected to each other by three radial flat springs. By choosing the radii of the rings to be equal and omitting one of the springs we obtain a construction that is known as a cross-spring pivot. In a recent paper,[2] I published the results of a calculation in respect to this constructional element and emphasized the remarkable phenomenon of its maximum rigidity for definite values of the compressive forces exerted upon the flat springs. In the paper by Schlitt I missed the occurrence of such a maximum.

In Figs. 3 and 4 of the paper[1] the curves near the vertical coordinate axis both point upward. This result is to be doubted for the following reasons. Although the separate treatment of the flat springs for tensile and compressive loads is necessary owing to the different mathematical expressions used (the hyperbolic functions change into the cyclic functions), the transition from the tensile to the compressive force is actually a gradual one, as will be evident from a physical point of view. Thus, when drawn in one single graph where the two opposite meanings of the axial load P_s are taken into account, the curves of the two separate figures for tensile and compressive loads must gradually pass into each other. Apart from the difference in the ordinates for $P_s=0$ caused by the differently chosen values of R_1/R_2, the curves may not show the sharp peak arising here.

For the case that R_1 and R_2 are equal the actual relation between the bending moment about the center and the axial force may be taken from my paper. The graph in question is here reproduced (Fig. 1); M_1 stands for M_0 and N for P_s or $-P_s$, while the other notations are the same as in Schlitt's paper. As mentioned, the rigidity M_1/φ has a maximum, at $N\approx 2\pi^2EI/L^2$. Further, in accordance with Schlitt's statement, it is seen that the rigidity can be reduced to zero by a tensile force as well as by a compressive force. The latter force is however much larger than presumed by Schlitt, namely about 80 percent of the buckling load of the spring, which for clamped ends is equal to $4\pi^2EI/L^2$. The success of the actual application of this property will therefore be questionable.

On closer examination of the calculation given it is found that some signs in Eqs. (15), (16) and (17) are mistaken and that R_1 and R_2 must be replaced by $-R_1$ and $-R_2$ respectively. Further, the right-hand member of Eq. (18) must be put equal to $-\tan(L/\lambda)$ instead of to $\tan(L/\lambda)$. This explains the observed discrepancy.

Reply to J. A. Haringx

Helmut Schlitt
Fort Bliss, Texas
October 21, 1949

I am very thankful to Mr. Haringx for calling my attention to a discrepancy between our investigations. Concerning the physical side of the problem, I entirely agree with his considerations. There must be a gradual transition between the torque curves plotted in Figs. 3 and 4 of my paper as far as they represent bearings of equal design. Since these curves refer to different design datas of a bearing (different value of R_1/R_2), I expected the maximum of the curve to be always on the opposite side of P_s/P_{s0}. Actually there was a sign mistaken in my calculations of the compression bearing. Correcting this mistake my formulas show the changes stated by Haringx. The revised Eq. (18) yields then for the first solution for L/λ the value 5.59 corresponding exactly to the one taken from his graph.

This higher value for L/λ causes a correction of the design figures for the suggested bearing combination which is supposed to be independent of temperature. Nevertheless it seems possible to me to achieve the desired features. The fact that the compression force for zero torque of the compression bearing is rather close to the buckling load seems to me of minor importance as long as there are used three springs for each bearing. For such a design obviously no buckling can occur since the position of the two rings with respect to each other is invariably fixed.

Comments on Creep and Damping Properties of Polystyrene

William N Findley
College of Engineering, University of Illinois, Urbana, Illinois
November 1, 1949

In a recent paper,[1] Sauer, Marin, and Hsiao presented data on creep and damping capacity of polystyrene together with speculations on a correlation between damping and creep rate.

Interpretation of Creep Data: It may be of interest to consider another interpretation than the power equation used by the authors. An examination of the data given in the authors' Fig. 6[2] disclosed that the data might be represented about equally well by an exponential equation since the data formed nearly a straight line on a plot of log creep rate *vs.* stress. Because the exponential function is a good approximation of the hyperbolic sine function for relatively large values of the stress the latter function was suggested. The equation

$$v=0.26\sinh(\sigma/540) \qquad (1)$$

was found to represent the authors' data fairly well. This fact is of particular interest since there is a theoretical basis for expecting a hyperbolic sine relation which is to be found in studies of the activation process.[3]

In connection with these speculations it may be of interest to consider the creep rate data obtained by the writer[4] for tension creep tests at the same temperature and humidity used by the authors (see Fig. 1). These data were obtained from tests of a polystyrene made by the same manufacturer and having the same molecular weight of about 68,000 (Staudinger).

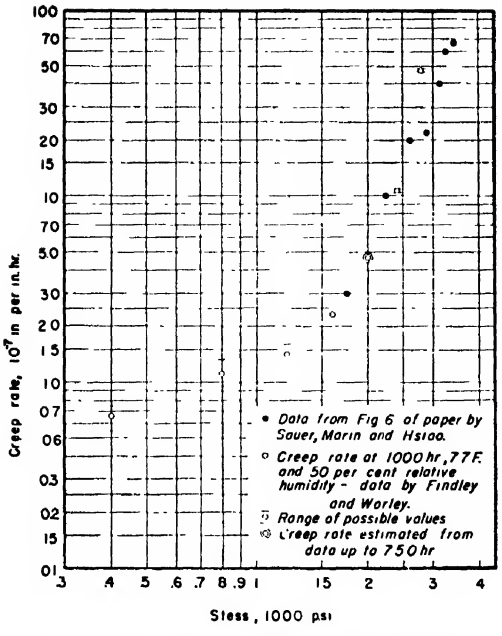

FIG. 1. Creep rate vs. stress for polystyrene in tension.

In Fig. 1 the data obtained by the authors as well as that obtained by the writer, are shown plotted on logarithmic coordinates. It is evident that the agreement is reasonably good over the interval of stress values covered in common by both tests. It is also apparent that the data obtained by the writer at the lower stresses indicate that the relationship between creep rate and stress was not a power function for the writer's tests, since the data form a curve rather than a straight line in Fig. 1.

The data obtained by the writer were represented more accurately by a hyperbolic sine function than a power equation. If the writer's datum at the largest stress is neglected, the remaining creep rates fit Eq. (1) within about $\pm 0.4\times10^{-7}$ in. per in. hr.

Interpretation of Dynamic Measurements: In view of the small scatter in the test data for damping presented by the authors, it seems appropriate to examine further the implications of these results as related to the test method and method of analysis employed, even though the method and analysis have been widely used to study the dynamic properties of many materials.

The equations used by these investigators were derived from the motion and forces present in resonant vibration of a single-degree-of-freedom system consisting of masses, linear spring, viscous damping and sinusoidal excitation. The differential equation for such a system is of the form[5]

$$M\ddot{x}+c\dot{x}+kx=F\sin\omega t, \tag{2}$$

where x, $\dot{x}$, and $\ddot{x}$ are the displacement, velocity, and acceleration respectively, M is the mass, c is the viscous damping coefficient, k is the stiffness of the spring, and $F\sin\omega t$ is the sinusoidal forcing function.

From the solution of Eq. (2) it is possible to calculate the energy dissipated per cycle, W_D, by the viscous damping.[6] The relationship obtained is

$$W_D=\pi c a^2\omega, \tag{3}$$

where a is the amplitude of vibration. For the mechanical system described above this dissipated energy is equal to the work done per cycle by the disturbing force F, as calculated by the authors, providing energy lost to the surroundings was negligible.

Equation (3) indicates that the energy dissipated per cycle by the damping is proportional to the square of the amplitude of the motion. If the stress, σ, in the specimen is understood to be defined in terms of the spring force alone and the spring force is linear as required in this solution, then the stress is proportional to the amplitude so that Eq. (3) becomes

$$W_D=C\sigma^2\omega, \tag{4}$$

where C includes the viscous damping constant and the dimensions and stiffness of the specimen.

That the tests reported by the authors showed the work done per cycle by the disturbing force (oscillator) to be proportional to the 2.3 power of stress may indicate that polystyrene behaves as a viscous material for damping. The fact that the 2.3 power was found instead of the 2.0 power may be a manifestation of the use of an equation for a system with a single viscous element, Eq. (2), to represent the behavior of a viscous material having a distribution of viscosities or relaxation times such as polystyrene is considered to have.

On the other hand it seems equally possible to the writer that the 2.3 power may result from some part of the mechanical equipment used by the authors not performing in accordance with the linear relationship required by the procedure used to calculate the damping capacity.

Further evidence that the test equipment may not function in the linear manner described by Eq. (2) are found in the facts that: (a) the so-called dynamic modulus calculated from the vibration test (5.3×10^6 p.s.i.) differs from the static modulus (4.5×10^6 p.s.i.) and in the opposite direction from that reported by previous investigators[7] using the same apparatus in tests of other plastics; (b) the dynamic modulus changed with stress. Neither of these conditions is in accord with Eq. (2) which requires the dynamic modulus to be constant and equal the static modulus.

Some of the possible sources of this disagreement may be: (A) the stiffness of the specimen changes with displacement; (B) the stiffness of the specimen changes with strain rate (or frequency); (C) the oscillator may not provide the required pure sine wave of disturbing force; (D) the damping in the specimen may not be viscous; and (E) there may be energy dissipated in non-linear friction in the grips or other connections. It is possible that the modulus increased *slightly* with increase in strain rate if the increase overlapped a portion of the spectrum of relaxation times for the material. But it seems more likely that the damping was not viscous.

An extensive study of the possible sources of extraneous energy dissipation in one type of damping testing machine has recently been reported.[8] These investigators found external losses of energy amounted to as much as 500 times the intrinsic energy dissipation of aluminum alloy specimens.

The following equation which has been considered for damping in structures[9] might prove to be more suitable in the present instance than the viscous equation for representing hysteresis damping:

$$M\ddot{x}+k(\cos b_1+i\sin b_1)x=Fe^{i\omega t}. \tag{5}$$

The damping in this equation, called complex damping, is represented in the equation by the phase angle of lag b_1.

A study of the solution of this equation shows that the damping capacity (energy absorbed per unit volume per cycle for a uniform rod vibration axially) is proportional to $\sin b_1$, the square of the stress, inversely proportional to the elastic modulus and independent of the frequency. The last three of these relationships are in accord with much of the reported data on damping capacity in materials: (A) Kimball and Lovell[10] found the damping capacity to be proportional to the square of the stress for a number of different materials. (B) They also gave rather conclusive evidence that the damping capacity is independent of frequency (or velocity). (C) The data on damping capacity reported in the literature indicates that in general materials with the highest elastic moduli have the lowest damping capacity and vice versa.

A comparison of the damping capacity described for complex damping with that predicted for viscous damping shows that the viscous damping capacity calculated from Eq. (3)

cannot be expressed (in terms of energy per unit volume) as a function of stress and factors which are properties of the unit volume of the material alone. Other quantities which depend on the particular configuration, such as the mass of the vibrating body and dimensions of the specimen tested, cannot be eliminated from the expression. Also the viscous damping capacity is not a function of the modulus of elasticity and is a function of frequency —the reverse of the relationship for complex damping.

Correlation of Damping Capacity and Creep Rate: It seems likely that damping and creep (also fatigue) are different responses to the same action at the atomic or molecular level of action in a material. Thus it would be likely that equations derived from the atomic or molecular behavior to describe these three different responses to mechanical loading would have at least one factor in common.

It would indeed be very useful if creep could be predicted from damping measurements. But to be dependable such predictions must be based on correspondence of fundamental behavior of the material under the two conditions.

The following observations may be of interest in trying to evaluate the correlation reported by the authors. For viscous behavior the damping capacity varies with the square of the stress and the creep rate varies with the first power of stress;[11] whereas the authors found a 2.3 power of stress for damping and 4.53 power of stress for creep rate.

The failure of the data for styrene to follow the same stress laws predicted for viscous behavior for both damping and creep does not seem too unreasonable in view of the differences in magnitude of strain and strain rate in the two phenomena. The behavior may result from quite different mechanisms, for example, rupture of secondary bonds between atoms in damping and movement during creep of groups of molecules of large molecular weight in a matrix of molecules of smaller molecular weight.

Dimensional considerations also suggest that the equations proposed by the authors are unlikely to be more than approximations of actual physical relations since a dimensional quantity raised to a variable or decimal power is dimensionally untenable.

On the Growth of Metallic Crystals from the Vapor Phase

GEORGE R. KEEPIN, JR.*
Massachusetts Institute of Technology, Cambridge, Massachusetts
November 7, 1949

GENERALLY speaking there are four methods of growing crystals: (1) from the melt; (2) from solution; (3) from metastable crystals in contact with the growing crystal in a continuous solid; and (4) from the vapor. Only the first three of these methods have been studied extensively. Recently, however, there has been increasing interest in the possibilities of the last method for growing large single crystals from certain metals and metal salts. Parameters affecting the growth of metallic crystals from their vapor phase are being studied in the hope that the results may indicate generally the conditions for growth of other metallic and metallic-halide crystals by this comparatively new technique.

TABLE I.

	Temperature of vapor gun source	Partial pressure of vapor source	Temperature of collecting surface	Pressure of nitrogen atmosphere
Cadmium	310–321°C	$\sim 10^{-1}$ mm	305±3°C	$10^{-3}-5\times10^{-3}$ mm
Zinc	409–419°C	$\sim 2\times10^{-1}$ mm	410±3°C	$10^{-3}-3\times10^{-3}$ mm

All crystallization processes may be subdivided into two main factors: the velocity of appearance of nuclei and the subsequent growth of these nuclei. The experimental conditions which have greatest effect on these two factors have been given by Sakui[1] as (1) density of vapor or temperature of vapor source, (2) temperature of collecting surface, and (3) pressure of atmosphere in which crystal growth occurs. These effects have been investigated in the case of metallic cadmium and zinc crystals grown from their vapor.

An internally heated molybdenum crucible containing the metal charge was used as a gun-type vapor source. Temperatures were measured at various points in the molybdenum gun and collector plate by copper-constantin thermocouples. The entire assembly was contained within an evacuated ten-inch bell jar. All work was done in an atmosphere of oil-pumped (dry) nitrogen which was freed of oxygen by passage through fine copper mesh at 375°C. In order to obtain the required degree of purity in the charge it was found necessary to use the spectroscopically pure metal which was then further purified by a multiple distillation procedure similar to that used by Overhage[8] in the purification of sodium metal. A silver collecting surface was found most satisfactory for cadmium while a copper or nickel surface proved best for the zinc runs. For convenience in taking data, observed crystalline forms were divided into eight categories ranging from a dense amorphous-like deposit to well-developed single crystals. Vapor gun temperatures were varied in five degree intervals from 30° below to 30° above the melting point of the metal under study. Nitrogen pressure was varied in appropriate steps from 10^{-5} to 760 mm. Collector plate temperature was increased in five degree intervals from room temperature to 10° above the melting point of each metal.

A predominance of dense amorphous-like deposit was found at low collector plate temperatures. This is to be expected since a metal vapor will condense (form growth nuclei) fastest where the difference between the vapor pressure of the solid phase and the supersaturated vapor is greatest. X-ray powder patterns of these amorphous-like deposits showed them to be microcrystals of mean diameter the order of 100A. Such studies indicated that no true amorphous deposits of either Cd or Zn were obtained in any of the work.

Conditions for the further growth of nuclei once they are formed are entirely different from those conditions necessary for their formation; thus the most perfectly developed single crystals were obtained at collector plate temperatures (T_{cp}) slightly below the respective melting points, *viz.*, optimum T_{cp} for Cd is 305±3°C and for Zn is 410±3°C. As T_{cp} is decreased from these optimum values, the amount of cadmium decreases steadily while the amount of zinc deposit, predominantly crystalline powder, was actually found to increase reaching a maximum at T_{cp}=350°C; thus we may say that the smaller zinc atoms possess a greater nuclei-forming ability than cadmium atoms in this temperature range. As T_{cp} is raised above its optimum value a rapidly diminishing yield of successively smaller crystals is obtained so that at five degrees above optimum T_{cp} values only traces of microcrystals are obtained in the case of either metal. These temperature effects are quite explicable: the mobility of atoms adsorbed by the growing crystal surface determines their rate of deposition in the crystal lattice. Accordingly, high T_{cp} means high mobility and high

rate of orientation of atoms within the lattice matrix. The potential energy of properly oriented atoms is a minimum and their chance of further migration is vanishingly small so they are effectively removed from the adsorption layer and may be replaced by new atoms arriving from the vapor gun. Orderly single crystal growth requires a dynamic balance between these two processes maintaining thereby a constant density of atoms in the adsorption layer.

For nitrogen pressures greater than 0.5 mm only traces of crystalline powder are obtained. As the pressure is decreased from 0.5 mm larger but imperfect crystalline deposits result until in the pressure interval 10^{-2} to 10^{-1} mm dendritic crystals are predominant at intermediate T_{cp} (250–350° for Cd and 200–350° for Zn). Finally, at optimum T_{cp} values well-developed hexagonal crystals were obtained in the pressure interval 10^{-2} to 5×10^{-2} mm for Cd and 10^{-2} to 3×10^{-2} for Zn. At lower pressures only small yields of dendritic, inhomogeneous crystals were found. These pressure effects become quite plausible when we recall that the surface temperature of a growing crystal is higher than that of the crystal interior due to heat of solidification and that the growth of the crystal is largely controlled by the rate of heat transfer from the growing surface. Since in a given volume cooling by convection depends critically on pressure we may expect to obtain the desired thermal equilibrium within the adsorption layer at some pressure which we here call optimum, i.e. on the crystal surface the rate of heat increase by solidification equals the rate of heat loss principally by convection.

In summary, optimum conditions have been found for the growth of large, single crystals of cadmium and zinc as shown in Table I.

Electromagnetic vibration of the collector plate at a proper frequency may represent a distinct improvement over the present method of employing thermal (random) agitation to aid atomic orientation in the growing crystal lattice. The study of other vapor crystallization processes using such a technique is contemplated.

The author is indebted to Professor D. C. Stockbarger for suggesting this problem. This research was supported in part by the Harshaw Chemical Company, Cleveland, Ohio.

Thermionic Emitting Properties of Thoria-Rhenium*

G. A. Espersen
Philips Laboratories, Inc., Irvington-on-Hudson, New York
December 12, 1949

SINTERED conducting type thoria emitters containing tungsten have been investigated by Fan.[1] Similar thoria emitters containing 250 mesh pure rhenium powder furnished by the University of Tennessee, Knoxville, Tennessee, have been studied by the writer.

Emitters consisting of 50 percent thoria—50 percent rhenium were fabricated into rods by extrusion, after which they were fired successively at 1500° C_b for 15 minutes in wet hydrogen and 2000° C_b for 15 minutes in dry hydrogen.

The emitter rods were assembled into guard ring type diodes using molybdenum anodes.

Thermionic emission data taken on a number of diodes indicated average values of $A=11.7$ amp/cm²/deg. K², $\phi=2.83$ ev for the Richardson equation.

It is interesting to note that the thermionic emission from thoria-rhenium at 1630°K is approximately 55 milliamperes while thoria-tungsten yields 0.2 milliampere/cm² at the same temperature. At 2040°K the emission for thoria-rhenium is 1.2 amp/cm² while thoria-tungsten is 0.88 amp/cm².

Activation of both the thoria-rhenium and thoria-tungsten emitters is effected by flashing them at 2400°K for approximately 30 seconds.

After 150 hours of life test at 2040°K the thoria-rhenium diodes indicated a smaller deposit of vaporized materials upon the walls of the glass bulb then the thoria-tungsten diodes.

Activation Energy for Copper Self-Diffusion

John H. Hollomon
General Electric Research Laboratories, Schenectady, New York
November 28, 1949

I HAVE read the paper by Dedrick and Gerds in the November, 1949, *Journal of Applied Physics*. From their data, plotted in their Fig. 5, they calculate 55,000 calories per gram mole—a heat of activation for self-diffusion in copper by taking the slope of the straight line they have drawn in that figure. A straight line through the points gives a heat of activation of approximately 40,000 calories per gram mole. This value is significantly smaller than any other previous experimental determinations obtained by widely accepted techniques.

Reply to "Activation Energy for Copper Self-Diffusion"

J. H. Dedrick and A. Gerds
Sylvania Electric Products, Bayside, Long Island, New York
December 19, 1949

THE authors appreciate the comment of Dr. J. H. Hollomon regarding the heat of activation for the self-diffusion of copper. It is true that if a line is drawn through all of the points in Fig. 5, the heat of activation is about 40,000 calories per gram mole as contrasted to the value of 55,000 calories per gram mole given in the paper. A recalculation by the authors shows the value to be 43,000 calories per gram mole. This is low, it is agreed, but close to the value of 46,800 calories per gram mole obtained by Raynor, Thomassen, and Rouse.[1]

However, the reason for drawing the line as shown in Fig. 5 was twofold. First, the interface radii obtained at 700°C were the smallest and, therefore, the least accurate, from the standpoint of measurement. Second, as Kuczynski[2] has pointed out, surface diffusion tends to become more effective at lower temperatures, which would effectively raise D_v. Therefore, the 700°C point was not weighted as heavily as the higher temperature points. The line as drawn thus represents the higher temperature data most rigidly.

Study of Crack Propagation Using High Speed Motion Pictures

Herbert I. Fusfeld and Josephine Carr Feder
Pitman-Dunn Laboratory, Frankford Arsenal, Philadelphia, Pennsylvania
November 30, 1949

HIGH speed motion pictures have been used to observe the process of deformation and rupture in metals at high strain rates. Preliminary studies of fracture were conducted by utilizing flat tensile specimens ½ in. wide and $\frac{1}{32}$ in. thick with grids photographically imprinted on a sensitized surface. A fixture to hold the specimens was placed in a crank press used in drawing metal sheet, and operated at a speed of 960 in./min. A Fastex camera

FIG. 1. Propagation of crack in aluminum strip under tension. Aluminum 75 SO, flat, 0.5 ×0.031 in. Time between frames = 102 μsec.

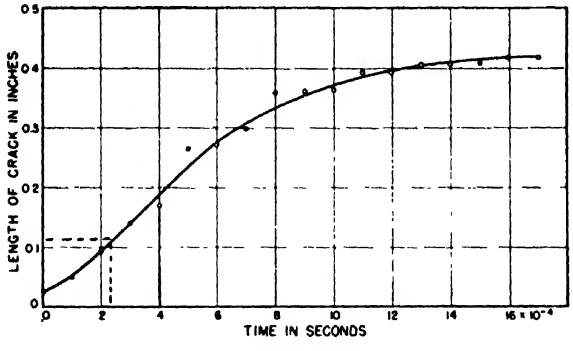

FIG. 2. Crack propagation as function of time.

was used to take motion pictures at a rate of 10,000 frames per sec.

Most of the aluminum and brass specimens tested broke along a line inclined at approximately 60° to the axis of the specimen. This break occurred too rapidly to be observed by the camera, i.e., in less than 10^{-4} sec. Thinning of the specimen along the line of fracture should be observed for approximately 5×10^{-4} sec. preceding the break.

Interesting observations have been made on the few specimens, three out of seventeen, which fractured along an irregular curve. The major portion of one such fracture is shown in Fig. 1 for aluminum 24 *ST*, showing a crack starting at the center and propagating to the edges. No noticeable thinning occurred prior to the appearance of the crack, indicating a more brittle behavior of the material than in the case where a straight line break occurs.

Measurements of the propagation of the crack are plotted in Fig. 2. The most interesting portion of the curve is at the start of propagation, as one can assume that the crack is in a uniform stress field and lines in the direction transverse to the axis of

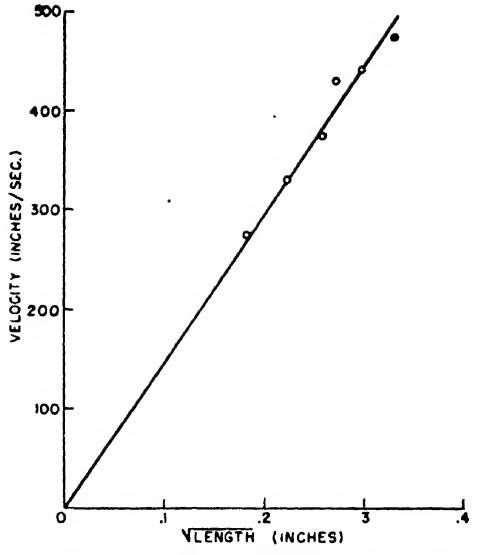

FIG. 3. Velocity of crack propagation *vs.* square root of crack length.

stress. Under these conditions, one can be guided by elasticity theory as applied to a narrow crack[1] to expect that the stress at the ends along the crack axis will increase as the crack length increases. It is therefore to be expected that the velocity of propagation would increase with the crack length, some data on which has appeared in the literature.[2]

To observe the dependence of velocity on crack length during the initial stages of propagation, the slope of the curve in Fig. 2 was measured at six points at which the ratio of crack length to specimen diameter varied from 0 to 0.64. The portion of the curve used is indicated on Fig. 2 within the dotted lines and the coordinate axes. Beyond this portion, the crack begins to extend in a direction away from that normal to the specimen axis, and the significance of "crack length" is uncertain.

A plot of velocity *vs.* length of crack on log-log paper gave a straight line with a slope of 0.47 computed on the principle of least squares. The same data is plotted in Fig. 3 as velocity *vs.* square root of crack length. A straight line through the origin provides a good fit. The slope computed by least squares is 1432 ± 26 in.$^{\frac{1}{2}}$/sec. It is therefore possible to represent the initial stages of crack propagation for the specimen of Fig. 1 by the expression:

$$v = k(s)^{\frac{1}{2}},$$

where v = velocity in in./sec.; k = slope in in.$^{\frac{1}{2}}$/sec.; s = crack length.

High Speed Digital Computers

An Elementary Survey of Present Developments and Future Trends

Louis N. Ridenour

University of Illinois, Urbana, Illinois

ONE of the most interesting, and possibly one of the most significant, of the post-war technical developments is the great effort that is currently being expended, both here and abroad, on the design, construction, and improvement of high speed automatic digital computing machines. In accordance with the present pattern of support for technical enterprises, the largest part of the effort on such computers is being financed by the federal government; private industry is investing substantial sums; and, somewhat curiously, the universities of the country do not appear to be supporting with their own resources more than a tiny fraction of the work.

Mechanical aids to computation are an old story, of course. But the high speed, automatic, digital, computer—when each of these qualifying adjectives is taken properly into account—is a very new development. Its practical realization cannot be said to have been achieved earlier than the completion of the celebrated ENIAC in 1945. Of this machine we shall have more to say later. Let us pause now to distinguish from other computing devices the type of machine that will occupy our attention here.

First of all, we shall deal with *digital* machines. This excludes a large class of calculating devices customarily lumped under the name of *analog* machines.[1] An analog machine is one which translates into some physical quantity each of the numbers entering a computation; that is, the physical quantity is the measure of the number. The analog machine then manipulates these physical quantities in accordance with the nature of the computation it is desired to carry out. Finally, the physical quantity resulting from such manipulation is measured—that is, turned back into a number—to obtain the numerical answer for the computation. A slide-rule is an analog machine. Numbers are represented, on the slide-rule, by lengths which are proportional to the logarithms of such numbers. To perform a multiplication, the lengths corresponding to the two factors are added, and the resulting total length corresponds to the product, being in fact proportional to the logarithm of the product. This total length is turned back into a number by means of the scales provided on the rule, and the calculation is finished.

A digital machine also uses physical representations for numbers, of course; but instead of using a single physical quantity as the *entire* representation of the number, and thus depending upon a highly accurate presentation, manipulation, and reproduction of the magnitude of this single physical quantity, a digital machine represents by a separate physical quantity each separate digit of a number. This permits a very much greater latitude in design for the digital machine; to handle numbers of ten digits, no part of a digital machine needs to be built with a precision of one part in 10^{10} An analog machine, on the other hand, has no better over-all accuracy than that conferred on it by the precision with which it is built.

Analog machines have been brought to a high stage of perfection and usefulness. Beginning about 1931, Vannevar Bush and his co-workers at M.I.T. developed the celebrated differential analyzer, which was a mechanical device in its first embodiment. During and since the war, electrical differential analyzers of various designs have been constructed, and some of

[1] For a description of analog computers and their uses, see D. R. Hartree, *Calculating Instruments and Machines* (University of Illinois Press, Urbana, 1949), Chapters 2, 3, and 4.

these machines are currently available on the commercial market. We shall not concern ourselves here, however, with such machines. We shall speak only of *digital* computers.

In fact, we shall speak only of *automatic* digital computers. The meaning of this qualification is that we shall not deal with digital machines of the sort represented by the familiar adding machine, or the Monroe or Marchant type of desk calculator. Such machines are very old in conception and in realization, of course.[2] The first practical adding machine based on the use of number wheels was devised by Blaise Pascal in 1642; a machine capable of multiplication (by repeated addition accompanied by suitable shifts) was designed by Leibnitz in 1671 and built in 1694. In 1820 Charles Thomas, a Frenchman, designed the first commercially successful machine; with minor modifications and improvements, this machine was being built in Paris right up to the Second World War.

We shall not even concern ourselves here with the familiar punched-card machines manufactured by the International Business Machines Company. These machines stem from the work of Herman Hollerith, an employee of the U. S. Census Bureau, who in 1889 conceived the idea of using, for entering numbers into a machine and for reading out the results, holes punched in a card. A similar scheme had long been used for controlling the weaving of complicated fabrics on the Jacquard loom, and its application to computing machines had been proposed two generations earlier by Charles Babbage, of whom we say more later.

Desk calculators and IBM machines are excluded from the present discussion because such a machine performs only one elementary computation at a time, and must be instructed anew before it can perform another. That is, we can enter on a desk machine the two factors entering a multiplication, and then rely on the machine to carry out the operation and display to us the product. But, before another multiplication—or indeed any other operation—is performed, we must ourselves inform the machine what numbers enter the new computation, and which operation is to be performed on these numbers.

In an automatic machine, on the other hand, sufficient instructions are given the machine at the beginning, and the machine has sufficient capabilities within itself, to permit the whole of a complicated sequence of manipulations on many numbers to be performed by the machine without human intervention, once the signal to start has been given. Thus an automatic machine is basically different from a desk calculator; it is more nearly a mechanized simulacrum of the whole complex: human computer plus desk machine plus tables of functions for reference plus work sheet on which the course of the computation is sketched out, and intermediate results can be recorded. The idea for such an automatic machine is more than a century old. Charles Babbage, who was Lucasian Professor of Mathematics at Cambridge, conceived such a device—the Analytical Engine—and began to build it (on British government money) in 1835.[3] The Analytical Engine was never completed, largely because the mechanical engineering of Babbage's day was not equal to the task of realizing his complicated designs, but its plan was astonishingly modern in terms of the ideas which still rule the automatic computer field today.

One more qualifier is left. We shall speak here of *high speed* automatic digital computers. Earlier than the ENIAC, at least two types of automatic digital computers were designed and built. Professor Howard Aiken, of Harvard, built with the help of the IBM Company his so-called Mark I machine which was an electrically controlled, mechanically operated, automatic computer that was hailed as "Babbage's dream come true."[4] About the same time, at Bell Telephone Laboratories, a machine was built which qualified as an automatic digital computer according to the present definitions, and used electromechanical relays as elementary computing and storage elements.[5] Both these machines were of limited speed because of their dependence on mechanical elements whose motion was necessarily slow in comparison with the actions in electrical circuits. In the ENIAC,[6] on the other hand, the operations within the machine are conducted entirely in terms of the circulation through electrical lines of electrical pulses, generated at a base rate of 100,000 per second, and in terms of the registration of the effects of such pulses by means of electronic "flip-flop" circuits which can rest stably in either of two stationary states, yet be transferred from one state to the other in a fraction of a microsecond by a pulse of the correct sign.

The time required in the ENIAC to add together two numbers, each of ten decimal digits, is 200 microseconds—200 millionths of a second. In terms of the times required by machines now under construction, this is long; addition times of about 10 microseconds are common in modern designs. But, in terms of the operation of machines having mechanical elements, this is very fast indeed.

In the remarks to follow, then, whenever the word "machine" is used, it will be understood to refer to a high speed automatic digital computing machine. Let us now turn to some general considerations on the overall design of such machines.

---

GENERAL REMARKS ON MACHINE DESIGN

While any given machine must be designed as a whole, it is often useful to distinguish as separate various parts of the machine which have various functions. The more important of such parts are:

First, the *arithmetic unit.* This device performs the individual arithmetical operations as required by the schedule of the computation being conducted. It is a very close electronic parallel to the familiar desk computing machine.

Second, the *inner* or *high speed memory unit.* This, which is presently the least satisfactory part of machines in existence or under design, is a device for registering numbers in a permanent way—either the numbers entering the problem or intermediate results—and keeping them accessible for use on demand as the computation proceeds. Any number in the memory must be available on demand in a very few microseconds. The memory is ordinarily so arranged that it can also store *orders,* which are instructions to the machine that govern the course of the computation.

Third, the *control unit.* This part of the machine is in charge of the whole operation. It keeps track of the calculation, determines which individual operation should be performed next, and causes its execution.

Finally, an *input-output unit.* This is necessary to enable the machine to communicate with its human masters. Through this unit, the machine is supplied initially with the data and instructions entering the problem; through this unit, the machine can also read out intermediate or final results. Often, the input-output unit is used to provide a large-capacity low speed storage (on magnetic wire or punched type) for numbers and orders. This outer memory supplements the inner memory, since the latter is seldom as capacious as one would desire.

When a mathematical problem is to be presented to such a machine, it must be programmed; that is, broken down into the individual steps to be performed successively. The numbers entering the problem must be supplied, and so must the *orders,* or instructions to the machine for handling those numbers. The input unit reads the program of numbers and orders into the memory unit of the machine at the beginning, and the work thereafter proceeds entirely within the machine.

A typical order might be translated: "Take the number in stored in memory location 1100 and multiply it by the number stored in memory location 2016. Put the product in memory location 1234 (erasing what stands there now) and then go to memory location 1161 for the next order." Orders are expressed in a code which gives them the appearance of numbers, so far as the machine is concerned. This has two advantages: each memory location can store either a number or an order, indifferently, and arithmetical operations can be performed on the pseudonumbers which are orders, thus changing one order into another when this is required as the computation progresses.

The example of an order just given calls for a multiplication. Similar orders govern addition, subtraction, multiplication, and sometimes certain other arithmetical operations. Another type of order, whose use greatly extends the scope of the machine, is the so-called "*conditional transfer*" order. This provides the machine with a sort of judgment, and enables the further course of a computation to be determined by the results to date, without the explicit intervention of a human operator. A typical conditional transfer order might say: "Compare the result of the last manipulation with the number stored in memory location 1648; if it is larger than that number, or equal to it, go to memory location 1174 for the next order; otherwise, go to memory location 1176 for the next order." Such decisions are a prominent feature of the control of a complicated calculation by a human computer using conventional methods.

Numbers are represented within the machine by groups of non-linear elements each of which has two stable states: on or off. For electronic machines of the present day, the non-linear elements are ordinarily the so-called "flip-flop" circuits derived from the multivibrator invented in 1919 by Eccles and Jordan.[7] Two tubes are so coupled, in a flip-flop circuit, that when one tube is conducting, the grid of the other tube is biased far beyond cut-off. If a signal is received in such a sense as to swing positive the grid of the cut-off tube, then the current in this tube rises and at the same time the grid of the other tube is driven negative. In a fraction of a microsecond, this action culminates in a stable situation in which the tube that was formerly cut off is carrying full current, while the grid of the tube that was formerly conducting is biased far beyond cut-off. Thus the system has two distinguishable stable states, and can by a pulse be transferred from one of these states to the other.

The flip-flop is not the only device which realizes practically this requirement of having two stable states which we may call on or off. We shall see later that there are other, and sometimes simpler and cheaper, ways of achieving this end. Indeed, it is in this direction that we can expect much of the short-term progress in computing-machine design to lie.

Since numbers are represented by a succession of elements which are either on or off, it seems natural to express numbers, for the purposes of the machine, in terms of the number system based on 2, rather than in the familiar decimal system based on 10. In the binary system—the base-2 system—each digit of a number has either the value 0 or 1, and the digits appearing in neighboring places with reference to the binary point (analogous to the decimal point in the base-10 system) differ in value by a factor 2, rather than by a factor 10

[7] W. H. Eccles and F. W. Jordan, Radio Review 1, 143 (1919).

as they do in the decimal system. Each number is then represented most economically, by a series of on-off elements, one for each digit of the number. The representation of decimal numbers in terms of on-off elements is somewhat less economical, since it requires the use, to represent each digit, of a collection of on-off elements so arranged that the collection has ten distinguishable stable states. These ten states are then used to represent the values, from 0 to 9, which the digit can assume.

Most of the machines presently under construction use the binary system for internal purposes; this necessitates a transformation of numbers from decimal representation to binary representation at the start and the end of each calculation, but the machine itself can perform this transformation, and the time required for this conversion is small in comparison to the time needed for the internal manipulations of numbers by a machine during the solution of a problem.

There is one other argument for the use of the binary system. Binary arithmetic is the arithmetic of logic, in a universe where a proposition is either true (one) or false (zero). The machine can, then, if it uses the binary representation of numbers, conduct its logical operations in the same formal terms as are used for its arithmetical manipulations.

Let us now pause for a moment to discuss what is called "balance" in the design of a computing machine. This term refers to the simple idea that the most efficient operation will be achieved when the times required to perform the various operations conducted by the machines are related to one another in a reasonable way. To take an absurd example, the requirement that the machine be able to perform whole sequences of computations automatically arises from its internal speed. There would be no sense in performing an addition in 200 microseconds (as the ENIAC does) or in 10 microseconds (as some of the new machines will do), if a slow-moving human operator had, at each stage, to copy off the result and then to enter the next two numbers to be summed.

At a more sophisticated level, we must consider the balance of operating times within the machine. This requires a careful weighing of the relative times required for access to the high speed memory, for addition, for transfer of a number from one place to another in the machine, and for the repeated operations involved in multiplication and division. To a certain extent, decisions on the balance of internal operating times will be made on the basis of the type of problem for which the machine will mainly be used; thus, for example, a machine whose main task was to be addition or comparison of numbers would desirably have a different internal balance of operating times from that appropriate to a machine intended for processes involving many multiplications. But the balance of a general-purpose computing machine can also be specified, and attention to this design consideration is important.

It has already been stated that numbers are ordinarily expressed in the machine in terms of their binary representation. There are two quite different ways of handling such numbers, both of which are in use in machines now building. One is called the serial method, the other the parallel method.[8] In serial operation, a number is transmitted from one place to another in the machine a single digit at a time, until the entire number is spelled out. In parallel operation, each digit of a number is transmitted on its own separate line, and all the digits of a given number are sent simultaneously.

As usual, each of these schemes has its advantages and its disadvantages. The parallel representation is inherently faster, since the entire number is transmitted at once, while in the serial scheme a number is sent one digit at a time. On the other hand, the amount of equipment needed in a parallel machine is greater than that required for a serial machine, since in the former as many lines are needed for transmitting a given number as there are digits in the number, while in serial operation all digits are sent successively down a single line. In a serial machine, exact timing is usually quite significant, since, for example, the successive digits of a number are distinguished from one another by their time of occurrence. In a parallel machine, on the other hand, timing is unimportant, since the place of a digit in a number is distinguished completely by the place at which it occurs in the machine. It is too early to say which of these schemes is the better absolutely, or the better under certain circumstances. They seem today to be competitors of approximately equal promise, and only further work and further development can determine which is the better.

The detailed design of the inner, high speed, memory has a substantial influence on the choice of serial or parallel operation for a machine. The requirements on the inner memory are very simple but very challenging. It must be able to store at least hundreds, and preferably thousands, of separate numbers or orders, and to do this in such a way that each is permanent and may be left stored for long periods without error, while at the same time it is accessible for transmission and use within a very few millionths of a second.

The earliest machines, such as the ENIAC, used for an inner memory banks of flip-flop circuits, so that at least one pair of triodes was required to store each digit of each number in the inner memory. This is such an extravagant scheme that not very many numbers could be so stored; the ENIAC has in its inner memory a capacity of only 20 numbers or orders.

It was clear that greater capacity of the inner memory is needed for achieving proper balance in a general-purpose computing machine. This problem has occupied machine designers for some time, and it still occupies them. The three types of inner memory in use are: first, a rapidly rotating magnetic drum on which the

[8] D. R. Hartree (reference 1, Section 5.6).

digits of numbers can be stored as patterns of magnetization; second, a tube containing mercury or other liquid down which the signals representing digits of numbers can be sent as pulses of sound; and third, electrostatic schemes in which the digits of numbers are stored as patterns of charge on the face of an insulator.

It is worth noticing that the magnetic drum and the sonic delay line are methods of *dynamic* storage in the sense that the numbers stored circulate continuously during storage, while the electrostatic scheme is one of *static* storage. It has therefore sometimes been said that the dynamic storage methods are best suited to a machine of serial type, while the static storage fits best a machine of parallel design. This is only partly true. A dynamic storage method produces one digit after another, to be sure; but a multiplication of the units used for dynamic storage (magnetic drums, mercury delay tubes) permits each digit of a given number or order to be entered on a separate memory unit, so that the whole number can be available at once, as it must be in a parallel machine. On the other hand, static methods of storage are not immediately suitable for use in a serial machine, but can be used if the digits of a number are read off from the static storage one after another.

Let us now turn to a consideration of the capabilities, uses, and limitations of computing machines currently under design or construction.

CAPABILITIES, USES, AND LIMITATIONS OF MACHINES

The nature of the orders presented to a machine has already been mentioned. What we must understand at this juncture is that the number of orders a machine can appreciate and act upon—its vocabulary—is built into it by its designer. An analysis of the operations of arithmetic discloses that the operations of addition, subtraction, multiplication, and division can be defined in terms of the elementary operations "join" and "meet." But the formalism necessary for this reduction is so complicated that it is more sensible to instruct the machine in terms of the four conventional operations of arithmetic than it is to reduce (in programming) every arithmetical operation to its basic terms as expressed by the operations "join" and "meet." How far can we profitably go in this direction of complicated arithmetical operation? Is it worth while, for example, to instruct the machine how to take square roots?

The ENIAC is so instructed. On a single order, the ENIAC will take the square root of a designated number. But the operation of extracting a square root is expressible in terms of the four elementary operations of arithmetic, and thus a machine which does not understand a one-word instruction to take a square root can nevertheless extract such a root if it is provided with a sequence of orders designed to produce such a result, by manipulations which the machine does understand.

This is not a trivial point. To increase the vocabulary of a machine—to increase the number of single orders which it understands—greatly complicates the design of the machine. To simplify the machine by reducing its vocabulary greatly complicates the business of programming a problem for the machine. Here, too, a balance must be struck: between machine complexity and program complexity.

In fact, we meet here one of the major differences of philosophy which has so far occurred in the design of machines. It can be illustrated by noticing that the Harvard Mark I machine is provided with a built-in table of four-place logarithms, so that it has the capability to take the logarithm of a number by looking it up in this table. The designers of other machines have asserted that, since reference to a table of function values is one of the least efficient elementary operations performed by a machine, it is better and faster to have the machine calculate for itself any function values needed, using the infinite series expressing the function. The inefficiency of tabular reference arises because either function values are stored in the inner memory (which is already too small for proper balance in most calculations, and therefore ought not to be used up for function tables), or else function values are stored in an outer memory, where consulting them takes a very long time on the extremely rapid time-scale of the machine. The storage of the form of a function makes far smaller total demands on memory space, and the computation of needed values of the function is, in general, far faster than is consultation of the outer memory to find such values. Thus, in this latter philosophy, tables of functions are an anachronism existing today only because not everyone interested in performing calculations yet has access to a high speed automatic digital computing machine.

Of course, the user of a machine often meets a situation in which he must perform repeated calculations of the same kind. If this calculation is not one comprised in the vocabulary of the machine, it must be programmed for the machine in terms of the elementary operations which are encompassed in that vocabulary. Once this is done, then the program which results can be preserved and used again and again. That is, an extended computation will ordinarily consist of a major routine and a number of sub-routines, the latter being of such a nature that they can be used, if necessary, over and over again as the main computation progresses. If, for example, the machine is not designed to understand an instruction directing it to take the square root of a number, then the square-root operation can be programmed in terms of the four basic operations of arithmetic. If that program is saved, it can be used over and over again whenever the major computation demands that a square root be taken. As a machine is used for extended periods, the number of

such sub-routines which are built up and filed away for future use will be extended; and it is not too much to expect that programming will thereby be greatly simplified.

It is of some interest to compare a high speed automatic digital computing machine to the human brain, and such comparisons have often been made in the past.[9] Such a comparison must be very carefully made. From what we know now, the central nervous system of animals, including men, is composed of individual neurons or nerve cells which are on-or-off devices like the flip-flop. However, man's central nervous system has ten thousand million such elements, while the most complicated computer so far built has only about ten thousand. This factor of a million which separates computing machines from brains is most important. For one thing, it permits the brain to perform its operations with a very considerable redundancy, so that a failure in a single element of a single chain of neurons is not important in terms of the result.

Present day machines, on the other hand, operate in a unitary way. The machine has so few "neurons" that it must use each as if it were infallible. This puts a fantastic premium on reliability in a computing machine. Von Neumann has estimated that, if a machine of the present complexity and design is not to commit errors more frequently than one per four hours, on the average, then its individual parts must have such a reliability that one failure occurs per million million elementary operations. This is some thousand times better reliability than has so far been achieved in conventional telephone practice, where one failure occurs, on the average, per thousand million operations. One of the unanswered questions about computing machines is whether such a reliability can be achieved.

This question has another side. We must ask whether such a reliability needs to be achieved. Are there not methods of checking which can, at every juncture, protect a machine from the consequences of error?

The answer is that there are. Claude Shannon, in his important paper on the "Mathematical theory of communication," has pointed the way to a method of checking which can correct automatically the errors that may be committed by a computer.[10] The scheme involved, which is due to Hamming, requires, to be sure, that other numbers beside those involved in the computation be handled and transmitted, but ensures that failures in the machine will not affect the results of a computation. In effect, the use of such a scheme introduces redundancy for the sake of reliability, and thus moves the logical design of computing machines a step nearer the logical design of the brain. The advantage of Hamming's method is that it provides a prescription for introducing the needed redundancy in the most economical and efficient way, as can be proved by Shannon's communication theory.

Probably one of the most promising directions of development now visible is this matter of evading intolerable requirements for reliability by suitably chosen means of checking. Various rather simple-minded schemes for checking have been proposed in the past—for example, to put the same problem simultaneously on two independent machines, and then to compare the results—but the checking method mentioned above is the first to have a sound theoretical basis.

Let us return to our comparison between computing machines and the brain. The individual on-off elements of a computing machine operate about a thousand times faster than do the neurons of the central nervous system. This constitutes the principal superiority of computing machines to brains; in almost every other respect the computing machines which we now can build are incomparably inferior to the nervous systems which we all possess.

We have already noticed the greatly superior complexity of the brain. Warren McCulloch, a professor of psychiatry at the College of Medicine of the University of Illinois, has observed that the complexity of the ENIAC, the most complicated machine yet built, is about that of the nervous system of the flatworm.

In terms of space and power, there is no comparison. Your brain is contained in your skull, and it dissipates less than twenty-five watts even when it is in full activity. The ENIAC, a million times less complicated, fills a large room and uses 120 kilowatts of power. Twenty kilowatts more are needed to run the blowers which keep it cool.

The great disparity between a machine and a brain must be taken into account in preparing a problem for solution on a machine. In the words of Lady Lovelace, the daughter of the poet Byron (she was speaking of Babbage's Analytical Engine): "The machine can do only what we know how to order it to perform."[11] It can obey instructions exactly, but it must have instructions or it will engage in an absurdity. This means that every possible eventuality of a complicated calculation must be visualized by the human computer when he programs the problem for the machine, and each such eventuality must be provided for in terms of explicit instructions.

Professor Hartree calls this "taking the machine's-eye view" of a computation, and he cites an instance of his own failure to do so.[12] He had failed to foresee that the argument in a trial solution might become negative, since he required finally a positive argument. In the absence of explicit instructions on this point, the machine "did its best, and this was something quite sensible according to its structure and the limited instructions which *had* been given to it, but quite different from the correct small extrapolation of those instruc-

[12] D. R. Hartree (reference 1, Section 7.9, p. 92).

tions which a human computor would make as a matter of course."

Up to this point we have emphasized, and perhaps overemphasized, the degree to which a computing machine is dependent upon its detailed design and on the orders it receives. The impression has probably been given that these determine entirely the operation of the machine. All this is quite true, under ordinary circumstances, but there is another way of using a machine which is worthy of remark.

I refer to the so-called "Monte Carlo" type of computation.[13] This method replaces the exact analysis of a complicated problem with a sort of statistical experimentation. That is, under properly chosen safeguards to ensure randomness, solutions of the problem at hand are secured for many special cases, and the results are examined to determine the relative probability of various over-all occurrences.

This will be clearer in terms of a specific example. The Monte Carlo technique has been applied to the problem of neutron diffusion in a scattering and absorbing medium. Neutrons of a known energy distribution fall on such a medium in a beam of known intensity; at 10 cm depth (say) what will be the neutron density and velocity distribution? At each encounter with a nucleus, a neutron has a certain chance of being captured, of being elastically scattered in one direction or another, or of being inelastically scattered with energy loss of some amount or other. The probabilities of all these events vary with the energy of the incident neutron and are different for different target nuclei (for the absorber may and usually will contain more than one nuclear type). Rather than seeking an analytical solution for this very complex problem, Ulam[13] has followed the detailed history of many individual neutrons through the absorber, at each encounter with a nucleus determining the outcome by casting dice (in effect), the dice being suitably loaded to reproduce the probability structure appropriate to the event concerned. When this has been done for very many individual neutrons, the statistics of their joint behavior presumably approaches that which would result from a full-dress analytical solution of the problem.

A high speed machine is admirably adapted to apply this method, for its speed enables it to obtain a statistically significant volume of results in a reasonably short time. However, if a machine is to do this, it must be instructed how to gamble. This is accomplished by providing to the machine, at each juncture where gambling is required, a random number whose size determines the result of the play. In fact, schemes exist for the generation by analytical processes—and therefore by and within the machine itself—of "pseudo-random" numbers which have all the necessary properties of randomness. D. H. Lehmer[14] has proposed a particularly elegant and useful scheme of this sort. The pseudorandom numbers produced according to Lehmer's prescription are easy to generate in a machine, and meet all of the standard tests for randomness. After one has made such tests, it comes as a distinct shock to find that all these numbers are divisible by 17.

There are good indications that the Monte Carlo method may be one of the best ways for solving partial differential equations on a machine. Certainly its power and scope seem destined to grow.

FUTURE TRENDS IN COMPUTING MACHINES[15]

There are three important questions which concern the future of computing machinery which I should like to discuss. The first is: "Who is likely to possess large high speed computing machines in the future?" Some workers in the computing-machine field seem quite pessimistic about the ultimate wide availability of such machines, on the grounds that they are complicated, expensive, and difficult to keep in order. This is a point of view with which I entirely disagree. I fully expect that a competent high speed computer will very soon be regarded as an important and inevitable part of the research equipment of any university having even the most modest research pretentions.

Thus, the computing machine is to be viewed not as being in the category of the large astronomical telescope, which is a pleasant but optional luxury for a university, but rather as being in the category of the electronuclear particle accelerator, which is a necessity for any university desiring to cultivate modern nuclear physics. It is a trifle surprising that so few American universities have accepted this view; in fact, only the University of Illinois is presently building a machine on its own funds for its own purposes.

Of course, the wide availability and the general acceptance of high speed computing machines will be greatly forwarded by improvements in reliability and reductions in cost. Such developments can be expected to arise from the continued developments in components and the improvement in the logical design of machines.

Let us now ask: "How large, how fast, and how complicated should a large, high speed, general-purpose computing machine be?" It seems unlikely that machines more involved than the ENIAC will ever be built. More recent machine designs are more ambitious in terms of speed of operation, in terms of the size of inner memory, and in terms of the general competence of the machine. In spite of this, such new machines have fewer tubes than the ENIAC; they use these tubes harder, so to speak. I think that the answer to the question of where to draw the line in designing a general-purpose computing machine is set entirely by con-

[13] S. Ulam, Symposium on Large-Scale Digital Calculating Machinery, Harvard University (September, 1949).

[14] D. H. Lehmer, Symposium on Large-Scale Digital Calculating Machinery, Harvard University (September, 1949).

[15] L. N. Ridenour, Symposium on Large-Scale Digital Calculating Machinery, Harvard University (September, 1949).

siderations of reliability. That is, a large general-purpose machine ought to be as big and complicated and competent as it can be made, subject to the limitation that it must not commit an error oftener than once every few hours. There is no other significant limitation on the total complexity of the device; for the machines which are now in design or construction are still quite inadequate to deal with many problems which we should like to put to them.

One simple example is contained in a remark of Hartree, quoted to me by Professor Aiken. Hartree said that the fastest computing machine available today is still too slow by a factor of 10^{10} to solve the problem of the wave equation for the copper atom. Similarly, the people who are designing the air traffic control plan for the country are proposing to put computers in key locations on the airways of the country, to handle the problems involved in air traffic control. Preliminary estimates of the scope of these problems have indicated that present-day machines will be severely taxed to deal even with the volume of air traffic that exists today.

We want, therefore, to make computing machines as large and as complicated as we can, for the most ambitious machine which we can realize today is powerless in the face of problems that we can readily pose, but not yet solve.

This brings us to my final question: "How can a computing machine be made more reliable, so that its complexity can be increased without increasing the chance of failure?" Much of the answer to this question will depend on the further development and the elaboration of the checking schemes which have already been referred to. However, the obvious way to increase the over-all reliability of present-day machines is to look toward as complete as possible an elimination from such machines of vacuum tubes and electromechanical relays. These two components are presently the major sources of failure in existing machines, partly because they are so numerous, and partly because they wear out with continued use. We need computing elements that can perform the same non-linear functions as those we now achieve with tubes or relays, but elements which are far less prone to depreciation in use.

The vacuum tube also has the disadvantage that it requires large amounts of standby power. McCulloch has remarked that, if a machine built on present principles were to have as many neurons as does the brain, it would require a skyscraper to house it, the power of Niagara to light its tubes, and the full flow of water over the Falls to keep it cool. There are now visible several developments which promise to compete with the vacuum tube for this and other purposes. First, semiconductor devices of the type of the transistor seem to have great promise. Second, magnetic devices like those reported by the Harvard group at the September symposium hold out the hope that they can serve in the place of tubes, with much greater reliability and without requiring power.[16] Finally, the pioneering work of Bowman[17] on electrochemical elements for computers offers a substantial promise in this same direction.

Probably there is no more rewarding direction for computer development than to explore the possibilities of using unconventional elements in the design of such machines. If the vacuum tube can be replaced with a cheaper, simpler, and more durable device, then the over-all competence of practicable computers can be greatly increased. Such a development will being in its train a greater availability for computers of the present sort, and a wider general use of computing machines of all kinds.

Contributed Original Research

A Lapping Technique: To Improve the Image Quality of Electron Microscope Lenses

F. A. Hamm
General Aniline and Film Corporation, Central Research Laboratory, Easton, Pennsylvania
(Received July 25, 1949)

One factor inherent in most electron microscopes is the magnetic asymmetry (astigmatism) in the objective lens. This is often due to imperfect machining, localized defects (impurities) in the iron, or grain anisotropies. The lapping technique described herein effectively reduces the effect of imperfect machining (misalignment of components). Critical faces and the bores through the pole piece are lapped with a series of powders (alumina) which increase in fineness until the final process is that of polishing. A set of jigs and laps (brass and hard wood) are described; their specifications and use so as to properly alter the critical pole piece surfaces are also described. Electron micrographs illustrating the value of this lapping procedure in the improvement in objective lens symmetry are included.

INTRODUCTION

DURING the past few years the electron microscope has become an important research tool. Certainly one of the reasons for this is the improvement in specimen preparation techniques. These improvements are the natural results of wider applications and the realization that artifacts must often be considered. However, because most laboratories, and especially the industrial laboratories, are usually hard pressed in applying the electron microscope to their particular urgent problems, relatively little time has been spent in improving the *performance* of the electron microscope itself. For example, each laboratory may have its own condition such as vibration, stray magnetic fields, high humidity and other accidental defects which may limit the performance of that particular instrument. With the ever increasing interest in greater resolution it has become imperative to evaluate more critically the various factors that may impair the instrument's resolution. Hillier and Ramberg[1] have very adequately evaluated both inherent and accidental instrumental defects, and critical investigators have relied heavily on the information already disclosed.

It is the purpose of this paper, first, to describe a lapping technique which has been found useful for eliminating most of the prohibitive magnetic asymmetries inherent in electron microscope objectives, and, secondly, to illustrate the practical results observed after applying this technique. Cognizance of these asymmetries is seldom taken until the investigator becomes interested in resolving structures of 50A or less (or until micrographs are taken at very high instrument magnification). When the electron microscope is used at high magnification (15,000× or greater) the aforementioned defects may be readily observed. Although at times vibration is troublesome, it was observed that the most serious factor limiting the resolution of the electron microscope in this laboratory was the *astigmatism* inherent in the *objective pole piece.* This asymmetry has been almost entirely eliminated by reducing the *mechanical inaccuracies* of an *objective pole piece* by means of a lapping technique. Both projector and objective pole pieces must be handled with care; mistakes in routine cleaning or in haphazard "polishing" techniques may be costly. It is hoped that the information disclosed herein may aid others who are interested in improving their instruments.

The contributions made by Hillier[1,2] and his coworkers should be emphasized again. It is hoped, however, that this paper will stimulate other investigators to report on similar instrumental procedures which they have found to be helpful in eliminating or minimizing conditions which may limit the resolution of their particular instrument. For example, there are undoubtedly some locations which are troubled by building vibrations.

It should be understood that asymmetries in magnetic lenses may also be due to inhomogeneities in the iron (pole pieces). Variations in the grain structure or orientation will obviously affect the distribution of the magnetic flux in the lens. These factors may be especially troublesome if they occur near critical openings. This lapping technique obviously does not eliminate these sources of trouble.

Occasionally small impurities are removed from the faces and the bores of the pole pieces. The small "pits" that remain should be eliminated insofar as possible by lapping until these surfaces are essentially smooth. These mechanical impurities are sometimes quite troublesome

TABLE I.

A. Jigs (Brass)

(1) One jig to hold (with a slide fit) the sections of both pole pieces when lapping their inside faces. The broad face of the jig that makes contact with the flat glass surface is three and one-half inches in diameter. This face is counterbored 0.031 in. deep with a 1.625-in. diameter. Item 6 in Fig. 1.

(2) One jig equipped with a 0.125-in. bushing. This jig is used to hold the pole piece sections when the bores (holes through) are lapped. The bushing guides the shank of the lap. Item 7.

(3) One jig to hold the short section of the objective pole piece when lapping the outside face. This jig has a hole (0.255 in.) to guide the lap. Item 5.

B. Laps[a] (All laps are about 1 in. long; over-all length including the 0.125-in. shank is 3–4 in.)

(1) *Objective pole piece*
- (a) 0.0610 in.–brass.
- (b) 0.0615 in.–brass. Item 2.
- (c) 0.0620 to 0.0625 in.—oak wood. Item 1.
- (d) 0.255 in.—brass; brass with soft solder babbit on one end—used with *A* and *B* powders. Item 3.

(2) *Projector pole piece*
- (a) *Short section*
  - (i) 0.0630 in.–brass. A section (0.0680 in.) was left ahead of the shank which could have been turned down to the required size if necessary. Item 9.
  - (ii) 0.0650 to 0.0655 in. oak wood. Item 11.
- (b) *Long section*
  - (i) 0.0700 in.—brass. Item 8.
  - (ii) 0.0710 in.—oak wood. A 0.0720-in. portion was separated from the first (0.0710 in.) portion by means of a deep undercut. The larger diameter lap was included in case it might have become necessary. The undercut prevents the larger lap from rubbing the inside pole piece face. Item 10.

C. Powders

Exolon[b] (aluminum oxide) 600 and 800 abrasives are used to lap. The soft iron in the pole piece is removed.

Linde[c] types *A* and *B* (finest) polishing powders (aluminum oxide) are used on the wooden laps. Little or no metal is removed with the *B* powder. Minute scratches are removed probably by a plastic flow type of deformation. The particle sizes are very uniform; the *B* type is reported to be less than 0.1 micron.

D. Fluid

Singer[d] high grade sewing machine oil was used to make pastes with the powders

[a] 600 and 800 abrasives used with the brass laps, *A* and *B* polishing powders used with the oak laps.
[b] The Exolon Company, Tonawanda, New York

[d] Singer Oil, Type D Stainless Heavy Grade, Singer Sewing Machine Company, New York, New York.

in that more time is required to lap until a glossy surface is observed. It is conceivable that the effect of impurities might never be effectively reduced in some pole pieces; consequently the use of a compensating pole piece spacer would become imperative.

It would be difficult to evaluate the relative importance of grain structure, orientations, impurities, mechanical inaccuracies, etc. Probably these factors are all present in all pole pieces in varying degrees. However, it is worth while to eliminate the last one insofar as possible. The electron microscopist has little control over the other sources of trouble.

Because the lapping technique was done critically and with good success, it was considered worth while to report on it, giving at least the essential details. It should be emphasized that lapping the *projector* pole piece does *not* affect resolution, but it is desirable because it does remove contamination, and it may make projector lens distortion more symmetrical.

DISCUSSION

This paper is concerned only with the *practical* aspects of improving the magnetic asymmetries inherent in perhaps all objective lens pole pieces. The *theoretical* aspects are described in an earlier reference.[1] The term *astigmatism* describes a difference in focus in two mutually perpendicular directions. This difference was originally estimated to be as high as 50 microns in some objective pole pieces. This *degree of astigmatism* could have been more accurately determined by plotting objective coil current against known object displacement. Thus the difference in lens current required to bring the image in one plane into the same focus initially observed along its mutually perpendicular plane would be a measure of the degree of astigmatism as read from a predetermined curve. Such determinations are time consuming and unnecessary *in practice*. A hole in a thin membrane (collodion, silica, polystyrene, etc.) or a round particle such as carbon black (camphor) serves as a convenient subject for evaluating objective lens asymmetries. High instrument magnification is a prerequisite to a study of this kind, and it is assumed that the terms "in focus," "overfocused," and "underfocused" are understood (precluding further discussion).

Since this manuscript was first written a very pertinent investigation has been presented.[3] Through the courtesy of James Hillier the asymmetries exhibited by most of the electron micrographs have been quantitatively evaluated. These asymmetries, expressed in microns, are included in the caption for each figure. These values represent the difference in focus between mutually perpendicular directions. Very slight differences of $\frac{1}{2}\mu$ can be detected.

LAPPING TECHNIQUE

The equipment[4] used in this lapping and polishing technique is listed in Table I with a brief description. The various items are illustrated in Fig. 1.

Hillier[1] has very briefly described his procedure. This technique differs from his in three important respects: (1) The use of a 400 (coarse) lapping powder appears to be undesirable because it sometimes "tears" the soft iron. (The 600 powder removes metal at a good rate.) (2) Unless the pole pieces are dried *immediately*, water corrodes the newly formed iron surfaces. Furthermore,

[3] James Hillier and Henry Froula, "On the testing of electron microscope objectives," Paper No. 4, RCA Laboratories, Princeton, New Jersey, presented at the EMSA meeting, Washington, D. C. (Oct. 6–8, 1949).

[4] The items first used had been made with good precision by the Beeman Manufacturing Company, 1030 Haddon Avenue, Collingswood, New Jersey. Modifications and additional items have since been made in our own machine shop.

it is difficult to maintain a stable water paste of the lapping powders because of evaporation. The highly refined Singer oil does not corrode and lends itself to making stable slurries of varying consistencies. This oil is readily removed with acetone. (3) Straight laps are preferred to tapered (1°) laps because considerably more metal must be removed from one end of the bore when using a tapered lap. This invites trouble. Furthermore, the bores through the pole pieces might become abnormally large if the lapping is repeated. At least 0.004 in. of metal would have to be removed from one end of the bore, whereas only about 0.0015 in. of metal was removed with the straight lap using the 600 powder. Although no deep pits were encountered during the processing of two sets of lenses, it is conceivable that large impurities (pits) might be troublesome. If this is the case, tapered laps would be more desirable because they would preclude the necessity of making several straight laps. Obviously, the amount of metal removed by a lap is a function of the size of the particles in the lapping powder.

It would be desirable to polish with a soft metal lap such as copper or lead. However, this is not feasible because these metals are not rigid enough. Hard wood (oak, maple) was found to serve better than brass for the final polishing with the fine powders.

Before beginning the lapping it is imperative to mark both sections (of each pole piece) with respect to some mark (scratch) on the brass spacer. The pole pieces should always be assembled in the same way using these markings as a guide. This should be done before inserting the pole pieces in the electron microscope or before lapping the bores. The bores through both sections of the *objective* pole piece should be lapped with the pole piece *assembled*.[5] This is not necessary with the projector pole piece; the bore through the long section has always been larger (0.070 in.) than that through the short section (0.063 in.). Should the bores in the objective pole piece not exhibit good alignment, lapping should be continued until good alignment is realized.

A sufficient supply of a fairly thick paste of each powder is prepared so that all surfaces may be lapped before proceeding to the next finer powder. The inside faces (within the spacer when assembled) were lapped first with the 600 powder. The pole piece section does not rotate within the jig; the lapping is done with a rotary motion on a thick glass plate, preferably of good quality (flat). The assembly is lifted occasionally from the plate, turned to a new position, and then lapped as before. The pole piece is also rotated within the jig to eliminate any results due to possible imperfections in the jig. If the assembly is periodically rotated and the lapping done with a rotary motion, all directional effects will be eliminated. This same procedure is carried out with all subsequent grades of powder. All traces of the powder last used should be removed before proceeding to the next one. This can best be done by using lens tissue[6] wet with the oil, wrapped around a toothpick when cleaning the bore. A little pressure (index finger) is used in lapping the faces. The outside of the pole piece may be lubricated with the oil so that it is more readily pressed through the jig (slide fit).

After lapping the faces, especially with the 600 powder, a "burr" usually forms around the lip of the bore. This burr should *not* be removed by inserting the bore lap from either end. Apparently the lap (brass or wood) picks up the soft iron in relatively large pieces; then on withdrawing the lap the bore is scratched and sometimes badly torn. Instead, these burrs are best removed from the entire bore periphery by rolling up a small piece of crocus cloth into a cone shape, inserting the apex of the cone into the bore and gently turning the cone against the burr. At no time was there any evidence of a bevelling action on this lip. *Both* the bores and the faces are lapped to give as smooth a finish as possible with the given powder before proceeding to the next finer powder. Burrs are not usually formed when the finer powders *A* and *B* are used.

Early in this investigation it was observed that the smaller faces (long section of objective pole piece) could always be polished to a higher gloss than the larger faces. It appeared that the larger face was picking up "dirt" from the brass jig which then "stained" the pole piece face. To eliminate this, the large face of the jig, which makes contact with the glass during lapping, was counter-bored 0.031 in. deep to a diameter of 1.625 in. The pole pieces were then lapped with a rotary motion using a *short stroke* so that the lapping paste remained within the counter-bore. This procedure permitted the polishing of the large faces to the same gloss that had been observed earlier on the small faces.

The outside face of the short section of the objective

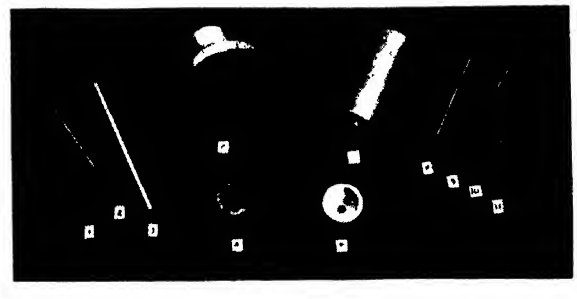

FIG. 1. Laps and jigs described in Table I.

[5] Since originally submitting this paper for publication it has been learned that some RCA e.m.u. electron microscopes have been equipped with objective pole pieces having sections with bores of unequal size. Thus, each section might be lapped separately, but it is almost imperative to lap this pole piece assembled to insure proper alignment of the openings. Consequently the bore through the one section must be carefully enlarged to the same size as the other one.

[6] Ross-Adams lens tissue sold by Clay-Adams Company, Inc., New York, does not readily tear and will not scratch the pole pieces.

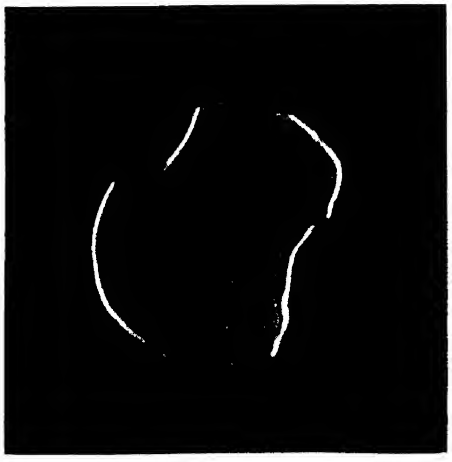

FIG. 2. 100,000×. Diatomaceous earth particle. Severe astigmatism. Note the several orders of Fresnel fringes in the vertical direction. Asymmetry of 20-25μ.

pole piece tarnishes very quickly because it is just below the specimen and because it is sprayed with electrons scattered by the specimen. This face should be polished occasionally, but care must be exercised so as to avoid introducing asymmetries. Furthermore a burr may form around the periphery of the bore when the bore is lapped; this must be removed. To accomplish these purposes, a jig was made to fit over this short section. A hole (0.255 in.) in the exact center guides a brass lap of similar dimension. This lap, used with the 600 and 800 powders, is used to lap the flat face and remove the burr. The lap must be "faced-off" (in a lathe) occasionally because the burr may cut into the brass lap. To polish this pole piece face, a similar lap is made, equipped on one end with a soft solder babbit which must also be faced-off periodically. The *A* powder embeds in the babbit so it must be removed before using the *B* powder. It is suggested that this babbit lap be used quite frequently with the *B* powder to remove the contamination that is the result of the effect of the electron beam.

Lapping the bores of the pole pieces must be done with caution. The hole must be enlarged gradually and symmetrically. The early work on the bores suggested the use of the 600 powder instead of the 400 powder. The Beeman[4] jig served its purpose very well. The 0.125-in. bushing (1.5 in. long) guides the shank of the lap so that it runs "true." The hole for the pole piece is about $1\frac{1}{2}$ in. long (slide fit) so that if the laps are properly made the finished bore should be perfectly symmetrical. In practice the abrasive paste is placed within the bore before inserting the pole piece in the jig. The clean lap is then inserted through the bushing (lubricated) and lapping carefully started when the lap meets the bore. The ends were pointed, merely to aid in starting the lap in the bore. The objective pole piece was inserted in the jig so that the lap went through the short section first.

Lapping is accomplished by rotating the lap back and forth through an arc of about 180°C. The lap is periodically withdrawn, rotated slightly, reinserted, and lapping continued as before. This ensures symmetrical action around the entire bore. The pole piece is tightly held in the jig with the index finger. Occasionally large scratches or tears developed during the early work. This was very probably caused by some hard grit which had accidentally gotten into the system.

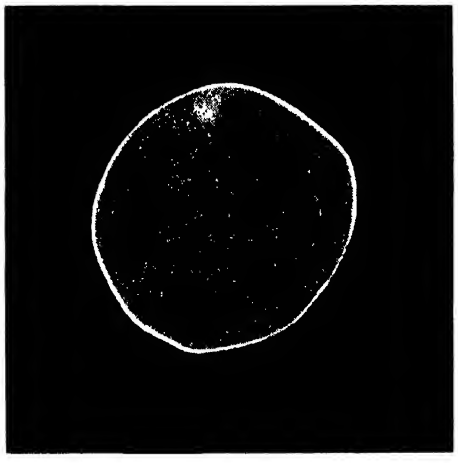

FIG. 3. 112,500×. Compare with Fig. 2. Very slightly underfocused. Different lens. 4-5μ.

The later work was carried out in a cleaner environment, and no trouble was experienced. The bore diameters of the pole pieces in the RCA e.m.u instrument have been varied slightly during the last few years; the bore in the long section of the projector pole piece is apparently always the largest. These bore diameters should, of course, be carefully measured before making the laps.

The hard wooden laps used for the final polishing show signs of wear after some use. By cutting a few grooves (with a razor blade) parallel to the long direction of the lap and soaking the lap in oil, a sufficient increase in diameter results so that these laps may be used repeatedly. It might be expected that these wooden laps do not wear evenly. Although this may be true at times, it is of no significance when polishing with the fine powders.

These wooden laps were used very successfully for polishing the bores. For this reason hard wood laps were made to polish several other surfaces. For example, the bores through the specimen holder and the special Armco iron sleeve in the intermediate screen assembly are occasionally polished with wooden laps (oak) to remove tarnish. This procedure is desirable because polishing these surfaces makes them smoother so that they are more readily cleaned with lens tissue in the routine way employed by many investigators. In both cases, the wooden laps may be held in a small drill press; the polishing is then done by moving the metal

surface up and down over the lap. Hand polishing is preferred because better control is realized.

The cleanliness of the inside conical face of the short section of the projector pole piece is very important, especially at high instrument magnification. At high projector lens current values the imaging beam of electrons is spread so that many of the rays strike the inside of the bottom (short) section of the pole piece. The final image may be of a poor quality if the beam is affected by contamination which may acquire a charge. A wooden lap (maple) was made to polish this face with the *A* or *B* powders. This lap is illustrated as item 4 in Fig. 1. The conical shaped portion (45° cone) is 0.853 in. long, with the sharp apex of the cone rounded. The short section of the projector pole piece is screwed into the brass spacer. The spacer is fitted into the jig

TABLE II. Instrumental operating conditions.

(1) Self-biased gun (saturating between 200 and 250 micro amperes), filament distance from grid (gun focusing aperture) about 4 mm. "Home made" filament sharp apex bent over a razor blade. "Cross-over" image of source approximately normal to the astigmatic plane.
(2) Primary fluorescent viewing screen removed. Brass plate substituted for the usual primary viewing window and copper screen. These changes eliminate some contamination, which may subsequently charge up and cause movement of the beam.
(3) Condenser current[a] = 84 milliamps; this provides an angular aperture of illumination to the specimen of about 4×10^{-4} radian.
(4) Mu-metal shielding between objective and projector lenses to eliminate stray magnetic fields.
(5) Intermediate fluorescent viewing screen removed. Armco iron sleeve in intermediate screen assembly to maintain magnetic symmetry within the upper part of the projector lens (see reference 1).
(6) Objective lens focusing circuit modified to give threefold sensitivity over the standard e.m.u.-2A circuit.
(7) Strict cleanliness of entire microscope column (gun) observed.
(8) Voltage alignment always used. Magnetic alignment is not superimposed; magnetic center of rotation just off the final viewing screen.
(9) No objective aperture.
(10) The micrographs were taken at tap 9 or 10 using the high gain projector spacer.

[a] Some of the data were calculated from information received in a private communication with Dr. James Hillier, RCA Laboratories, Princeton, New Jersey.

with the 0.125-in. bushing, having used tissue paper as a shim. The jig is then placed in the collet of a lathe, which is run at about 400 r.p.m. Polishing is accomplished by moving the wooden lap in and out (by hand) along one side of the cone face. A shoulder at the base of the cone prevents the cone from being inserted too far. Thus, this lap does not touch the bore. This procedure removes the surface contamination, and the tin plating, so that the copper plating is exposed. Sometimes the tin plating on a new pole piece separates from the iron *within* the bore of the pole piece. A burr of this type could be troublesome and might readily tend to catch small contaminating particles. The lapping technique described earlier effectively removes this tin plating.

After carrying out any of the aforementioned steps in the lapping procedure, the oily paste is best removed by wiping the surfaces with a good quality lens tissue.[6] After the lapping has been completed, the oil and last traces of powder are best removed by immersing the lens components in two successive baths of high grade (dirt-free) acetone. The critical surfaces should not be allowed to dry for the last time without first wiping them with lens tissue wet with fresh acetone. No evidence to suggest the incomplete removal of oil has ever been observed. Complete removal of the oil is absolutely imperative for several reasons, the most important being the fact that the electron beam would probably act on the oil (radiation-chemical) so as to cause severe contamination.

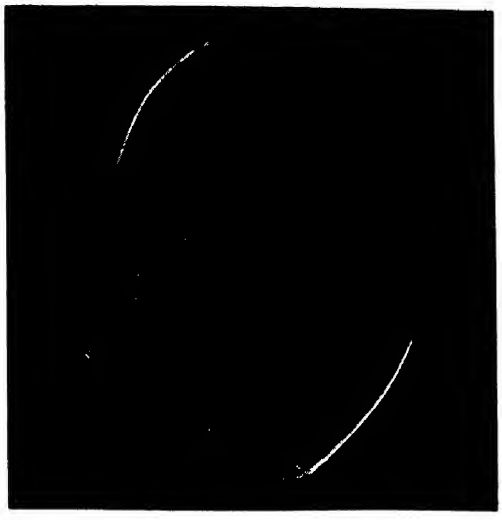

FIG. 4. 112,500×. Portion of a diatom. The astigmatism is manifest as a ghost image due to overfocusing along one direction Before lapping. Abnormally bad asymmetry of about 60μ.

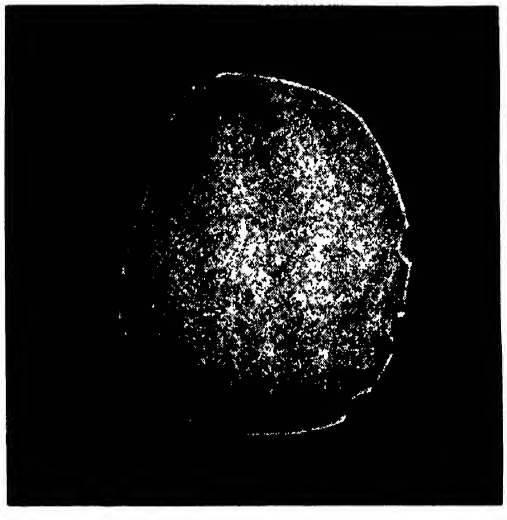

FIG. 5. 112,500×. Diatom very slightly underfocused. Same lens after lapping. 1½μ. This very small asymmetry would have been more obvious at exact focus.

FIG. 6. 112,500×. Thin film of Formvar. 1½μ. Possibly a trace of specimen drift.

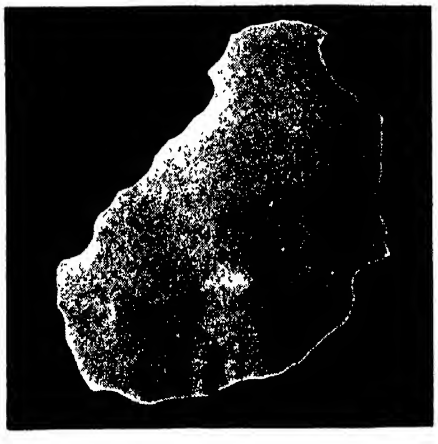

FIG. 7. 48,000×. 200A (calc.) thick film of silica. Too far underfocused to detect the 1½μ-asymmetry.

DISCUSSION OF ELECTRON MICROGRAPHS

The practical use to which the electron microscope is put is very largely based on the photographic record of the images observed. Because it was the purpose of this investigation to increase the "instrumental resolving power" most of the micrographs will be interpreted with this in mind. The "Report of the electron microscope society of America's Committee on Resolution"[7] has been used as a guide in choosing the terminology. Thus, the "instrumental resolving power" is based on measurements made on the photographic record of an image taken under ideal conditions (specimen, photographic, instrumental, etc.). The "quality of the micrograph" is more closely associated with the information revealed in relation to what was hoped for in any given investigation; although it is a function of the performance of the microscope it is probably most closely related to the quality of the electron microscope specimen. A few electron micrographs are illustrated to demonstrate their high quality as a result of better instrument performance. For the sake of convenience the "minimum distance between adjacent particle centers" is used to evaluate the instrumental resolving power. Reliance on micrographs is, of course, necessary. Most of the micrographs are illustrated in an effort to demonstrate the effectiveness of the pole piece lapping technique in eliminating astigmatism rather than to claim some specific optimum resolving power.

In order to make a fair appraisal of the lapping technique it is imperative to eliminate the effects of all other variables. Unless otherwise stated, the operating conditions apropos of these micrographs are briefly summarized in Table II.

Figure 2 illustrates an extreme case of astigmatism. The underfocused portion of the image shows at least

FIG. 8. 160,000×. Sublimed organic pigment. Poor image quality. Before lapping.

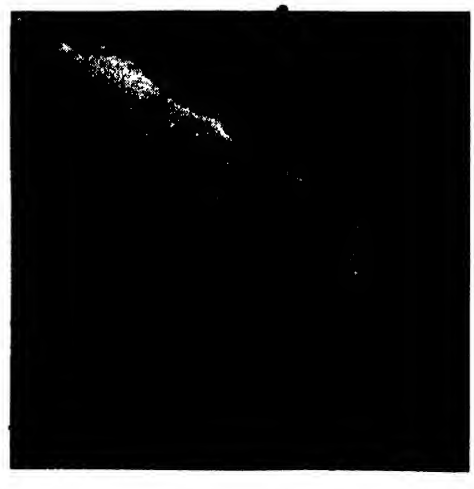

FIG. 9. 160,000×. Unshadowed silica replica of a silver bromide crystal. Good image quality. After lapping.

[7] J. App. Phys. 17, 989–996 (1946)

four orders of Fresnel fringes, indicative of good instrument performance. On the other hand, the image along the horizontal plane is in better focus (exhibiting no diffraction fringes) thereby demonstrating the astigmatism of this objective pole piece. Experience suggests that this amount of asymmetry (20–25μ) is not uncommon in many objective lenses.

Figure 3 is a very slightly underfocused image of the same specimen photographed with a different objective pole piece. The image is too close to being in focus so that only the first-order Fresnel fringe is exhibited. The symmetrical distribution of the white halo around the entire periphery of the hole (diatom) indicates a lens of good quality.

Astigmatism always becomes more pronounced as the image is brought toward exact focus. This is significant because in any critical investigation requiring high resolution, reliance on well-focused images should be made. In cases where the specimen is extremely thin and has little scattering power, a slightly underfocused image reveals more information because of its greater contrast due to phase delay phenomena. By varying the current in the vernier (fourth potentiometer) of the modified objective focusing circuit, the astigmatism can be detected and measured qualitatively in terms of vernier divisions.

Figures 4 and 5 again illustrate the effect of the lapping technique. The holes in diatoms conveniently serve this purpose. The image (Fig. 4) in the plane perpendicular to the arrow is badly overfocused (focal length too short); the parallel direction is in better focus. Figure 5 illustrates a high quality image of the same specimen after lapping. Because diatoms are relatively thick, a thin white halo appears just within the holes even though the image is, for all intents and purposes, in focus. (As a result of the quantitative evaluation[3] this image is now considered to be one or two microns underfocused.)

About one month after the pole pieces had been lapped and polished for the first time it became necessary to polish them again. The bores through and faces (especially on the objective pole piece) had become badly "tarnished." (This tarnish may have been a contamination coming from the particular type of specimen during exposure to the electron beam.) It was decided to lap the objective pole piece again lightly, starting with the 800 powder. The micrographs in Figs. 6 and 7 were taken subsequently. Although the contrast in these figures is poor (no objective aperture) the images still exhibit about the same amount of asymmetry. Because the asymmetries were almost entirely eliminated, it has been unnecessary to use a compensating objective pole piece spacer described earlier by Hillier and Ramberg.[1] It is felt that it is more desirable to eliminate the asymmetries insofar as possible by lapping rather than by using a compensating spacer because laps and jigs must be made anyway in order to occasionally remove the pole piece tarnish by *polishing*. If this is done, only a little more effort is required to complete the job by carrying out the entire lapping procedure. It is conceivable that a compensating objective pole piece spacer might be very desirable for routine work even after lapping, depending upon how badly asymmetrical the pole piece might have been initially due to reasons discussed earlier. In any case, the last traces of astigmatism can perhaps only be removed by compensation.

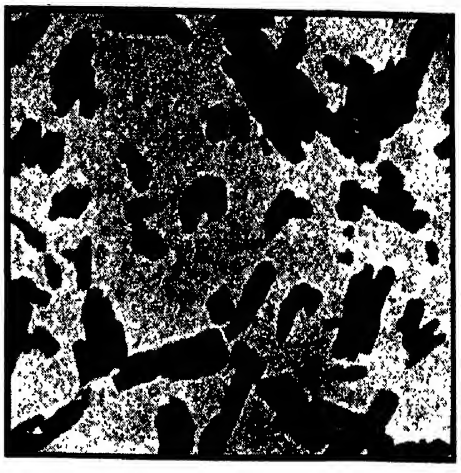

FIG. 10. 56,000×. Dispersed pigment. Poor image quality.

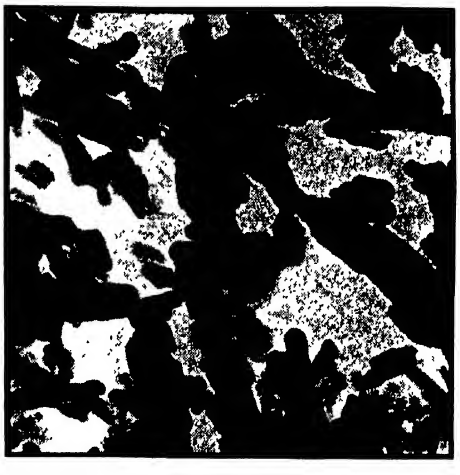

FIG. 11. 56,000×. Same preparation as above. Good image quality.

Admittedly, it is not entirely fair to compare the image quality of micrographs taken of different specimens. However, Figs. 8 and 9 are illustrated for comparison. Both types of samples are very stable in the electron beam, and both micrographs (photographed at 20,000×) represent the optimum quality possible at the time that the micrograph was taken. The difference in image quality is undoubtedly due to the difference in the performances of the lenses. The magnification in both these figures is 200,000 diameters. The absence of

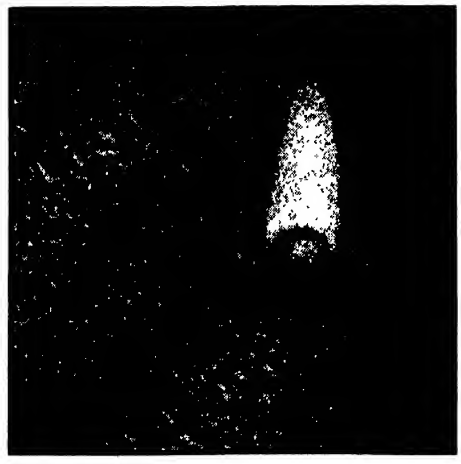

FIG. 12. 160,000×. A silicon monoxide replica of mica shadowed with Pt-Pd. Good image quality.

specimen drift, always a serious problem, should be noted.

Experience during the past several years suggests that image quality is often attributable to the performances of the electron microscope lenses. Figure 8 is several years old, whereas Fig. 9 was taken since the lenses were first lapped and polished. Note how much more "crisp" the latter image is. The contrast is poor; the specimen was not shadowed. The latter image is however, capable of resolving structure at least on the order of 25A.

Figures 10 and 11 represent a comparison of the same specimen, Indanthrene Blue RS, dispersed ultrasonically, demonstrating the "before and after" version of the lapping technique. Figure 10 is slightly underfocused. Underfocusing invariably causes the image to be more crisp and to have more aesthetic appeal. Nevertheless, Fig. 11, taken after the pole pieces had been processed, is much more crisp and suggests, even at this low magnification, the improvement in resolving power due to the lapping technique.

The structure in Fig. 12 was exhibited by a silicon monoxide replica of mica, shadowed at 10° with a platinum-palladium alloy. This structure appears as an undesirable "background grain" when the replica is used as a substrate for other objects (viruses, bacteria, etc.). The structure is typical of platinum-palladium shadowing metal, especially when the metal is relatively thick. Although the image is slightly underfocused, the quality is good and superior to that possible with an "average" objective lens. It should be emphasized that this micrograph and all the others were taken at very high instrument magnification.

CONCLUSION

The effect of astigmatism, an objective lens asymmetry, has been illustrated. A procedure for minimizing this inherent defect is outlined. This process involves lapping and polishing with fine abrasives all critical surfaces on the objective (most important) and projector pole pieces. Routine polishing with the *B* powder should be done frequently to remove contamination. High quality high magnification electron micrographs necessitate routine polishing at least once a month and preferably more often.

Improvement in the instrumental resolving power based on measurements made on micrographs was illustrated. No specific optimum resolving power is claimed. The elimination of astigmatism and the general improvement in image crispness unquestionably permit greater resolution. A reduction in objective lens asymmetry from about 60μ to about 1½μ has been illustrated.

Since this initial investigation was completed, another objective pole piece was processed in the same way. The gratifying results add weight to the significance of this technique.

ACKNOWLEDGMENTS

The author is indebted to A. McNevin for his suggestions and care in carrying out much of the lapping procedure. The interest and constructive criticisms expressed by M. C. Banca and James Hillier of the Radio Corporation of America have also been appreciated.

Separation of Gases by Fractional Permeation through Membranes

SOL WELLER* AND WALDO A. STEINER†
Research and Development Branch, Bureau of Mines, Pittsburgh, Pennsylvania
(Received September 19, 1949)

The permeability of a number of thin organic films toward oxygen and nitrogen has been measured. For an ethyl cellulose film the studies were extended to include CO_2, A, He, and H_2. The enrichment of a binary gas mixture in a single stage of permeation has been calculated for the extreme cases of perfect mixing and no mixing. Application of these results indicates that the use of a fractional permeation process may be of practical importance in effecting the separation of oxygen from air, helium from natural gas, and hydrogen from coke-oven gas, as examples.

INTRODUCTION

THE fact that non-porous rubber membranes show a higher permeability to O_2 than to N_2 has been known for almost 120 years[1] and has formed the basis for several old patents for the enrichment of air.[2] Apparently, little attention has been paid in the interim to the possible practical importance of this selective permeability behavior. Most of the work which has been reported on the phenomenon has been done on rubber membranes,[3] although scattered investigations have been made on other materials.[4,5]

In 1942, von Elbe,[6] working with stretched films of natural rubber, found that air, diffusing from a pressure of 4 atmos. to atmospheric pressure, was enriched to an O_2 content of 33 percent, corresponding to a value of 2.4 for the ratio of the permeability constants of O_2 and N_2. Von Elbe's stretched films, which had a thickness of only 0.00038 cm, possessed a permeability coefficient toward O_2 of 1.6×10^{-6} mole O_2 atmos.$^{-1}$ cm^{-2} min.$^{-1}$. Calculations based on these results indicated that a multistage permeation process for obtaining O_2 from air was economically unfavorable compared with the Linde process by a factor of about 2, with the possibility of major improvements if films of superior properties could be found. It was realized that, for possible practical use in effecting the separation of gases, films should have the following qualities: (1) high absolute permeability, to minimize the area of film required; (2) high selective permeability toward the desired gas, to reduce the power required for the separation; and (3) chemical and physical stability. Consideration of literature data[4,5] showed that many types of films probably would not be useful because of failure to satisfy the first requirement; among these were Cellophane, cellulose acetate, Nylon, polyvinyl chloride, polyvinylidene chloride, and rubber hydrochloride. It was considered desirable to test at least rubber, ethyl cellulose, polyethylene, and polystyrene.

EXPERIMENTAL PROCEDURE

The apparatus used to measure permeability was quite simple. A small Seitz bacterial filter was modified to hold the sample of film which was supported on one side by filter paper backed by 30-mesh wire screen. The exposed area of film was 18 sq. cm. In determining permeability to pure gases, the film holder, which was immersed in a thermostated water bath, was simultaneously evacuated on both sides of the film with a rotary oil pump. The pump was then closed off, the pure, dried gas was admitted on the unsupported side of the film to the desired pressure, and the rate of gas permeation was followed by measuring the rate of pressure increase in an enclosed volume on the supported (low pressure) side of the film with a tilting McLeod gauge (0–5 mm range). The enclosed volume on the low pressure side was calibrated so that the permeability could be expressed in standard units. Typical pressure-time curves, in this case for O_2 and N_2 through a 0.023 mm polyethylene film, are shown in Fig. 1.

The determination of pressure-time curves was convenient for the study of pure gases but not for gas mixtures. In several cases when gas mixtures were used, the composition of the permeated gas was determined by connecting the low pressure side of the film holder

directly to the intake of a mass spectrometer. The procedure was otherwise identical with that outlined. In some experiments with air, superatmospheric pressure (4 atmos.) was used, which resulted in the production of enough sample in 16 hours to permit analysis of the permeated gas by Orsat apparatus.

Most of the films studied were commercial films supplied by the manufacturer (see Table I). Films of ethyl cellulose and of rubber were also cast from solution in the laboratory with the use of Bird film-applicators. It was found possible to make a multiply drawn film of ethyl cellulose, having a total thickness of only 0.0075 mm (0.0003 in.), which did not show any leakage; i.e., the film maintained its selective permeability toward oxygen.

CALCULATION OF ENRICHMENT IN SINGLE STAGE

We assume the permeation of components A and B in a binary gas mixture to obey Fick's law, the rates of permeation of each component through the film area, $d\sum$, being

$$-dn_A=Q_A d\sum[P(n_A)/(n_A+n_B)-p(n_A')/(n_A'+n_B')]$$
$$-dn_B=Q_B d\sum[P(n_B)/(n_A+n_B)-p(n_B')/(n_A'+n_B')]. \quad (1)$$

P is the high pressure, p the low pressure, n_A and n_B the moles of A and B, respectively, flowing per unit time on the high pressure side, n_A' and n_B' the corresponding moles flowing on the low pressure side, and Q_A and Q_B the permeability coefficients (uncorrected for thickness) of A and B.

In the limiting case, where the composition of gas on the high pressure side is held equal to the inlet composition and the permeated gas is immediately removed by evacuation of the low pressure side, maximum enrichment of A is obtained (for $Q_A>Q_B$) and the ratio of molar flow rates for the components of the permeated gas is given by

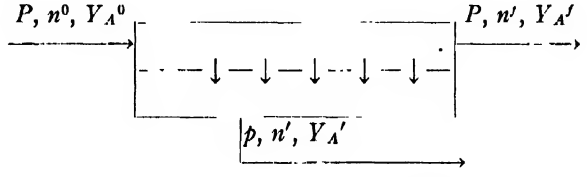
$$n_A'/n_B'=dn_A/dn_B=Q_A/Q_B\cdot n_A^0/n_B^0=\alpha n_A^0/n_B^0, \quad (2)$$

where $\alpha=Q_A/Q_B$ and n_A^0 and n_B^0 are the entering molar flow rates of A and B.

If a finite fraction of gas entering a stage permeates during that stage, the composition of the permeated gas depends on the nature of the flow conditions on the high and low pressure sides of the film. Only two extreme cases, corresponding to perfect mixing and to no mixing, will be considered.

Case I

Perfect mixing of gases occurs on both sides of the film. The conditions are represented by the following diagram.



n^0 moles of gas per unit time ($n^0=n_A^0+n_B^0$) of composition Y_A^0 [$Y_A^0=n_A^0/(n_A^0+n_B^0)$] enter the stage at pressure P. Leaving the stage per unit time, still at pressure P, are n' moles of unpermeated gas having a mole fraction of A equal to Y_A'. The n' moles of gas permeating per unit time at pressure p have the composition described by Y_A'. It is assumed that the rate of mixing on the high pressure side is so rapid, compared with the rates of flow, that the unpermeated gas has, at all points in the stage, the same composition as the unpermeated gas leaving the stage. In the steady state, the following equations of continuity and conservation must be satisfied:

$$n'Y_A'=Q_A\sum[PY_A'-pY_A'] \quad (3)$$
$$n'(1-Y_A')=Q_B\sum[P(1-Y_A')-p(1-Y_A')] \quad (4)$$
$$n^0=n'+n' \quad (5)$$
$$n^0Y_A^0=n'Y_A'+n'Y_A'. \quad (6)$$

Let $\alpha=Q_A/Q_B$, $\beta=n'/\sum Q_A$. From Eqs. (3) and (4) is obtained

$$Y_A'=\frac{\alpha-(P-p)/\beta}{\alpha-1}, \quad Y_A'=\frac{(\beta+p)[\alpha-(P-p)/\beta]}{P(\alpha-1)}$$
$$=(\beta+p)Y_A'/P. \quad (7)$$

Y^0 is assumed known, and in any particular case a

value of n'/n^0 may be assumed. Let $n'/n^0=\gamma$; by Eq. (5), $n'/n^0=1-\gamma$. From Eqs. (6) and (7),

$$Y_A{}^0=\gamma Y_A{}'+(1-\gamma)Y_A'$$

$$=\left[\frac{\gamma(\beta+p)}{P}+(1-\gamma)\right]\left[\frac{\gamma-(P-p)/\beta}{\gamma-1}\right]. \quad (8)$$

β is found by solution of this quadratic equation, all the other quantities being known; combination with (7) then gives Y_A'. This solves the problem, since the enrichment of A in the permeated gas is obtained from Y_A', and the area $\sum$ required to sustain an arbitrary rate of permeation is obtained from β.

Case II

Laminar flow (no mixing) occurs on either side of the film; the gas composition at any point on the low pressure side is given by the relative rates of permeation of the individual constituents at that point. From Eq. (1) there results

$$-dn_1=Q_A d\sum\left(P\frac{n_A}{n_A+n_B}-p\frac{dn_A}{dn_A+dn_B}\right) \quad (9)$$

and

$$-dn_B=Q_B d\sum\left(P\frac{n_B}{n_A+n_B}-p\frac{dn_B}{dn_A+dn_B}\right). \quad (10)$$

Let $x=dn_A/dn_B$, $i=n_A/n_B$, and $\alpha=Q_A/Q_B$; divide (9) by (10). Then

$$x=\alpha\left(P\frac{i}{i+1}-p\frac{x}{x+1}\right)\Big/\left(P\frac{1}{i+1}-p\frac{1}{x+1}\right). \quad (11)$$

Solution of this quadratic gives

$$x=f(i)=Ai+C+[A^2i^2+(2AC+\alpha)i+C^2]^{\frac{1}{2}}, \quad (12)$$

where

$$A=\tfrac{1}{2}[(1-\alpha)p/P+\alpha] \quad \text{and} \quad C=\tfrac{1}{2}[(1-\alpha)p/P-1].$$

Separation of variables in (12) can be achieved by noticing that $x=dn_A/dn_B=f(i)=f(n_1/n_B)$. Use of n_B and i as variables results in

$$\frac{dn_B}{n_B}=\frac{di}{f(i)-i}=\frac{di}{(A-1)i+C+[A^2i^2+2Bi+C^2]^{\frac{1}{2}}}, \quad (13)$$

where $2B=2AC+\alpha$. The right side of Eq. (13) can be rationalized by the introduction of a new variable t, defined by $i=\frac{1}{2}(C^2-t^2)/(At-B)$; the result is:

$$\ln\frac{n_B}{n_B{}^0}=-\int_{t^0}^{t}\frac{At^2-2Bt+AC^2}{(At-B)(t-\alpha+C)(t-C)}dt,$$

or

$$\ln\frac{n_B}{n_B{}^0}=R\ln\frac{t^0-B/A}{t-B/A}+S\ln\frac{t^0-\alpha+C}{t-\alpha+C}+T\ln\frac{t^0-C}{t-C}, \quad (14)$$

where $R=1/(2A-1)$, $S=[\alpha(A-1)+C]/(2A-1)[(\alpha/2)-C]$, and $T=1/(1-A-B/C)$; the superscript ^{0} designates entering gas. This solves the problem of determining the enrichment of the permeated gas for an arbitrary choice of n^0 $(=n_A{}^0+n_B{}^0)$, i^0, and i'; for a given $n_B{}^0=n^0/(1+i^0)$, n_B' is then found by Eq. (14), and n_A' is determined by $n_A'=i'n_B'$. The fraction of inlet gas which permeates is $(n^0-n')/n^0$; the fraction of A in the permeated gas is $(n_A{}^0-n_A')/(n^0-n')$.

It may be noted that the solution of Eq. (11) is particularly simple in the case $p=0$, for then $x=\alpha i$, or $dn_A/n_A=\alpha dn_B/n_B$, and

$$n_A/n_A{}^0=(n_B/n_B{}^0)^\alpha. \quad (15)$$

Computation of the permeation area required in Case II is somewhat involved. Assume there are no concentration gradients normal to the direction of gas flow. Use of Eqs. (12) and (13) in Eq. (11) then results in

$$\sum=-\frac{n_B{}^0}{Q_B}\int_{i^0}^{i'}\frac{\text{antiln}[n_B(i)/n_B{}^0]di}{[f(i)-i]\left[P\frac{1}{i+1}-p\frac{1}{f(i)+1}\right]}. \quad (16)$$

The integral on the right side is perhaps most conveniently evaluated numerically or graphically.

Because of the small magnitude of the permeability coefficients, it is probable that any practical design of a permeation process will involve flow conditions corresponding to Case II (laminar) rather than to Case I

(perfect mixing). It is interesting to note that, for a given set of conditions, Case II also results in a greater enrichment than does Case I. As an illustration, for the particular situation where normal air at 8 atmos. enters the stage and half of the entering air is permitted to permeate during the stage to the low pressure side at 1 atmos., the composition of the permeated air in Case I is 29.2 percent O_2, and in Case II 32.5 percent O_2. (A value of 3.4 was assumed for α.)

EXPERIMENTAL RESULTS

The permeability of various films toward O_2 and N_2, determined by experiments with the pure gases, is shown in Table I. The specific permeability, K, given is corrected for film thickness; $K=Qd$, where d is the thickness and Q is defined by Eq. (1). Where the comparisons are available, the specific permeability observed is seen to be in reasonable agreement with those previously reported. Of the materials investigated, natural rubber is outstanding in showing the highest permeability; its selectivity, however, as measured by the quantity $\alpha(\alpha=K_{O_2}/K_{N_2})$, is not as great as that of several other materials. Ethyl cellulose appears to satisfy best the joint requirements of high permeability and high selectivity.

Table II shows the permeability coefficients at 30°C of a laboratory-cast ethyl cellulose film toward the major constituents of air. Also shown is a comparison of the relative permeability (with respect to N_2) obtained from the pure gas studies and from the mass spectrometer analysis of air permeating through the film into a vacuum. The concentration of argon is increased along with that of O_2 in the permeated gas, though to a smaller extent than O_2. The permeability toward CO_2 is very high; in a multistage process to obtain high purity oxygen, it would probably be desirable to remove CO_2 after the first permeation stage.

The temperature dependence of the permeability of a 0.025-mm ethyl cellulose film toward several gases is illustrated in Table III. For each gas, the permeability increases with increasing temperature. The temperature dependence (and therefore the activation energy for permeation) is about the same for O_2, He, and H_2 but is greater for N_2. Van Amerongen[5] found a similar situation to hold for the same gases and natural rubber, N_2 having the highese activation energy for permeation and H_2, O_2, and He having lower and approximately equal activation energies. For the enrichment of air, a compromise has to be established between the use of higher temperatures to obtain higher permeability, and lower temperatures to obtain higher selectivity (α).

DISCUSSION

Primary consideration has been given above to a single stage of permeation. In the absence of a perfectly selective film, it is clear that to obtain gases of high purity it would be necessary to employ a multistage recycle system. The principles of such multistage arrangements have been discussed elsewhere.[7,8] Extension of the calculations given for a single stage to a multistage arrangement is straightforward but will not be considered here.

Since a practical permeation process probably would involve flow conditions leading to Eq. (14), calculation has been made of the enrichment of air to be expected from a single stage of permeation under a particular set of conditions. The high pressure has been chosen as 8 atmos., the low pressure as 1 atmos., and the enrichment factor $\alpha(=Q_{O_2}/Q_{N_2})$ as 3.4, the highest value which has been observed. Normal air (20.9 percent O_2) enters the stage. Under these conditions, Fig. 2 shows the composition of the permeated gas as a function of the fraction a of entering gas which permeates $[a=(n^0-n')/n^0]$. For negligible permeation ($a\doteq 0$), maximum enrichment of the permeated gas is observed, and the permeated gas contains 42.5 percent O_2. As $a\doteq 1$, the percent O_2 in the permeated gas approaches 20.9 percent, the inlet composition. For $a=0.5$, the permeated gas contains 32.5 percent O_2. Figure 2 is important for the computation of the net work required for the permeation, since the inlet air must be initially compressed by an imperfect compressor, and the energy of the nonpermeated, compressed gas leaving the stage must be utilized by some machine also of less-than-ideal efficiency.

It is clear from Table III that permeation processes may be of value for systems other than O_2-N_2. The usual separation of He from natural gas involves a relatively easy separation of He from CH_4 in one step, followed by a second step of more intense refrigeration to separate He from residual N_2. For the ethyl cellulose film of Table III, Q_{CH_4}/Q_{N_2} has been found to be about 1.5. The separation factor for He with respect both to N_2 and to CH_4 is quite large, which means that high enrichments can be achieved in each stage. Again, the permeability of ethyl cellulose to H_2 is much larger than to any other permanent gas with the exception of He. This has obvious applications, for example to the

separation of H_2 from coke-oven gas or from the tail-gases of various hydrogenation processes.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the suggestion of the problem and the continuing encouragement by Dr. H. H. Storch. Discussions with Dr. G. von Elbe and E. L. Clark have been most helpful. The authors wish also to thank Dr. R. A. Friedel and J. Sharkey for furnishing the mass-spectrometric analyses, and the companies listed in Table I for their generosity in furnishing samples of films.

D.C. Characteristics of Silicon and Germanium Point Contact Crystal Rectifiers. Part II. The Multicontact Theory*

V. A. Johnson, R. N. Smith,** and H. J. Yearian
Purdue University, Lafayette, Indiana

(Received August 29, 1949)

Part I has described the d.c. current-voltage characteristics obtained for typical Si and Ge crystal rectifiers, has given a summary of the published theories of the rectifier, and has shown that none of these theories accounts for the principal features of the observed characteristics. Part II describes the multicontact theory, an extension of the diode theory, and shows that this theory does account for the behavior of the observed characteristics. There also is described a graphical treatment, based upon the multicontact theory, which may be used in the analysis of experimental characteristics. The multicontact theory assumes that the contact potential at the metal-semiconductor surface varies from spot to spot. It is shown that an exponential distribution function for contact potentials may be used to account for the observed logarithmic slopes and that the observed temperature behavior of the characteristics may be explained by assuming that the distribution function varies with temperature in a manner dependent upon the nature of the contact.

1. INTRODUCTION

In Part I Yearian[1] has described the d.c. current-voltage characteristics obtained for typical silicon and germanium crystal rectifiers. A detailed knowledge of such characteristics and a complete theory of the rectifying behavior of such crystals have been the aim of extensive study in recent years because of the widespread use of silicon and germanium crystal rectifiers in microwave radar. Part I contains a summary of the heretofore published theories of the rectifier, and the discussion shows that none of these theories accounts for the salient features of the observed characteristics.

In Part II an extension of the diode theory, the multicontact theory, is described. It is shown that this theory does account for the essential properties of the observed characteristics. A graphical treatment based upon the multicontact theory is described and its application to the analysis of experimental characteristics is explained. The theory is used in a discussion of the observed change in characteristic for a given point contact with change in temperature of the contact region.

2. MULTICONTACT THEORY

It has been suggested (by Mott, Schottky, Lark-Horovitz, and Bethe) that the small slope of a typical observed log current *vs.* voltage characteristic may be due to a rapid variation in the properties of the blocking layer within the region of contact.[2] Since the thickness of the natural blocking layer is of the order of magnitude of the distance between impurity centers, it is quite probable that the contact potential at the surface of the semiconductor may vary from place to place. It is also likely that external impurities and adsorbed layers may produce fluctuations in contact potential.[3] The currents flowing across regions of low (negative or small positive) contact potential are essentially ohmic. In such regions the rate of change of current with applied voltage is much smaller than the exponential variation which occurs for higher contact potentials. The total current is the sum of the currents for regions of low and high contact potentials; hence, if the region of low contact potential is large enough in comparison to the region of high contact potential, the variation in total current with voltage rise is much less than the value predicted by pure diode theory for a contact with constant positive contact potential.

The multicontact theory assumes that the contact area consists of a number of spots, that the contact potential φ varies from spot to spot, and that the observed current is the sum of the contributions of

[2] Preliminary studies based upon the multicontact theory have been discussed by R. G. Sachs, NDRC Div. 14 Report No. 168, Purdue University (June 15, 1943); Phys. Rev. **69**, 682 (1946).

[3] For a different approach to the problem of how surface imperfections, foreign atoms on the surface, etc., may affect rectification, see John Bardeen, "Surface states and rectification at a metal semiconductor contact," Phys. Rev. **71**, 717 (1947).

the partial currents from these spots. The number of spots may be considered to be quite small with discretely separated contact potentials; in this case a graphical treatment of the summation is convenient. Or, a continuous distribution may be assumed such that the probability of finding a given contact potential between φ and $\varphi+d\varphi$ can be represented by a continuous probability density which is a function of φ, and so that the area of the spot having contact potential φ can also be represented as a probability function of φ. The spreading resistance in series with each spot is taken as $(2\sigma d)^{-1}$, where σ is the bulk conductivity of the semiconductor and d is the spot diameter. It follows that the spreading resistance is a function of φ determined by the dependence of spot area upon φ.

A graphical study shows that the addition of diode type currents for a group of spots corresponding to very few (three or four) different contact potentials produces a total current which is closely exponential, or linear on a semilogarithmic plot, over an appreciable voltage range. Any value of the logarithmic slope, less than e/kT, may be obtained by a suitable choice of the parameters governing the distribution. The graphical treatment is extended to provide a method whereby a total current curve may be rapidly synthesized to fit any given experimental characteristic.

One assumes that the contact consists of a number of small diodes, each with its own spreading resistance in series. These diodes are effectively in parallel, and so the total current is given by

$$i=\sum_j i_j, \tag{1}$$

where

$$i_j=j_0 a_j(\varphi_j)n_j(\varphi_j)\exp(-e\varphi_j/kT) \times[\exp\{(e/kT)(V_a-i_jR_{sj})\}-1] \tag{2}$$

is the current flowing through all spots for which the contact potential is φ_j. V_a is the applied voltage; j_0 denotes the current density due to the N free electrons (or holes) per unit volume in the semiconductor traveling with mean thermal velocity:

$$j_0=Ne\bar{v}/4=Ne(kT/2\pi m)^{\frac{1}{2}} \tag{3}$$

$a_j(\varphi_j)$ is the area of each spot having contact potential φ_j, and $n_j(\varphi_j)$ is the number of spots having contact potential φ_j. The spreading resistance R_{sj} for all spots with contact potential φ_j is calculated by considering the spreading resistances of such spots to be in parallel with one another. Then

$$R_{sj}=(\pi/a_j)^{\frac{1}{2}}(4\sigma n_j)^{-1}. \tag{4}$$

A template of a master curve (Fig. 1) to be used in the analysis of experimental characteristics, in the forward direction with $V_a>0.1$ volt, may be designed as follows: Using semilogarithmic paper with the same choice of scales as is made in plotting the experimental log$i$ *vs.* V_a characteristics, draw a straight line with logarithmic slope e/kT, i.e., the characteristic of a diode of single contact potential and zero spreading resistance. Choose an arbitrary value for the spreading resistance, compute the corresponding potential drops in the spreading resistance for a series of current values, and plot the characteristic of log$i$ *vs.* V_a, using the relation $V_a=V+R_{sj}i$. Mark on the template the point at which the iR_{sj} potential drop has a known value, such as 0.01 volt. This template may be used to reproduce the current-voltage curve for any diode of any φ_j; R_{sj} refers to the local series spreading resistance rather than to the equivalent spreading resistance of the whole contact.

In order to analyze a given experimental characteristic, by trial and error slide the template into several positions such that the sum of the partial currents so obtained closely approximates the given curve. Each partial current corresponds to a group of spots on the contact having the same contact potential, φ_j. The simplest numerical interpretation of the partial currents is made by assuming $a_j(\varphi_j)$ to be a constant with a reasonable value such as $a=10^{-10}$ cm^2. Then φ_j and $n_j(\varphi_j)$ may be evaluated as follows: Let i_j' represent the value of the partial current for which the potential drop in the spreading resistance is 0.01 volt, i.e., i_j' is the current at the index mark on the template. Then $R_{sj}=(100i_j')^{-1}$ ohm. Extend the low voltage straight

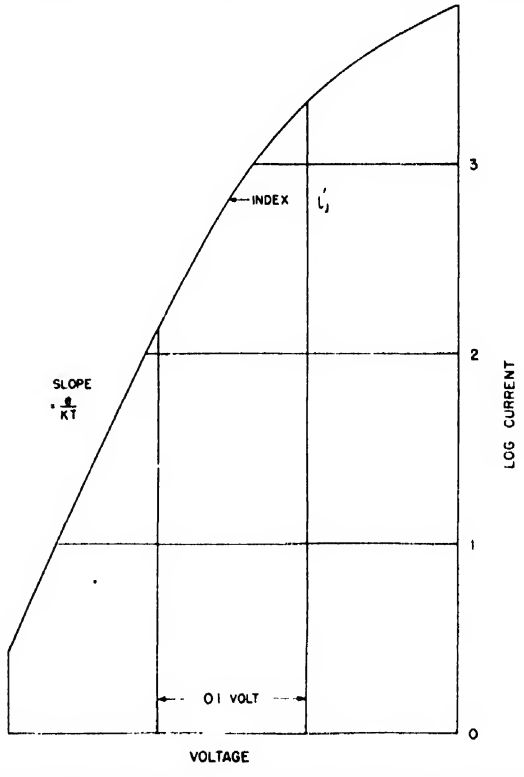

FIG. 1. Multicontact potential template such as is used in the analysis of experimental characteristics in the forward direction (applied voltage>0.1 volt). The index mark indicates the point on the characteristic for which the potential drop in the spreading resistance is 0.01 volt.

portion of the partial current back to find its intersection, i_{j0}, with the $V_a=0$ axis. Eq. (2) indicates that

$$i_{j0}=j_0 a n_j \exp(-e\varphi_j/kT). \qquad (2')$$

When σ and j_0 are known from resistivity and Hall effect measurements on the semiconductor, n_j may be computed by use of Eq. (4) and then Eq. (2') is used to determine φ_j. The product an_j represents the total area of the spots having contact potential φ_j. The choice of a different value for the area a will yield different values for the n_j, but the distribution of total areas (an_j) over the φ_j values will be much the same.

Figure 2 illustrates the application of the graphical method just described to the analysis of the characteristic obtained for contact in vacuum between a tungsten whisker and a germanium sample prepared in vacuum.[4] It is found that the observed characteristic may be treated as due to three groups of spots with $\varphi_j=0.1$, 0.4, and 0.8 volt, respectively.

Analogous templates and equivalent treatments may be designed for the analysis of experimental characteristics in the back direction and in the forward direction for $V_a<0.1$ volt.

It is to be noted that, in a construction of the type illustrated by Fig. 2, the chief contribution by a spot of contact potential φ_j to the approximately linear portion of the total current curve is made only over a range of V_a in the immediate neighborhood of φ_j. This affords an interpretation of any abnormal characteristic curve; e.g., if the curve of Fig. 2 were slightly concave upward in the region about $V_a=0.4$ volt, there would be a corresponding decrease in the total area corresponding to "B" spots. It is evident that, if the observed current-voltage curve is linear (on semilogarithmic plot) over a considerable range, the distribution of numbers of spots (for the simplest case of assumed constant area) must cover a similar range of φ and that, to obtain the linear total curve, the value of n_j must increase very rapidly with increasing φ_j.

The forward current intercept I_F is determined almost completely by the spots for which φ_j is greater than about 0.05 to 0.1 volt, and it may be seen that I_F is necessarily larger than the sum of the i_{j0} intercepts of the partial currents, $\sum_j i_{j0}$, where i_{j0} is given by Eq. (2). This sum is the contribution of these spots to the limiting diode current in the back direction. Thus one expects the observed diode back current I_B to be less than I_F. This is usually the case (Part I). The sum may be increased to give an I_B approaching I_F by introduction of spots of very low φ_j; this will affect I_F and the logarithmic slope α only slightly, but it will contribute noticeably to the observed diode current in the back direction. The ohmic component of the current in the back direction can be reproduced by any suitable distribution of spots having negative contact potentials; for such spots there is no barrier and only

[4] This figure and its analysis were supplied by Dr. R. M. Whaley of Purdue University; the authors thank him for this courtesy.

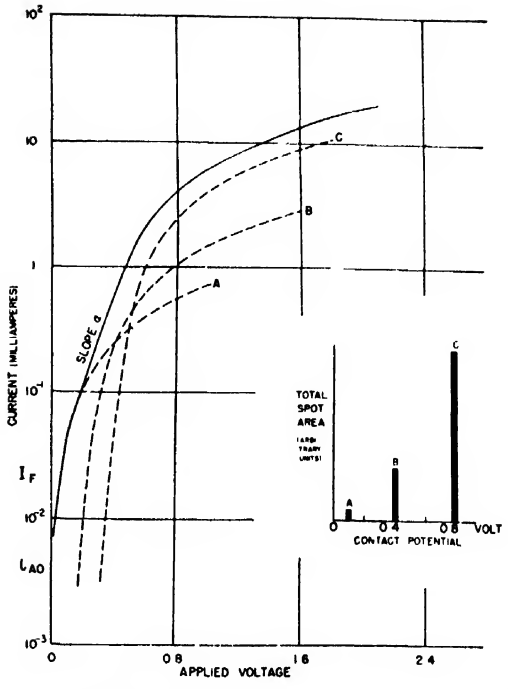

FIG. 2. Application of the multicontact theory to the analysis of an experimental characteristic. The solid line, indicating the experimental curve, is synthesized in a non-unique manner from three partial currents, A, B, and C, which correspond to three discrete contact potential groups. The insert indicates the distribution of spot area among the contact potentials 0.1, 0.4, and 0.8 volt, respectively.

R_{sj} need be considered. The observed back resistance usually can be accounted for by the existence of a very small total area of spots with negative φ_j. If the barrier lowering due to image force and tunneling effects (Part I) is considered, the spots of very small positive contact potenial will also be essentially ohmic in nature for current in the back direction.

3. EXPONENTIAL DISTRIBUTION

If a distribution function $P(\varphi)$ is introduced to describe the dependence of spot area upon contact potential, it is found that the theoretical current-voltage characteristic calculated with the use of such a distribution is essentially independent of the details of the function $P(\varphi)$. Only the tail of the distribution function at low contact potentials influences the shape of the characteristic in that part of the voltage range which is of practical interest. Hence it is not possible to determine the shape of the entire distribution function by use of an experimental characteristic. Since the theoretical characteristic depends only upon the tail of the distribution, one is free to choose a distribution function primarily on the basis of convenience in calculation. An exponential type distribution function is simple and convenient to use.

Hence it is assumed that

(1) The spot area depends upon φ_j according to

$$a(\varphi_j)=a_0 \exp(q\varphi_j). \qquad (5)$$

(2) The number of spots having contact potential φ_j is given by

$$n(\varphi_j)=n_0\exp(p\varphi_j). \tag{6}$$

p and q are parameters which may be chosen to fit experimental data.

(3) Insertions of Eqs. (5) and (6) into Eq. (4) yields for the spreading resistance due to all spots having contact potential φ_j:

$$R_{sj}=(4\sigma n_0)^{-1}(\pi a_0)^{-\frac{1}{2}}\exp(-p\varphi_j-q\varphi_j/2). \tag{7}$$

Equation (2) may now be written

$$i_j=n_0a_0j_0\exp\{(p+q-e/kT)\varphi_j\}\times[\exp(e/kT)(V_a-R_{sj}i_j)-1]. \tag{8}$$

If V_a is greater than about 0.1 volt, the -1 in the last bracket may be neglected, and Eq. (8) becomes

$$i_j=n_0a_0j_0\exp\{eV_a/kT-(e/kT-p-q)\varphi_j-R_{sj}i_j\}. \tag{9}$$

Figure 3 illustrates the construction of a total current curve by the summation of partial currents as given by Eq. (9) with $p=20$ volt^{-1} and $q=0$. Such a construction yields a total current curve which is straight over an appreciable range on a semilogarithmic plot and which is parallel to the envelope of the partial current curves. The logarithmic slope of the envelope can be shown to be

$$\alpha=\frac{p+q/2}{e/kT-q/2}\,\frac{e}{kT}\ \text{volt}^{-1};\quad (p+q)\gg e/kT. \tag{10}$$

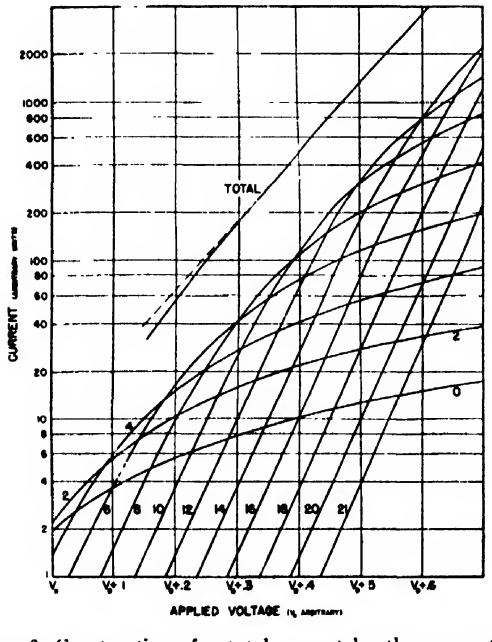

FIG. 3. Construction of a total current by the summation of partial currents. In this case the spot area is taken as constant and the number of spots having contact potential φ-volts is taken as $n_0\exp(20\varphi)$. The partial currents identified by $k=0, 2, \cdots$ are to be identified as passing through spots having $\varphi=\varphi_0+k/40$ volts, where φ_0 is an arbitrary contact potential.

By suitable choice of p and q, any value of α between 0 and e/kT may be obtained. The magnitude of i, but not the slope of the characteristic, depends upon constants of the material, such as σ, j_0, a_0, and n_0.

The assumptions used in the preceding analysis are the basis for the following theoretical treatment in which continuous distribution functions are employed. The dependence of spot area on contact potential is written

$$a(\varphi)=a_0\exp(q\varphi). \tag{11}$$

The number of spots having contact potential between φ and $\varphi+d\varphi$ is given by

$$n(\varphi)d\varphi=n_0\exp(p\varphi)d\varphi. \tag{12}$$

The spreading resistance due to all spots having contact potential φ is

$$R_s(\varphi)=(\pi/a_0)^{\frac{1}{2}}(4\sigma n_0)^{-1}\exp(-p\varphi-q\varphi/2). \tag{13}$$

Equations (11)–(13) may be used to set up an expression for the current in the forward direction. It is considered that the tendency is for diode type currents to flow through spots for which φ is positive and for ohmic currents to flow through spots for which φ is negative. These tendencies are restricted by the fact that the current density flowing through any group of spots is limited to the current density j_0 due to N electrons per unit volume traveling with thermal velocity. Reference to Eq. (2) for a diode type current shows that the current density cannot exceed j_0 if $\varphi>V$, but the current density will exceed j_0 if $\varphi<V$ unless some restriction is introduced. In order to conveniently express the total forward current, it is assumed that if V is large enough to produce the limiting current through a given group of spots, then further increase in V does not change the current. Since the current through a single spot is limited to $j_0a(\varphi)$, the corresponding potential drop in the spreading resistance in series with this spot is $j_0\{\pi a(\varphi)\}^{\frac{1}{2}}/4\pi\sigma$. This quantity has a small magnitude (usually less than 0.01 volt) and so the $iR_s(\varphi)$ drop may be neglected without serious error. V is assumed to be large enough ($\gg kT/e$) so that one may replace $\{\exp(eV/kT)-1\}$ by $\exp(eV/kT)$. Then the forward current ($V>0$) becomes

$$i(V)=j_0a_0n_0\exp(eV/kT)\times\int_V^\infty\exp\{-(e/kT-p-q)\varphi\}d\varphi+j_0a_0n_0\int_{-\infty}^V\exp\{(p+q)\varphi\}d\varphi \tag{14}$$

$$=\frac{j_0a_0n_0}{\alpha(e/kT-\alpha)}\,\frac{e}{kT}\exp(\alpha V),$$

where $\alpha=p+q$. By setting $V=0$ in Eq. (14) one ob-

TABLE I. Values obtained from study of the d.c. characteristics at various temperatures for germanium crystals in contact with tungsten whiskers. Columns 2, 3, 4, 5, and 7 give measured slopes, intercepts, and back resistances. Columns 6 and 7 permit checking the predicted relation $I_B = sI_F$. Columns 8, 9, and 10 list bulk properties of the germanium samples. Columns 11, 12, and 13 give calculated quantities characteristic of the exponential distribution used in applying the multicontact theory to these samples.

tains the forward current intercept

$$I_F = \frac{j_0 a_0 n_0}{\alpha(e/kT-\alpha)} \frac{e}{kT}. \tag{15}$$

The diode type current in the back direction is due to all spots having positive contact potentials. Current limitation need not be considered because of the smallness of the diode current for $V<0$, and for the same reason the $R_s i$ potential drop may be neglected. Then the diode current in the back direction ($V<0$) becomes

$$i(V) = j_0 a_0 n_0 \{\exp(eV/kT)-1\} \times \int_0^\infty \exp\{-(e/kT-p-q)\varphi\} d\varphi$$

$$= \frac{j_0 a_0 n_0}{e/kT-\alpha} \{\exp(eV/kT)-1\}. \tag{16}$$

The magnitude of the limiting current in the back direction is found by letting $V \to -\infty$; hence

$$I_B = j_0 a_0 n_0 (e/kT-\alpha)^{-1}. \tag{17}$$

The ohmic current in the back direction is due to all spots having negative contact potentials. The resistance in the back direction is given by

$$1/R_B = 4\sigma n_0 (a_0/\pi)^{\frac{1}{2}} \int_{-\infty}^0 \exp\{(p+q/2)\varphi\} d\varphi$$

$$= 4\sigma n_0 (a_0/\pi)^{\frac{1}{2}} (p+q/2)^{-1}. \tag{18}$$

The value of the quantity $n_0 a_0$ may be found directly from either Eq. (15) or Eq. (17); Eq. (15) is preferable because I_F is usually determined with greater accuracy than I_B. A consistency test for the theory is provided by the fact that the values of $n_0 a_0$ obtained by use of Eqs. (15) and (17) should agree within limits dependent upon the experimental errors in the values of I_F and I_B. These values of $n_0 a_0$ will be equal if

$$I_B = sI_F, \tag{19}$$

where s is the fractional slope $\alpha kT/e$. Table I shows corresponding values of I_B and sI_F, which are found to agree in order of magnitude. For the same reasons as given in the discussion on the discrete distribution of spots of various contact potentials, I_F is determined by only the spots for which the contact potential is greater than about 0.1 volt, whereas I_B is increased by the presence of spots of lower positive contact potential. Hence I_B may exceed the value given in Eq. (19). In addition, the effect of barrier lowering on the spots of low contact potential tends to increase the measured value of I_B.

The maximum value of $n_0 a_0^{\frac{1}{2}}$ may be calculated from Eq. (18) by setting $q=0$; the minimum value of $n_0 a_0^{\frac{1}{2}}$ is one-half of the maximum value and corresponds to setting $p=0$. A combination of $n_0 a_0$ and $n_0 a_0^{\frac{1}{2}}$ values yields values for a_0 and n_0; such values are listed in Table I.

In general the values of $n_0 a_0$ are reasonable, i.e., they are small compared to the total whisker area of 10^{-6} to 10^{-5} cm^2. There is a noticeable tendency for $n_0 a_0$ values to increase with rising temperature. At the lower temperatures the a_0 values tend to exceed the $n_0 a_0$ values, thus yielding fractional values for n in the neighborhood of zero contact potentials. Such a result is contradictory to the basic assumption of a statistical distribution of a very large number of spots.

One possible explanation of the small n_0 values is that the assumed exponential distribution may not be valid in the region of negative contact potential. The back resistance determines the value of

$$\int_{-\infty}^0 n(\varphi)\{a(\varphi)\}^{\frac{1}{2}} d\varphi$$

and, for any assumed distribution, the value of $n_0 a_0^{\frac{1}{2}}$.

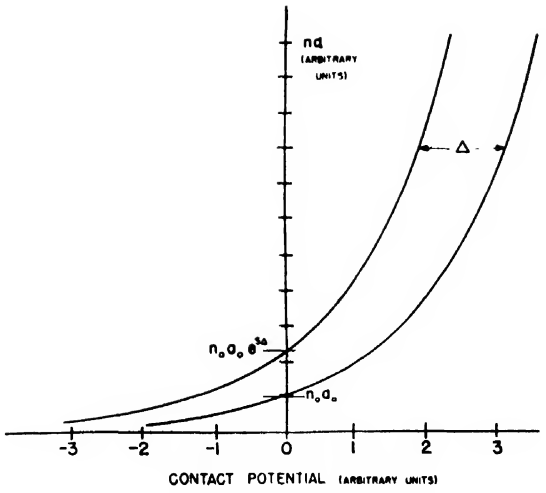

FIG. 4. Effect of temperature change upon the distribution function for "welded" contacts. Ordinates represent the contact areas corresponding to various contact potentials.

A distribution falling off more rapidly with increasing negative φ than an exponential distribution leads to a larger value of $n_0a_0^3$ for a fixed n_0a_0. This produces a smaller calculated value of a_0 and hence a larger value of n_0, as is desired.

A second explanation is that the effective conductivity of the small ohmic spots is less than the measured bulk conductivity of the sample. Then a_0 is less in proportion as σ^2 drops below the bulk value. Weisskopf[5] has advanced the hypothesis that the small spots with negative contact potential may be "overloaded" and that "overloading" decreases the effective conductivity. The exponential dependence of spot area on contact potential may lead, for negative φ, to spot diameters equal to or smaller than the electronic mean-free-path in the semiconductor; Lark-Horovitz has pointed out that in such a case a reduction in conductivity is to be expected.

A section of Part I described the effect of image force and tunneling in producing a barrier lowering in the point contact rectifier. A quantitative introduction of barrier lowering into the diode rectifier theory has been made by Courant.[6] Since the multicontact theory is based upon the diode theory, calculations have been made to ascertain the effects of introducing barrier lowering into the multicontact theory. For the forward direction the changes are small and may be summarized as follows: (1) at high voltage the logarithmic slope is constant at the same value given by the multicontact theory without barrier lowering, but at lower voltages (less than about 0.4 volt) the logarithmic slope with lowering considered decreases slightly with decreasing voltage; (2) for a fixed n_0a_0 value the current calculated with barrier lowering considered is greater than the current at the same voltage without lowering; the factor varies from 1.0 to 1.2, increasing with increasing α; (3) for a fixed n_0a_0 value one obtains a higher I_F intercept on the theoretical curve including barrier lowering; I_F is higher by about 5 percent to 20 percent, depending upon α. Another way of stating this result is to say that, for an I_F value taken from a measured characteristic, one calculates on the basis of barrier lowering a value for n_0a_0 that is from 5 percent to 20 percent lower than he would obtain by neglecting barrier lowering.

Since the effect of tunneling alone is to give rectification in the opposite direction from the observed direction, one would expect the inclusion of tunneling, through barrier lowering, in the multicontact theory to give rather marked effects in the back direction characteristic. Such is found to be the case; both the ohmic and diode contributions as calculated without barrier lowering are altered. The back resistance corresponding to the ohmic current is considerably reduced and hence the ohmic current considerably increased. The diode contribution is markedly changed; the extent of the change depends upon the electron concentration with the change greatest for the highest concentration. The tunneling produces an exponentially increasing current that, at higher voltages, has a logarithmic slope equal to or even greater than the forward slope. This exponential current tends to cover up the saturation current, denoted by I_B. The tendency is for the ohmic current to dominate at the lower back voltages; the extent of barrier lowering determines the voltage at which the exponential current surpasses the ohmic current.

The barrier lowering calculations of Courant assume an electron concentration of 5×10^{18} cm^{-3}; the use of these results in the multicontact theory yields calculated back currents too high to agree with experiment. The agreement would be improved by noting that the actual electron concentrations in germanium and silicon point contact rectifiers are one or two orders of magnitude less than that assumed by Courant, and hence the effect of barrier lowering would not be as great as calculated by Courant.

4. TEMPERATURE BEHAVIOR

In Part I a description was given of the changes in characteristic observed for a given contact as the temperature is varied. Sets of characteristics for different temperatures were obtained both for "free" contacts between tungsten whiskers and germanium and for "welded" contacts between whisker and germanium in General Electric cartridges. The temperature behavior of α is dependent upon the type of contact. For free contacts, α decreases with increasing temperature in such a way that the fractional slope is approximately constant. For welded contacts, the value of α is prac-

[5] V. F. Weisskopf, Radiation Laboratory Report 133 (May, 1943).

[6] E. Courant, NDRC Div. 14, Cornell University Report, Contract OEMsr-429 (May 17, 1943); Phys. Rev. 69, 684 (1946). A report of Courant's results is given in a paper by W. E. Meyerhof, Phys. Rev. 71, 727 (1947).

tically independent of temperature. Figures of Part I show that the back resistance R_B decreases with increasing temperature and that the forward intercept I_F and limiting diode current in the back direction, I_B, increase with rising temperature. The plot of $\log R_B$ against temperature can be represented by a straight line of negative slope; the plots of $\log I_F$ and $\log I_B$ against T can be approximated by straight lines of positive slope.

Equation (14) shows that the forward logarithmic slope α is equal to the sum of the distribution parameters p and q, and so α determines the shape of the distribution. The constancy of α with changing temperature for the "welded" contacts suggests that the shape of the distribution is independent of T for these contacts, but the dependence of R_B, I_F, and I_B on T implies that the distribution has some type of temperature dependence. Assume that, although the shape of the distribution curve is unchanged, the whole curve is shifted by an amount Δ depending upon the temperature change. Let φ' be contact potential, at the new temperature, corresponding to the ordinate of the distribution curve at φ at the original temperature (see Fig. 4). Then

$$\varphi' = \varphi - \Delta. \tag{20}$$

Introducing this assumption into Eqs. (14), (16), and (18) yields

$$I_F' = \frac{j_0' a_0 n_0}{\alpha(e/kT' - \alpha)} \frac{e}{kT'} \exp(\alpha\Delta) \approx I_F \exp(\alpha\Delta) \tag{21}$$

$$I_B' = j_0' a_0 n_0 (e/kT' - \alpha)^{-1} \exp(\alpha\Delta) \approx I_B \exp(\alpha\Delta) \tag{22}$$

$$R_B' = (\pi/a_0)^{\frac{1}{2}} (4\sigma' n_0)^{-1} (\alpha - q/2) \exp\{-(\alpha - q/2)\Delta\}$$
$$\approx R_B \exp\{-(\alpha - q/2)\Delta\}. \tag{23}$$

The introduction of the shift Δ makes it possible to treat n_0 and a_0 as temperature independent in Eqs. (21), (22), and (23). If j_0 is taken as proportional to $T^{\frac{1}{2}}$, the temperature dependence predicted by Eq. (21) is

$$(T')^{\frac{1}{2}}(e/kT' - \alpha) I_F' \sim \exp(\alpha\Delta).$$

Plots against T of $\log I_F'$ and $\log\{(T')^{\frac{1}{2}}(e/kT' - \alpha) I_F'\}$ give lines of equal slopes and so justify the use of the simpler expression. As shown in Part I, the plots of $\log I_F'$, $\log I_B'$, and $\log R_B'$ against T are quite straight over a considerable temperature range. This suggests the relation

$$\Delta = B(T' - T) \tag{24}$$

that is, the distribution curve is shifted laterally by an amount proportional to the temperature change. A change in temperature shifts the distribution so that the total area corresponding to negative contact potential increases with rising temperature. The value of B may be found from the known values of α and of the slopes of $\log I_F'$ *vs.* T and $\log I_B'$ *vs.* T lines. For the welded samples, $B = 1.1$–1.2 millivolts per degree as determined from the I_F plot and $B = 1.8$–2.0 mv per degree from the I_B plot.

The foregoing discussion does not apply to free contacts. Since the value of α decreases with rising temperature, the shape of the distribution curve changes and p and q are functions of temperature. The approximately constant value of the fractional slope implies that α, p, and q are inversely proportional to T. In order to explain the temperature behavior of the characteristics for free contacts, one must assume that the distribution curve for φ is not only shifted but is also flattened as the temperature rises.

5. SUMMARY

In conclusion, one can say that (1) the multicontact theory accounts for the frequently observed forward logarithmic slopes much less than e/kT, and for the diode and ohmic components of current in the back direction, (2) a distribution of spots with discrete contact potentials can readily be found such that it will yield any given observed characteristic; although such a discrete distribution is non-unique, it is useful in interpretation of the given characteristic, (3) an exponential distribution function, with parameters determined by experimental values, is satisfactory and convenient, and (4) the observed temperature behavior may be accounted for by assuming that the distribution function varies with temperature in a manner dependent on the nature of the contact. It should be noted that the treatment just described is incomplete in the sense that the constants of the distribution may be found empirically from the observed characteristics, but the constants cannot be determined by independent physical reasoning.

Analysis of a Sampling Servo Mechanism

KENNETH S. MILLER* AND RALPH J. SCHWARZ†
Columbia University, New York, New York
(Received October 3, 1949)

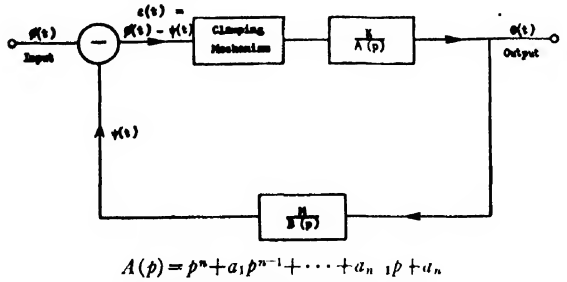
An analysis of a sampling servo mechanism with an error-clamping device and linear forward and return paths is given. The method leads to a determination of the continuous output of the system in terms of quadratures and gives explicitly the value of the output at the discrete sampling instants. Frequently this is all that is needed in order to study the output variation with time. The question of stability is discussed and a criterion for testing the stability of the system is given in terms of the system parameters.

I. INTRODUCTION

IN a large class of servo mechanisms, error data are supplied continuously, the error being a measure of the instantaneous deviation of some function of the output from the input. In another important class of servos, called sampling servo mechanisms,[1,2] error data are supplied at discrete, equally spaced instants only. The servo mechanism is then given no information about the error in the intermediate periods. Such systems may be analyzed by using the theory of filters with pulsed data.[3]

In many applications, the error data, supplied only at discrete sampling instants, are passed through a device whose output at any time is equal to the input at the preceding sampling instant. Such a mechanism is called a "clamping device." The output of the error-clamping device is thus constant for a period equal to the interval between sampling instants. This interval will be called the sampling period, T_s. Sampling occurs at the instants $t=0, T_s, 2T_s, \cdots, NT_s, \cdots$.

The mathematical analysis below is carried out by employing the "one-sided Green's function." Using this and associated concepts, explicit relations are derived for the error, response to a step input, and asymptotic value of the output; further, a stability criterion is formulated. The output is a continuous function of time, and an integral representation is obtained. An explicit formula, however, can be given for the output at the sampling instants.



$A(p)=p^n+a_1p^{n-1}+\cdots+a_{n-1}p+a_n$
$B(p)=p^m+b_1p^{m-1}+\cdots+b_{m-1}p+b_m$

FIG. 1. Sampling servo system.

II. MATHEMATICAL ANALYSIS

1. Introduction

The feed-back system which is to be operated as a sampling servo mechanism in the sense of the definition given in Section I is illustrated in Fig. 1. $A(p)$ and $B(p)$ are polynomials in p with constant coefficients. p is the differential operator d/dt. Explicitly,

$$A(p)=p^n+a_1p^{n-1}+\cdots+a_{n-1}p+a_n \tag{1}$$

$$B(p)=p^m+b_1p^{m-1}+\cdots+b_{m-1}p+b_m. \tag{2}$$

K and M are constants and

$$R=KM$$

is defined as the "loop gain."

It will be assumed that the system is initially unexcited. This implies that

$$\psi^{(\alpha)}(0)=0, \quad \alpha=0, 1, \cdots, m+n-1 \tag{3}$$

where $\psi(t)$ is defined in Fig. 1.

In accordance with Fig. 1,

$$A(p)\theta(t)=K\cdot\epsilon(t) \tag{4}$$

and

$$B(p)\psi(t)=M\cdot\theta(t).$$

Hence

$$A(p)B(p)\psi(t)=MK\cdot\epsilon(t)\equiv R\cdot\epsilon(t). \tag{5}$$

Since the initial conditions (3) have been specified, the inverse operator $[A(p)B(p)]^{-1}$ is well defined. In fact,

$$\psi(t)=\int_0^t G(t,\zeta)[R\cdot\epsilon(\zeta)]d\zeta \tag{6}$$

where $G(t,\zeta)$ is the "one-sided Green's function" for the incompatible system[4]

$$\left.\begin{aligned} &A(p)B(p)\psi(t)=0 \\ &\psi^{(\alpha)}(0)=0, \quad \alpha=0, 1, \cdots, m+n-1 \end{aligned}\right\} \tag{7}$$

and is given by

$$G(t,\zeta)=(-1)^{m+n-1}\frac{\begin{vmatrix}\phi_1(t) & \phi_2(t) & \cdots & \phi_{m+n}(t)\\ \phi_1(\zeta) & \phi_2(\zeta) & \cdots & \phi_{m+n}(\zeta)\\ \phi_1'(\zeta) & \phi_2'(\zeta) & \cdots & \phi_{m+n}'(\zeta)\\ \cdots & \cdots & \cdots & \cdots\\ \phi_1^{(m+n-2)}(\zeta) & \phi_2^{(m+n-2)}(\zeta) & \cdots & \phi_{m+n}^{(m+n-2)}(\zeta)\end{vmatrix}}{\begin{vmatrix}\phi_1(\zeta) & \phi_2(\zeta) & \cdots & \phi_{m+n}(\zeta)\\ \cdots & \cdots & \cdots & \cdots\\ \phi_1^{(m+n-1)}(\zeta) & \phi_2^{(m+n-1)}(\zeta) & \cdots & \phi_{m+n}^{(m+n-1)}(\zeta)\end{vmatrix}}. \tag{8}$$

In this determinant, $\phi_\alpha(t)$, $\alpha=1, 2, \cdots, m+n$, are $m+n$ linearly independent solutions of $A(p)B(p)\psi(t)=0$.

It should be noted that no loss of generality results by considering R a constant. For if R were a polynomial in p,

$$R\equiv R(p)=p^q+c_1p^{q-1}+\cdots+c_{q-1}p+c_q \tag{9}$$

then

$$R(p)\epsilon(t)\equiv c_q\epsilon_{N-1}$$

in any sampling interval $(N-1)T_s<t\leqq NT_s$ since $\epsilon(t)$ is a "staircase function" (see Section I). Also, it is permissible to use a "one-sided Green's function" instead of the more familiar "two-sided" one[4] since symmetric properties of the integral operator of Eq. (6) are of no interest in this paper.

Since the operator $A(p)B(p)$ has constant coefficients, the linearly independent solutions $\phi_\alpha(t)$ are of the form

$$\phi_\alpha(t)=t^re^{st}, \quad \alpha=1, 2, \cdots, m+n. \tag{10}$$

It will now be assumed that the $m+n$ roots, v_α, $\alpha=1, 2, \cdots, m+n$ of the characteristic equation for $A(p)B(p)$ are all distinct and non-zero. The analysis of cases not in this category will be readily apparent from the treatment given here.

With this assumption,

$$\phi_\alpha(t)=e^{v_\alpha t}, \quad \alpha=1, 2, \cdots, m+n. \tag{11}$$

Substituting these values of $\phi_\alpha(t)$ in the Green's function, Eq. (8), yields

$$G(t,\zeta)=(-1)^{m+n}\sum_{\beta=1}^{m+n}(-1)^\beta e^{v_\beta t}e^{-v_\beta\zeta}W_\beta W^{-1} \tag{12}$$

where W is the Vandermonde determinant[5]

$$W=\begin{vmatrix}1 & 1 & \cdots & 1\\ v_1 & v_2 & \cdots & v_{m+n}\\ \cdots & \cdots & \cdots & \cdots\\ v_1^{m+n-1} & v_2^{m+n-1} & \cdots & v_{m+n}^{m+n-1}\end{vmatrix}=\prod_{\substack{\alpha,\beta=1\\ \alpha>\beta}}^{m+n}(v_\alpha-v_\beta) \tag{13}$$

and W_β is the minor of the element in the last row and β^{TH} column of W.

$$W_\beta=\prod_{\substack{i,j=1\\ i>j\\ i,j\neq\beta}}^{m+n}(v_i-v_j), \quad \beta=1, 2, \cdots, m+n. \tag{14}$$

2. The Linear Recurrent Relation for $\epsilon(t)$

Since $\epsilon(t)$ is a staircase function, the value of $\psi(t)$ at the sampling instant $t=NT_s$ is

$$\psi(NT_s)\equiv\psi_N=R\sum_{\alpha=0}^{N-1}\epsilon_\alpha\int_{\alpha T_s}^{(\alpha+1)T_s}G(NT_s,\zeta)d\zeta \tag{15}$$

where $\epsilon(t)=\epsilon_\alpha$ for $\alpha T_s<t\leqq(\alpha+1)T_s$. Introducing the notation

$$\left.\begin{aligned}&\omega_\beta=e^{v_\beta T_s}\\ &X_\beta=(-1)^{m+n+\beta}W_\beta W^{-1}(1-\omega_\beta^{-1})v_\beta^{-1}\end{aligned}\right\} \quad \beta=1, 2, \cdots, m+n, \tag{16}$$

Eq. (15) becomes, after a few simple algebraic reductions,

$$\psi_N=R\sum_{\alpha=0}^{N-1}\epsilon_\alpha\sum_{\beta=1}^{m+n}X_\beta\omega_\beta^{N-\alpha}, \quad \beta=1, 2, \cdots, m+n. \tag{17}$$

Letting

$$Z_{j,\nu}=\sum_{\alpha=0}^{\nu-1}\epsilon_\alpha\omega_j^{-\alpha}, \quad j=1, 2, \cdots, m+n, \tag{18}$$

yields

$$Z_{j,N+q}=Z_{j,\nu}+\sum_{\beta=0}^{q-1}\epsilon_{N+\beta}\omega_j^{(N+\beta)}, \quad \begin{matrix}j=1, 2, \cdots, m+n\\ q=1, 2, \cdots.\end{matrix} \tag{19}$$

The second term of Eq. (19) does not involve any summation "up to N." It is desired to obtain a relation among the ψ_N's which is free of $Z_{j,N}$. Toward this end the ψ_{N+q}'s are considered.

$$\psi_{N+q}=R\sum_{\alpha=1}^{m+n}X_\alpha\omega_\alpha^{N+q}Z_{\alpha,N}+R\sum_{\alpha=1}^{m+n}X_\alpha\sum_{\beta=0}^{q-1}\epsilon_{N+\beta}\omega_\alpha^{q-\beta}. \tag{20}$$

Introducing the $m+n+1$ multipliers λ_q and summing

[5] G. Kowalewski, *Einfuhrung in die Determinantentheorie* (Chelsea Publishing Company, New York, 1948), p. 38.

the products $\lambda_q\psi_{N+q}$ up to $m+n$ yields

$$\sum_{q=0}^{m+n}\lambda_q\psi_{N+q}=R\sum_{q=0}^{m+n}\lambda_q\sum_{\alpha=1}^{m+n}X_\alpha\omega_\alpha{}^{N+q}Z_{\alpha,N}$$

$$+R\sum_{q=0}^{m+n}\lambda_q\sum_{\alpha=1}^{m+n}X_\alpha\sum_{\beta=0}^{q-1}\epsilon_{N+\beta}\omega_\alpha{}^{q-\beta}. \quad (21)$$

The λ_α, $\alpha=0, 1, \cdots, m+n$ will be so determined that the first member of Eq. (21) on the right vanishes without all the λ_α being identically zero. It is seen that

$$\sum_{q=0}^{m+n}\lambda_q\omega_\alpha{}^q=0, \quad \alpha=1, 2, \cdots, m+n \quad (22)$$

is a sufficient condition. If $\lambda_{m+n}=1$, then Eq. (22) becomes a system [Eq. (23)] of $(m+n)$ equations for the $(m+n)$ unknowns $\lambda_0, \lambda_1, \cdots, \lambda_{m+n-1}$:

$$\sum_{q=0}^{m+n-1}\lambda_q\omega_\alpha{}^q=-\omega_\alpha{}^{m+n}, \quad \alpha=1, 2, \cdots, m+n. \quad (23)$$

Since the determinant of this system is again a Vandermonde determinant, it is $\neq 0$ since $\omega_\alpha\neq\omega_\beta$ (and $\alpha\neq\beta$) by hypothesis. Hence the system of equations is consistent. Since $\lambda_{m+n}=1\neq 0$, not all the λ_α vanish. With this choice of the λ's, Eq. (21) reduces (after some algebraic manipulations) to

$$\epsilon_{N+m+n}+\sum_{\beta=0}^{m+n-1}\{\lambda_\beta+R\sum_{q=\beta+1}^{m+n}\sum_{\alpha=1}^{m+n}\lambda_qX_\alpha\omega_\alpha{}^{q-\beta}\}\epsilon_{N+\beta}$$

$$=\sum_{q=0}^{m+n}\lambda_q\phi_{N+q}. \quad (24)$$

Equation (24) is an equation for the ϵ_N's with constant coefficients. It is not a difference equation in the usual sense since it is valid only at the sampling instants $0, T_s, 2T_s, 3T_s, \cdots$. Hence, strictly speaking, Eq. (24) is a linear recurrence formula.[6]

From Eq. (23) it is seen that the λ's are the indicated coefficients of the algebraic equation

$$x^{m+n}+\lambda_{m+n-1}x^{m+n-1}+\cdots+\lambda_1x+\lambda_0=0, \quad \lambda_{m+n}=1 \quad (25)$$

whose roots are ω_α, $\alpha=1, 2, \cdots, m+n$.

If Eq. (24) is written in the compact form

$$\sum_{\alpha=0}^{m+n}A_\alpha\epsilon_{N+\alpha}=\sum_{q=0}^{m+n}\lambda_q\phi_{N+q} \quad (26)$$

where

$$A_{m+n}=1, \quad A_\beta=\lambda_\beta+R\sum_{q=\beta+1}^{m+n}\sum_{\alpha=1}^{m+n}\lambda_qX_\alpha\omega_\alpha{}^{q-\beta}, \quad (27)$$

$$\beta=0, 1, \cdots, m+n-1,$$

it is seen that the solution of the homogeneous equation

$$\sum_{\alpha=0}^{m+n}A_\alpha\epsilon_{N+\alpha}=0 \quad (28)$$

is

$$\epsilon_N=\sum_{\beta=1}^{m+n}P_\beta r_\beta{}^N \quad (29)$$

where the r_β are the roots of the algebraic equation

$$\sum_{\alpha=0}^{m+n}A_\alpha r^\alpha=0 \quad (30)$$

and P_β are periodic constants of period T_s. Since Eq. (24) is a linear recurrence formula and not a difference equation, the P_β are precisely constants in the ordinary sense. In writing Eq. (29), it has been tacitly assumed that all the roots of Eq. (30) are distinct. If this is not the case, the obvious modification

$$\epsilon_N=\sum_{\beta=1}^{k}[P_\beta N^{\beta-1}]r_1{}^N+\sum_{\alpha=k+1}^{m+n}P_\alpha r_\alpha{}^N$$

is made, where r_1 is a root of multiplicity k.

The particular integral $h(N)$ corresponding to the non-homogeneous equation can be obtained by the usual method of undetermined coefficients.[7] Hence the solution of Eq. (26) is

$$\epsilon_N=\sum_{\beta=1}^{m+n}P_\beta r_\beta{}^N+h(N). \quad (31)$$

The constants P_β in the solution [Eq. (31)] corresponding to the boundary conditions of Eq. (3) can readily be obtained in the following manner.

At the time $t=0$, $\psi(0)=0$; hence

$$\phi(0)=\epsilon(0) \quad \text{or} \quad \phi_0=\epsilon_0. \quad (32)$$

From Eq. (15)

$$\psi_1=R\epsilon_0\int_0^{T_s}G(T_s, \zeta)d\zeta. \quad (33)$$

Since ϵ_0, $\int_0^{T_s}G(T_s, \zeta)d\zeta$ and R are known, ψ_1 is known. ϕ_1 is known since the input $\phi(t)$ is a given function. Since at the sampling instants

$$\epsilon_N=\phi_N-\psi_N, \quad (34)$$

in particular

$$\epsilon_1=\phi_1-\psi_1 \quad (35)$$

and hence ϵ_1 is known. Proceeding in this pedestrian fashion, $\epsilon_0, \epsilon_1, \cdots, \epsilon_{m+n-1}$ are calculated. From Eq. (29)

$$\epsilon_\alpha=\sum_{\beta=1}^{m+n}P_\beta r_\beta{}^\alpha+h(\alpha), \quad \alpha=0, 1, \cdots, m+n-1. \quad (36)$$

The determinant of the P_β is non-zero. (It is a Vander-

[6] T. Fort, *Finite Differences* (Oxford University Press, London, 1948), p. 115.

[7] T. Fort (reference 6, p. 126).

monde determinant if the r_β are distinct and non-zero.) Hence the system (36) may be solved for P_β, $\beta=1, 2, \cdots, m+n$.

3. Stability of the Sampling Servo Mechanism

The servo system illustrated in Fig. 1 will be said to be stable if $\epsilon_N \to 0$ as $N \to \infty$ for any bounded input $\phi(t)$ of finite duration. If $\phi^*(t)$ is such a function, $\phi_N{}^*=0$ and $h(N)=0$ for N sufficiently large. Therefore, Eq. (31) may be written as

$$\epsilon_N = \sum_{\beta=1}^{m+n} P_\beta r_\beta{}^N. \tag{37}$$

It is evident from Eq. (37) that a necessary and sufficient condition that $\epsilon_N \to 0$ as $N \to \infty$ is that $|r_\beta|<1$. In other words, all the roots r_β, $\beta=1, 2, \cdots, m+n$ must lie inside the unit circle in the complex domain. Since the unit circle in the z plane can be transformed into the left half-plane of the complex w plane, the Nyquist criterion can be applied to determine the stability of the system without actually calculating the roots.

4. Determination of the Output $\theta(t)$

To determine the output $\theta(t)$, it is noted from Fig. 1 that

$$A(p)\theta(t)=K\epsilon(t). \tag{38}$$

Also, from the feed-back loop

$$B(p)\psi(t)=M\theta(t). \tag{39}$$

Since $\psi^{(\alpha)}(0)=0$, $\alpha=0, 1, \cdots, m+n-1$ by Eq. (3), it follows that

$$\theta^{(\alpha)}(0)=0, \quad \alpha=0, 1, \cdots, n-1. \tag{40}$$

Hence the "Green's function method" is applicable and

$$\theta(t)=K\int_0^t g(t, \zeta)\epsilon(\zeta)d\zeta \tag{41}$$

where $g(t, \zeta)$ is a one-sided Green's function.

If it is desired to compute $\theta(t)$ at the sampling instants nT_s, a method exactly analogous to the one discussed for $\epsilon(t)$ leads to the equation

$$\sum_{q=0}^{n} l_q\theta_{N+q}=M\sum_{q=0}^{n} l_q\sum_{\alpha=1}^{n} Y_\alpha\sigma_\alpha{}^q\sum_{\beta=0}^{q-1}\epsilon_{N+\beta}\sigma_\alpha{}^{-\beta} \tag{42}$$

where

$$\sigma_\alpha=e^{u_\alpha T_s}, \tag{43}$$

$u_1, u_2, \cdots, u_n$ are the distinct non-zero roots of the algebraic equation

$$x^n+a_1x^{n-1}+\cdots+a_{n-1}x+a_n=0, \tag{44}$$

$$Y_\alpha=(-1)^{n+\alpha}\Delta_\alpha\Delta^{-1}(1-\sigma_\alpha{}^{-1})u_\alpha{}^{-1}, \quad \alpha=1, 2, \cdots, n, \tag{45}$$

$$\Delta=\prod_{\substack{i,j=1\\ i>j}}^{n}(u_i-u_j), \tag{46}$$

$$\Delta_\alpha=\prod_{\substack{i,j=1\\ i>j\\ i,j\neq\alpha}}^{n}(u_i-u_j), \quad \alpha=1, 2, \cdots, n, \tag{47}$$

and l_α are the indicated coefficients of the algebraic equation

$$x^n+l_{n-1}x^{n-1}+\cdots+l_1x+l_0=0, \quad l_n\equiv 1, \tag{48}$$

whose roots are $\sigma_1, \sigma_2, \cdots, \sigma_n$. Hence if $f(N)$ is any particular solution of the non-homogeneous Eq. (42),

$$\theta_N=\sum_{\alpha=1}^{n} Q_\alpha\sigma_\alpha{}^N+f(N). \tag{49}$$

The constants Q_α, $\alpha=1, 2, \cdots, n$ can be obtained in the same manner in which the P_β were determined in Section II.2.

5. Response to a Step Input

If the input $\phi(t)$ to a stable system is given by $u(t)$ where $u(t)$ is the unit step function defined by

$$\left.\begin{aligned} u(t-\alpha)&=0 \quad t<\alpha\\ u(t-\alpha)&=1 \quad t>\alpha \end{aligned}\right\}, \tag{50}$$

then

$$\phi_0=\phi_1=\cdots=\phi_N=\cdots=1 \tag{51}$$

and

$$\sum_{q=0}^{m+n}\lambda_q\phi_N=\sum_{q=0}^{m+n}\lambda_q. \tag{52}$$

Hence,

$$h(N)=[\sum_{q=0}^{m+n}\lambda_q][\sum_{\alpha=0}^{m+n}A_\alpha]^{-1}\equiv H \tag{53}$$

is a particular solution of Eq. (26).

As $N\to\infty$, $\epsilon_N\to H$ since $|r_\beta|<1$, $\beta=1, 2, \cdots, m+n$. Hence it is seen that the system does not close out the error arising from a step function input. In order to adjust the system so that it will close out the steady state error, it is sufficient for $A(p)$ to have a simple zero at $p=0$. In this case

$$\omega_1=e^{v_1T_s}\equiv 1, \tag{54}$$

and the only modification of Eq. (24) is that X_1 becomes

$$X_1=(-1)^{m+n-1}W_1W^{-1}T_s. \tag{55}$$

From Eq. (23) for $\omega_1=1$,

$$\sum_{q=0}^{m+n-1}\lambda_q=-1 \quad \text{or} \quad \sum_{q=0}^{m+n}\lambda_q=0 \tag{56}$$

since $\lambda_{m+n}=1$. Hence Eq. (26) reduces to a homogeneous equation and, if the system is stable,

$$\epsilon_N=\sum_{\beta=1}^{m+n}P_\beta r_\beta{}^N\to 0 \quad \text{as} \quad N\to\infty. \tag{57}$$

Now the output θ_N satisfies Eq. (42). Since $\epsilon_N \to 0$ as $N \to \infty$, Eq. (49) can be written

$$\theta_N = \sum_{\alpha=1}^{n} Q_\alpha \sigma_\alpha{}^N + \delta \tag{58}$$

where δ is an infinitesimal for $N \to \infty$. Equation (58) gives the output at the sampling instants for a step input.

The asymptotic value of the output is readily obtained. Since the system is stable by hypothesis and $\phi(t)$ is bounded, $\theta(t)$ must be bounded. This implies

$$|\sigma_\alpha| \leqq 1, \quad \alpha = 1, 2, \cdots, n. \tag{59}$$

But $\sigma_\beta = \omega_\beta$, $\beta = 1, 2, \cdots, n$ and since $\omega_1 = 1$, $\sigma_1 = 1$. All the other σ_α must be less than one since $v_1 = 0$ is the only pole of $M/A(p)$ at $p = 0$. Hence

$$\theta_N = Q_1 + \sum_{\alpha=2}^{n} \sigma_\alpha{}^N + \delta, \tag{60}$$

and thus

$$\theta_\infty = Q_1. \tag{61}$$

It is noted that the condition $|\sigma_\alpha| \leqq 1$ implies Real part $(u_\alpha) \leqq 0$, $\alpha = 1, 2, \cdots, n$. In other words, a necessary condition that the system be stable is that the forward transmission have no poles in the right-half of the complex p plane.

Variation of Elastic Moduli and Wave Velocity with Pressure and Temperature in Plastics*

D. S. Hughes, E. B. Blankenship, and R. L. Mims†
Department of Physics, University of Texas, Austin, Texas
(Received September 6, 1949)

The variations in velocity of dilatational waves in the pressure range 0 to 15,000 lb./in.² and temperature range 30° to 90°C have been measured for samples of polystyrene, Lucite, and polyethylene. The velocity of rotational waves was also measured for polystyrene and Lucite. In polyethylene no trace of a rotational wave could be identified. The elastic moduli and Poisson's ratio are computed over the experimental range.

INTRODUCTION

A QUICK and simple method of measuring the velocity of waves in rods is to measure the time of transmission of a pulse through a known length. This pulse in long thin rods usually travels with the "acoustic" velocity given by

$$V_S = (E/\rho)^{\frac{1}{2}} \tag{1}$$

where E is the Young's modulus of the material and ρ is the density. For short, relatively thick rods the first arrival is the dilatational wave whose velocity is given by

$$V_D = [(K + \tfrac{4}{3}\mu)/\rho]^{\frac{1}{2}} \tag{2}$$

where K is the bulk modulus and μ is the rigidity modulus. It has been found that following the dilatational wave[1] there are other arrivals which arise by transformation of the original dilatational pulse at the boundaries of the rod into rotational waves. These rotational waves cross the rod and at the opposite boundary give rise again to a dilatational wave traveling parallel to the axis of the rod. The angle between the normal to the rotational waves and the axis of the rod is given by

$$\sin\Theta = V_R/V_D. \tag{3}$$

In reference 1 it is shown that the arrival times to be expected are given by

$$t_{nm} = m\alpha D + n\beta L \tag{4}$$

where n is any odd integer and m is subject to the condition

$$0 \leq mD \tan\Theta \leq nL$$

$$\beta = 1/V_D \quad \alpha = [(V_D{}^2 - V_R{}^2)/V_D V_R]^{\frac{1}{2}}. \tag{5}$$

Thus t_{10} is the direct dilatational wave, t_{11} is a dilatational wave that was transformed into a rotational wave and back into a dilatational wave, t_{12} has been transformed twice into a rotational wave, t_{30} is a dilatational wave that has traversed the rod three times without transformation, t_{31} has traversed the rod three times with one transformation, etc.

In practice, values of m greater than five or six are rarely observed even with metals of good acoustic properties. With polystyrene, t_{10}, t_{11}, and t_{30} could always be identified. With Lucite, only t_{10} and t_{11} could be read dependably, and with polyethylene, only t_{10}.

The values of α and β are computed from Eq. (4) and the observed times, and from these, the dilatational and rotational velocities may be derived.

$$V_D = \beta^{-1}$$
$$V_R = (\alpha^2 + \beta^2)^{-\frac{1}{2}}. \tag{6}$$

From these velocities and the density ρ, the elastic constants may be derived.

Define

$$R = V_D/V_R. \tag{7}$$

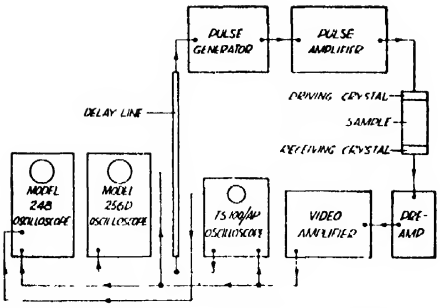

FIG. 1. Block diagram of electronic equipment.

Then, Poisson's ratio is

$$\sigma=(\tfrac{1}{2}R^2-1)/(R^2-1),$$

the rigidity modulus is

$$\mu=\rho V_R^2,$$

the Young's modulus is

$$E=2(1+\sigma)\mu,$$

and the bulk modulus is

$$K=E/3(1-2\sigma).$$

APPARATUS

Figure 1 shows a block diagram of the apparatus. This is essentially the same as described in reference 1. The TS-100/AP oscilloscope is used as standard for all time measurements. This instrument has a circular sweep of 80.86-kc frequency of 12.368 μsec. per revolution. A trigger circuit is provided that operates at submultiples of this frequency in the range 150 to 500 pulses per second. This trigger is accurately synchronized with the circular sweep. The instrument is also provided with an intensity gate so that any one selected revolution, after the trigger, appears on the screen. The trigger is sent through a delay line to synchronize the pulse generator. The pulse generator provides pulses with a rise time of about 0.3 μsec., 180-v amplitude and length from 0.5 to 60 μsec. A volume control was added so that the amplitude could be varied from 20 to 180 v. For materials with poor transmission these pulses are insufficient. A pulse amplifier consisting of a 6AG7 tube to invert and sharpen the pulse, an 807 as an amplifier, and a second 807 as a cathode follower for an output tube was constructed. This amplifier when driven by the pulse generator will provide pulses of about 800-v amplitude and rise time of 0.2 μsec., with an exponential decay of about 5 μsec. This sharp rise and slow decay both impressed on the driving crystal give a very simple pulse in the sample. The driving and receiving crystals are 3.5 Mc, x-cut, quartz crystals, 1.125 in. in diameter.

The signal from the receiving crystals is amplified by a preamplifier similar to that described by Jordan and Bell[2] but modified so that the gain is about 10 and the band width extends to some 5 Mc. This is followed by a video amplifier[3] which has a gain of about 800 and an upper frequency limit of about 8 Mc. The output of this amplifier is sent to the radial deflection electrode of the TS-100/AP and the vertical plates of the 248 and 256D oscilloscopes. The 25-μsec. R sweep of the 256D is triggered by the TS-100/AP generator. This scope is used for qualitative observations of wave form and approximate time checks. The 248 is triggered by the delayed intensity gate of the TS-100/AP so that any delayed 25- or 100-μsec. portion of the record may be displayed. This scope is fitted with a blue tube and camera for photography.

The sample may be used either in open air or placed in the pressure chamber, Fig. 2. The pressure chamber is constructed of Type 309 stainless steel, 4 in. in diameter by 12 in. high. The inner chamber is 2 in. in diameter by 7 in. high. The cylinder sets in a brass tank filled with SAE 30 oil and fitted with heating element, circulating stirrer, and cooling coils. The leads from the crystals are brought out through the head of the cylinder.

perature and pressure. With increase in pressure the arrivals become slightly sharper and, with increase in temperature, somewhat less sharp; but the changes are minor except that with Lucite the t_{11} arrival disappears at low pressures and elevated temperatures. The trace length is about 100 μsec. The arrivals falling in this range are indicated.

The arrivals can be read on the TS-100/AP with a probable error of about ±0.03 μsec. This permits a determination of V_D and V_R with a probable error of about 0.2 percent. From these velocites and the density ρ, Poisson's ratio σ, the rigidity modulus μ, Young's modulus E, and the bulk modulus K, may be computed using Eq. (7). These values are slightly erroneous since the length, diameter, and density as measured at room temperature and pressure are used. However, this first computation gives an approximate value for K as a function of pressure at a given temperature. The length at any given temperature and room pressure may be computed from a knowledge of the coefficient of thermal expansion. Thus,

$$L_{T_0}=L_0[1+\alpha(T-T_0)], \tag{8}$$

where α is the coefficient of thermal expansion, T_0 is room temperature, T is temperature at which the run was made, L_0 is the length or diameter at room temperature and pressure, and L_{T_0} is the computed length at temperature T and room pressure. From the approximate value of K already computed, the length at any temperature and pressure is given by

$$L_{T_P}=L_{T_0}[1-(P/3\bar{K})], \tag{9}$$

where P is the pressure and $\bar{K}$ is average bulk modulus over the pressure range zero to P. Using Eqs. (8) and (9), the length and diameter were computed for all pressures and temperatures. The density ρ and the velocities V_D and V_R were recomputed as a function of pressure and temperature and then Eq. (8) used to re-

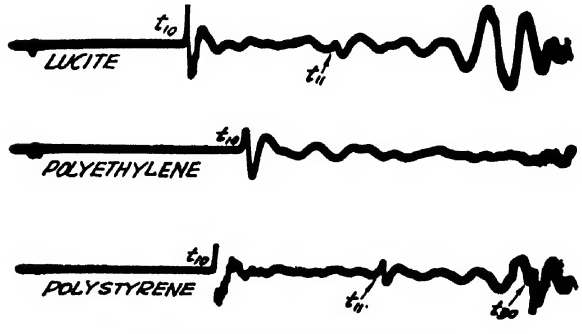

FIG. 3. Pulse transmission in plastics.

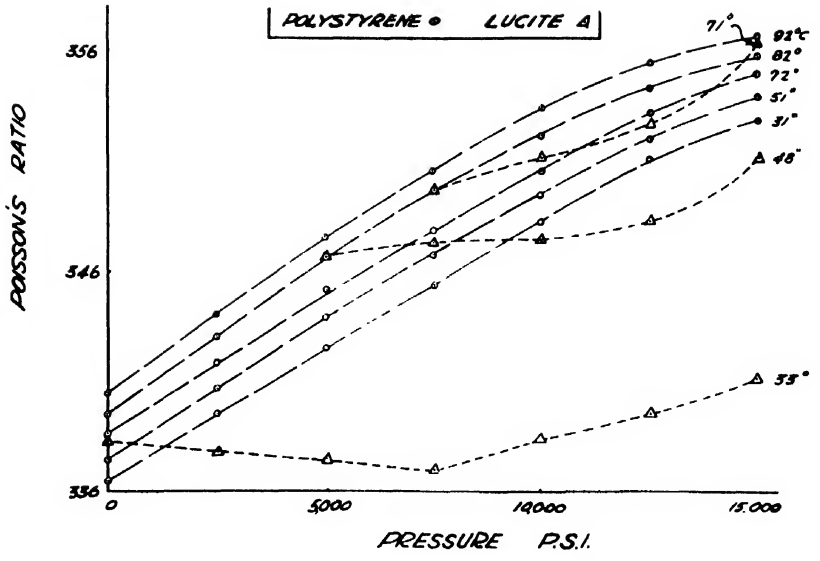

FIG. 4. Comparison of Poisson's ratio for Lucite and polystyrene.

compute values of σ, μ, E, and K. The largest correction is about two percent. It is assumed that for the purpose of this correction the differences between the adiabatic and isothermal moduli can be neglected.

Table I lists the velocities and elastic moduli for polystyrene over the range of pressures and temperatures. The variation in the rotational velocity with both temperature and pressure is very much less than that in the dilatational velocity. Similarly, the rigidity modulus increases by approximately six percent for an increase in pressure of 15,000 p.s.i. whereas the bulk modulus increases over the same range by about 30 percent. Corresponding to this rise in bulk modulus, Poisson's ratio, σ, increases uniformly.

Table II lists the velocities and elastic moduli for Lucite. Although the elastic moduli vary in a somewhat similar way to those of polystyrene there are fundamental differences. At room temperature Poisson's ratio decreases slightly as the pressure is raised reaching a minimum at 7500 p.s.i. and then increases slightly thereafter. At 48°C the first transformed wave cannot be read until a pressure of 5000 p.s.i. is reached and at 71°C a pressure of 7500 p.s.i. is required.

This almost certainly indicates a large change in viscous damping of the rotational waves. The first appearance of the transformed waves as the pressure increases is not sudden but gradual. The pressures listed above are those at which a clear definite arrival can be identified. At the elevated temperatures, Poisson's ratio rises very rapidly with pressure in contrast to its behavior at room temperature for Lucite and polystyrene over the experimental range as shown by Fig. 4.

Table III lists the dilatational velocity for polyethylene. No trace of a transformed wave could be detected and the elastic constants could not be computed.

The Summation of Fourier Series by Operational Methods

LOUIS A. PIPES
Department of Engineering, University of California, Los Angeles, California
(Received September 26, 1949)

A method for the summation of certain types of Fourier series by the use of Laplace transforms is presented. The procedure enables one to easily obtain graphical representations of functions defined by Fourier series in many cases of practical importance.

I. INTRODUCTION

IN the mathematical analysis of problems in electric circuit theory, mechanical vibrations, heat conduction, and other branches of mathematical physics, one frequently arrives at solutions that are expressed in the form of infinite Fourier series. In many cases, it is more convenient to have the solutions of these problems expressed in closed form for purposes of calculation.

Oliver Heaviside[1] in the second volume of his *Electromagnetic Theory* used his rather informal "resistance operator" methods to interpret and sum Fourier series. As is well known, his mathematical processes were sometimes open to question. However, his methods frequently lead to useful results most simply, and he himself said in several instances, "I feel quite certain that this could be shown by conventional mathematics."

It is the purpose of this discussion to present a method for summing certain types of Fourier series of frequent occurrence in applied mathematics by the use of the modern Laplace method of the "Operational Calculus."

II. FUNDAMENTAL TRANSFORMATIONS

The method to be described is based upon the fact that certain hyperbolic functions can be expressed as an infinite series of exponential functions. If we use the notation,

$$A_k = e^{-kap} = \exp(-kap) \tag{2.1}$$

then the following expansions may be written

$$\tanh(ap) = 1 - 2A_2 + 2A_4 - 2A_6 + \ldots, \tag{2.2}$$

$$\coth(ap) = 1 + 2A_2 + 2A_4 + 2A_6 + \ldots, \tag{2.3}$$

$$\frac{1}{\sinh(ap)} = 2(A_1 + A_3 + A_5 + A_7 + \cdots) \tag{2.4}$$

$$\frac{1}{\cosh(ap)} = 2(A_1 - A_3 + A_5 - A_7 + \cdots), \tag{2.5}$$

a is a positive real number, and p is a number whose real part is positive.

By the use of a method due to Mittag-Leffler,[2] it is possible to obtain the following expansions,

$$\tanh(ap) = \frac{2}{ap}\left\{\frac{1}{1+(\pi/2ap)^2} + \frac{1}{1+(3\pi/2ap)^2} + \frac{1}{1+(5\pi/2ap)^2} + \cdots\right\} = \frac{2}{ap}\sum_{n=1}^{\infty}\frac{1}{1+\{[(2n-1)\pi]/2ap\}^2}, \tag{2.6}$$

$$\coth(ap) = \frac{1}{ap}\left\{1 + \frac{1}{1+(\pi/ap)^2} + \frac{2}{1+(2\pi/ap)^2} + \cdots\right\} = \frac{1}{ap}\left\{1 + \sum_{n=1}^{\infty}\frac{2}{1+(n\pi/ap)^2}\right\}, \tag{2.7}$$

$$\frac{1}{\cosh(ap)} = \frac{1}{a^2p^2}\left\{\frac{\pi}{1+(\pi/2ap)^2} - \frac{3\pi}{1+(3\pi/2ap)^2} + \cdots\right\} = \frac{1}{a^2p^2}\sum_{n=1}^{\infty}\frac{(-1)(2n-1)\pi}{1+(n\pi/2ap)^2}, \tag{2.8}$$

$$\frac{1}{\sinh(ap)} = \frac{1}{ap}\left\{1 - \frac{2}{1+(\pi/ap)^2} + \frac{2}{1+(2\pi/ap)^2} - \cdots\right\} = \frac{1}{ap}\left\{1 + \sum_{n=1}^{\infty}(-1)^n\frac{2}{1+(n\pi/ap)^2}\right\}. \tag{2.9}$$

It is possible to expand other combinations of hyperbolic functions in a similar manner, however, the above expansions are sufficient to illustrate the general principles of the method to be described.

III. THE LAPLACE TRANSFORMATION

Modern rigorous "operational calculus" is based upon the Fourier-Mellin integral equations.[3]

[1] O. Heaviside, *Electromagnetic Theory* (D. Van Nostrand Company, Inc., New York, 1925), Vol. II, pp. 107–119.
[2] E. T. Whittaker, and G. N. Watson, *Modern Analysis* (Cambridge University Press, London, 1927), pp. 134–136.
[3] L. A. Pipes, *Applied Mathematics for Engineers and Physicists* (McGraw-Hill Book Company, Inc., New York, 1946), Chapter XXI.

These equations state that, if

$$g(p)=p\int_0^\infty e^{-pt}h(t)dt, \tag{3.1}$$

then

$$h(t)=\frac{1}{2\pi j}\int_{c-j\infty}^{c+j\infty}\frac{g(p)e^{pt}dp}{p}, \tag{3.2}$$

where $j=(-1)^{\frac{1}{2}}$ and c is a real constant of such magnitude that the poles of the integrand lie entirely to the left of the path of integration. For brevity, the notation

$$g(p)=Lh(t) \quad \text{or} \quad h(t)=L^{-1}g(p) \tag{3.3}$$

is used to denote the above relations between the functions $g(p)$ and $h(t)$. The function $g(p)$ is said to be the Laplace transform of $h(t)$ and the function $h(t)$ is said to be the inverse Laplace transform of $g(p)$. Extensive tables of Laplace transforms have been compiled.[3] In this discussion we require the transforms of the sine and the cosine. These transforms are given by

$$L\sin(nwt)=\frac{nwp}{p^2+n^2w^2}=\frac{nw}{p}\cdot\frac{1}{1+(nw/p)^2} \tag{3.4}$$

and

$$L\cos(nwt)=\frac{p^2}{p^2+(nw)^2}=\frac{1}{1+(nw/p)^2}. \tag{3.5}$$

Another result of the theory of Laplace transform that is required is the following one.[3]

If

$$L^{-1}g(p)=h(t) \tag{3.6}$$

then

$$L^{-1}e^{-kp}g(p)=\begin{cases}0 & t<k\\ h(t-k) & t>k,\end{cases} \tag{3.7}$$

where k is a positive constant.

IV. SUMMATION OF FOURIER SERIES

The general method of summation will now be illustrated by applying it to several special cases.

Example I

In certain investigations of physical problems the following Fourier series is obtained:

$$F_1(t)=4[(\sin t/1)+(\sin 3t/3)+(\sin 5t/5)+\cdots]$$

$$=4\sum_{n=1}^{\infty}\frac{\sin(2n-1)t}{(2n-1)} \qquad t>0. \tag{4.1}$$

The Laplace transform of the function $F(t)$ represented by the series (4.1) may be obtained by taking the Laplace transform of each term of the series using (3.4). In this manner one obtains

$$LF_1(t)=\frac{4}{p}\left[\frac{1}{1+(1/p)^2}+\frac{1}{1+(3/p)^2}+\frac{1}{1+(5/p)^2}+\cdots\right]. \tag{4.2}$$

We now note that, if in Eq. (2.6) we let

$$a=\pi/2, \tag{4.3}$$

then we can express the series term of (4.2) in the following form:

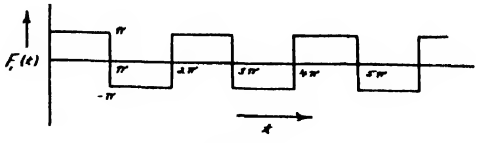

FIG. 1.

$$\left[\frac{1}{1+(1/p)^2}+\frac{1}{1+(3/p)^2}+\frac{1}{1+(5/p)^2}+\cdots\right]$$

$$=ap/2\tanh(ap). \tag{4.4}$$

Hence, comparing (4.2) and (4.4) we see that

$$LF_1(t)=2a\tanh(ap)=\tanh(\pi p/2). \tag{4.5}$$

We now use the expansion (2.2) and obtain

$$LF_1(t)=\pi[1-2e^{-\pi p}+2e^{-2\pi p}-2e^{-3\pi p}+\ \ldots]. \tag{4.6}$$

This is the Laplace transform of the Fourier series (4.1). To obtain the inverse Laplace transform of (4.6) and then obtain a representation of the series (4.1) we use the result (3.7). The inverse Laplace transform of the first term of (4.6) is a step function of height π formed at $t=0$. The inverse transform of the second term is a step function of height -2π formed at $t=\pi$. The inverse transform of the third term is a step function of height $+2\pi$ formed at $t=2$ and so on. The sum of all these step functions is illustrated in Fig. 1.

Example II

As a second example let it be required to interpret the following Fourier series that occurs in certain electrical and heat conduction problems.

$$F_2(t)=\frac{2}{\pi}\sum_{n=1}^{\infty}\frac{1}{n}\sin\left(\frac{n\pi t}{s}\right). \tag{4.7}$$

By the use of (3.4), the Laplace transform of (4.7) is obtained and is given by:

$$LF_2(t)=\frac{2}{\pi}\sum_{n=1}^{\infty}\frac{n\pi}{nsp}\cdot\frac{1}{1+(n\pi/sp)^2}$$

$$=\frac{1}{sp}\sum_{n=1}^{\infty}\frac{2}{1+(n\pi/sp)^2}. \tag{4.8}$$

If we now compare (4.8) with (2.7) it is seen that we have,

$$LF_2(t)=\coth(sp)-1/sp. \tag{4.9}$$

By the use of (2.3) this may be written in the following form,

$$LF_2(t)=(1-1/sp+2e^{-2sp}+2e^{-4sp}+2e^{-6sp}+\ldots). \tag{4.10}$$

To obtain the inverse transform of F_2 we note that the inverse transform of the first term is a unit step function, the inverse transform of the term $-1/sp$ is $-t/s$, the inverse transform of $+2e^{-2sp}$ is a step function of height that begins at $t=2s$, etc. The sum of the various transforms gives the function $F_2(t)$. The result is given graphically in Fig. 2.
This figure is a graphical representation of the Fourier series $F_2(t)$.

Example III

As another example, let it be required to obtain the graph of the following Fourier series:

$$F_3(t)=(\sin t-\tfrac{1}{2}\sin 2t+\tfrac{1}{3}\sin 3t-\cdots)$$

$$=-\sum_{n=1}^{\infty}(-1)^n\frac{1}{n}\sin(nt). \tag{4.11}$$

In this case we transform (4.11) by the use of Eq. (3.4) and note the similarity to Eq. (2.8). Then the expansion (2.4) gives the result

$$LF_3(t)=(1/p-2\pi e^{-\pi p}-2\pi e^{-3\pi p}-2\pi e^{-5\pi p}+\ldots). \tag{4.12}$$

Now the inverse transform of $1/p$ is t, the inverse transform of $-2\pi e^{-\pi p}$ is a step function of height -2π that begins at $t=\pi$, etc. The sum of the various inverse transforms is $F_3(t)$. This function is given graphically in Fig. 3.

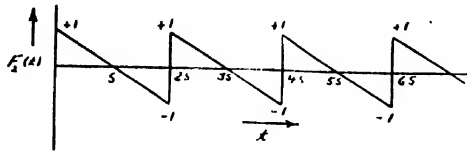

Fig. 2.

Example IV

An interesting series which arises in the analysis of the propagation of charge along a cable will now be considered. This series represents a row of impulses and the function it represents is important in the analysis of the disturbances created when lightning hits a transmission line. The series to be considered is the following one:

$$F_4(x)=\frac{2}{s}\sum_{n=1}^{n=\infty}\sin\left(\frac{n\pi x}{s}\right)\sin\left(\frac{n\pi b}{s}\right). \tag{4.13}$$

To study this series more easily, the product of sines may be transformed into two cosines and written in the following form:

$$F_4(x)=\frac{1}{s}\sum_{n=1}^{n=\infty}\left[\cos\frac{n\pi(x-b)}{s}-\cos\frac{n\pi(x+b)}{s}\right]. \tag{4.14}$$

Let us first consider the first series of (4.14) and let,

$$t=x-b. \tag{4.15}$$

This series may be written in the form:

$$\phi(t)=\frac{1}{s}\sum_{n=1}^{\infty}\cos\left(\frac{n\pi st}{s}\right). \tag{4.16}$$

By (3.5) it can be transformed to:

$$L\phi(t)=\frac{1}{s}\sum_{n=1}^{\infty}\cos\frac{1}{1+(n/sp)}. \tag{4.17}$$

By the use of Eqs. (2.7) and (2.3) this may be written in the form,

$$L\phi(t)=p/s(1+2e^{-2sp}+2e^{-4sp}+\ldots). \tag{4.18}$$

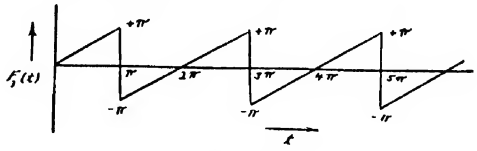

Fig. 3.

To obtain the inverse transform of this function we note that,[3]

$$L^{-1}p=\delta(t). \tag{4.19}$$

The function, $\delta(t)$, is an impulse function known in the literature as the Dirac function. It has the following properties:

$$\delta(t)=\begin{cases}0 & t\neq 0\\ \infty & t=0\end{cases} \tag{4.20}$$

and

$$\int_{-\infty}^{+\infty}\delta(t)dt=1. \tag{4.21}$$

As a consequence of (3.7), the inverse transform of (4.18) is

$$\phi(t)=1/s[\delta(t)+2\delta(t-2s)+2\delta(t-4s)+\ldots]. \tag{4.22}$$

We note that the first term is an impulse at $t=x-b=0$ or at $x=b$. The second term is an impulse located at $t=2s$ or $x=2s+b$, and so forth. The second series of (4.14) may be transformed in a similar manner if the substitution $t=x+b$ is made and it can be shown that this series represents a row of negative impulses at $x=-b$, $x=2s-b$, etc. A graphical representation of the function $F_4(x)$ defined by (4.13) is given in Fig. 4.

The function $F_4(x)$ is zero for all values of x except at the places where it has the values of positive and negative pulses of the Dirac type.

V. GENERAL CONSIDERATIONS

The general Fourier series may be written in the form:

$$F(t)=A_0+\sum_{n=1}^{\infty} A_n \cos(nwt)+\sum_{n=1}^{\infty} B_n \sin(nwt). \quad (5.1)$$

The coefficients A_n and B_n are known functions of n. By the use of Eqs. (3.4) and (3.5), it is possible to transform (5.1) into

$$LF(t)=A_0+\sum_{n=1}^{\infty} \frac{An}{1+(nw/p)^2}+\frac{w}{p}\sum_{n=1}^{\infty} \frac{nBn}{1+(nw/p)^2}. \quad (5.2)$$

The success of the method of interpretation described in this discussion depends upon the possibility of effecting the summations of (5.2) by the use of the Eqs. (2.6)–(2.9) or by formulas derivable from them.

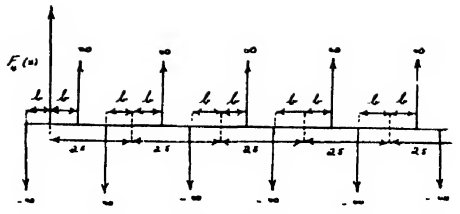

FIG. 4.

The interpretation of the Fourier series can then be carried out by the use of Eqs. (2.2)–(2.5) or combinations of these expansions.

In many cases, however, the summation of the fractions of (5.2) may present insurmountable difficulties and in such cases, this method of interpretation is not applicable.

Effect of Change of Scale on Sintering Phenomena

CONYERS HERRING
Bell Telephone Laboratories, Murray Hill, New Jersey
(Received November 16, 1949)

It is shown that when certain plausible assumptions are fulfilled simple scaling laws govern the times required to produce, by sintering at a given temperature, geometrically similar changes in two or more systems of solid particles which are identical geometrically except for a difference of scale. It is suggested that experimental studies of the effect of such a change of scale may prove valuable in identifying the predominant mechanism responsible for sintering under any particular set of conditions, and may also help to decide certain fundamental questions in fields such as creep and crystal growth

FOR the purposes of this paper "sintering" will be understood to mean any change in shape which a small particle or a cluster of particles of uniform composition undergoes when held at high temperature. In the absence of externally applied stresses, such changes are believed to be motivated by surface tension, since the surface free energy decreases as the particles grow together and assume a more compact shape. The transport of matter which is involved can take place by any of four mechanisms: viscous or plastic flow, evaporation and condensation, volume diffusion, and surface migration. With the aid of certain plausible assumptions the rates of transport by each of these mechanisms can be computed in terms of the geometrical parameters and certain constants of the material such as surface tensions, diffusion coefficients, etc.[1] Foremost among the assumptions involved is the assumption that the building up or tearing down of the surface can occur quite readily in response to conditions in the immediately adjoining solid or vapor phase. This assumption is closely related to the controversial problem of the mechanism of crystal growth, and it would be incorrect, at least in cases involving plane crystal facets, if growth normal to such facets required a "two-dimensional nucleation" process.[1,2] It is the purpose of this note to point out that useful information can probably be obtained, both on the fundamental question of the way in which crystals grow and on the more specific question of the relative importance of the four transport mechanisms in specific cases, by a comparison of sintering rates for particles or clusters of different sizes but geometrically similar shapes.

THE SCALING LAWS

We shall use the term "cluster" to refer to any particle or to a number of particles which have started to grow together. Consider two partially sintered clusters which are geometrically similar, the linear dimensions of number two being λ times those of number one. For example, if each cluster consists of spherical

[1] C. Herring, paper presented at the Symposium on the Physics of Powder Metallurgy organized by Sylvania Electric Products, Inc., Bayside, Long Island, New York (August 24–26, 1949). Plans have been made to publish the papers of the Symposium in book form.

[2] The theory of growth by two-dimensional nucleation is summarized in the book of M. Volmer, *Kinetik der Phasenbildung* (Verlag von Theodor Steinkopff, Dresden and Leipzig, 1939; Edwards Brothers, Inc., Ann Arbor, 1945). An alternative theory of crystal growth has been proposed by F. C. Frank, to appear in *Trans. Faraday Soc.* (paper presented at the Discussion on Crystal Growth sponsored by the Faraday Society and held at Bristol, England, April, 1949).

grains of radius R, sintered until the radius of the area of contact of adjacent grains is a, similarity will require $R_2=\lambda R_1$, $a_2=\lambda a_1$. The question to be considered is, how is the time Δt_1 required to produce a given change in shape of cluster number one in the sintering process related to the time Δt_2 required, at the same temperature, to produce a geometrically similar change in the second cluster? This relation turns out to be quite simple in the following four cases, if the same one of the basic mechanisms predominates for both clusters and if the above-mentioned assumption of facile growth and recession of the surface is valid.

Viscous Flow of an Amorphous Material

It is well known that the surface tension γ of a spherical drop of liquid of radius R produces a pressure p in the interior of the drop, given by

$$2\pi R\gamma=\pi R^2 p$$

or

$$p=2\gamma/R. \tag{1}$$

This equation can be shown to give, in more general cases, the normal stress p_{rr} immediately under a curved surface of any shape, provided R^{-1} is interpreted as the mean of the principal curvatures of the surface, these being counted positive if convex, negative if concave. It can be applied to "amorphous solids" provided the temperature is high enough so that the surface layers of atoms are reasonably free to rearrange themselves; however, the simple form (1) is not valid for crystals.[1]

If the surface of a cluster is inhomogeneously curved, the normal stresses given by (1) will vary over the surface, and to compensate this there must be shearing stresses in the interior. For the two sizes of cluster mentioned, the stress tensors at corresponding points, being determined by (1) and the linear conditions of equilibrium, must satisfy

$$p_{ij}^{(2)}(\lambda\mathbf{r})=p_{ij}^{(1)}(\mathbf{r})/\lambda. \tag{2}$$

Thus assuming viscous behavior the strain rates ds_{ij}/dt at corresponding points will satisfy

$$(ds_{ij}/dt)_2=(1/\lambda)(ds_{ij}/dt)_1$$

and so the times required for a given change of shape to take place will be related by

$$\Delta t_2=\lambda\Delta t_1. \tag{3}$$

Evaporation and Condensation

It will be assumed that the mean free path of an atom or molecule in the vapor is long compared with the dimensions of the particles being sintered, and that only one kind of atom or molecule is involved. For a liquid or an amorphous solid it is well known that the equilibrium vapor pressure over a spherically curved surface of radius R is greater than that over a flat surface by the ratio[3]

$$p_R/p_\infty=\exp(2\Omega_0\gamma/kTR), \tag{4}$$

where Ω_0 is the atomic or molecular volume and γ the surface tension. Application of a similar thermodynamic argument to crystals yields a relation which, though more complicated, agrees with (4) in having an exponent which varies inversely with the first power of the linear scale.[1] If the exponent is small, as is likely to be the case if R is of the order of 10^{-5} cm or greater, (4) can be written

$$p_R=p_\infty(1+2\Omega_0\gamma/kTR). \tag{5}$$

Now consider any two elements of surface dS_a and dS_b on nearby portions of the cluster being sintered. The evaporation rates from these two will be in the ratio of their areas and of their equilibrium vapor pressures.* If these vapor pressures are different, as they will be if the radii of curvature R_a and R_b are different, the amount of material which in any given time is evaporated from a, passes directly to b, and condenses there, will be different from the amount passing in the reverse direction. Ignoring factors of proportionality which are independent of the linear scale factor λ, one may write

$$\text{rate } (a\to b)-\text{rate } (b\to a)\propto dS_a dS_b(p_a-p_b)/r_{ab}^2$$

where r_{ab} is the distance of dS_a from dS_b. Thus the rates for the two geometrically similar aggregates we are considering bear the ratio

$$\frac{\text{rate } (a\to b)_2-\text{rate } (b\to a)_2}{\text{rate } (a\to b)_1-\text{rate } (b\to a)_1}=\lambda^2\cdot\lambda^2\cdot\lambda^{-1}\cdot\lambda^{-2}=\lambda. \tag{6}$$

A similar equation obviously holds for material transported from a to b by any type of trajectory involving reflection from some intermediate surface. Since the total amount of material which must be transported in these ways to produce geometrically similar changes in cluster 2 is λ^3 times that for cluster 1, the intervals of time required will be related by

$$\Delta t_2=\Delta t_1\lambda^3/\lambda=\lambda^2\Delta t_1. \tag{7}$$

Volume Diffusion

It can be shown that in a crystal the diffusive flux of matter, i.e., of interstitial atoms or lattice vacancies, is proportional to the local gradient of the chemical potential of the diffusing substance. (Use of the chemical potential takes account of the effects of both pressure gradients and concentration gradients.) Now the value of this chemical potential at any place on the boundary

[3] See, for example, E. A. Guggenheim, *Modern Thermodynamics by The Methods of Willard Gibbs* (Methuen and Company, Ltd., London, 1933), p. 172.

* This statement may not be true if the "sticking coefficients" α_a and α_b for the two surface elements are different. However, since both the probability of evaporation and the probability of condensation contain the sticking coefficient as a factor, (6) will be correct in any case.

of the crystal must coincide with the chemical potential of the vapor which is in equilibrium with that portion of the crystal surface. For a one-component substance we have from (4), or from its extension to the crystalline case[1]

$$\text{chemical potential at surface} = \text{const.} + kT \ln(p_R/p_\infty) = \text{const.} + B/(\text{linear dimension}), \quad (7)$$

where B is a quantity which is the same at corresponding points of the surfaces of the geometrically similar clusters 1 and 2. Thus, when a quasi-steady distribution of diffusion currents has been set up we have at corresponding points of the interiors of the two clusters

$$(\text{chem. pot.})_2 = (\text{chem. pot.})_1/\lambda$$

and

$$(\text{flux})_2 = (\text{flux})_1/\lambda. \quad (8)$$

Since corresponding areas in the two clusters bear the ratio λ^2 and the amount of material which must be transported goes as λ^3, the times required to produce corresponding amounts of sintering satisfy

$$\Delta t_2 = (\lambda^3 \cdot \lambda^2/\lambda^2)\Delta t_1 = \lambda^3 \Delta t_1. \quad (9)$$

Surface Migration

The scaling law for sintering due to surface migration can be derived in a similar way, by starting from the assumption that the rate of migration over a given type of surface is proportional to the gradient of the chemical potential in the plane of the surface. Thus (8) will hold for the surface flux as well as for the volume flux. In the present case, however, the total rate of transport is the product of the flux not by an area but by a length in the plane of the surface and normal to the flux direction. Thus, instead of (9) we have

$$\Delta t_2 = (\lambda^3 \cdot \lambda^2/\lambda)\Delta t_1 = \lambda^4 \Delta t_1. \quad (10)$$

DISCUSSION

In attempting to draw conclusions from experimental comparisons of sintering times for similar systems of different sizes, several obvious precautions must be observed. One must be sure that the factors determining the degree of contamination of the surface are kept the same for all the cases being compared. If possible, the orientations of the various crystals making up each cluster should be the same for the clusters of different sizes which are being compared: surface tension, surface mobilities, evaporation rates, etc., can be quite different for differently oriented surfaces, the more so because preferential adsorption can cause different surfaces to acquire widely different degrees of contamination. If there is an appreciable delay in the formation of the initial bond between two particles, time should be measured from the moment when this bond is first established.

When experimental data fail to follow one of the scaling laws one must decide whether this is merely because more than one of the above mechanisms is operative over the range of sizes covered by the experiment or whether mechanisms basically different from those assumed above are involved. In the former case there will usually be certain accessible ranges of temperatures and particle sizes over which only one of the four mechanisms contributes appreciably to the changes involved, and if data from these ranges are available, the transition ranges can easily be identified as such. If basically different mechanisms are involved, on the other hand, the variation of sintering time with linear scale may be of a sort quite inconsistent with the hypothesis of a gradual transition from one of the above power laws to another. For example, if a change were produced by slip or creep which set in abruptly at a given critical stress, the sintering time might vary discontinuously with linear scale. An almost discontinuous variation might also result if growth of crystal facets by two-dimensional nucleation were involved.

If a given type of sintering experiment is found to obey one of the scaling laws, the predominant mechanism of transport can be inferred. This inference can probably be drawn with less ambiguity than in the method used by Kuczynski,[4] who inferred the mechanism of sintering by comparing the observed rate of growth of the neck between a particle and a flat block with rates computed theoretically according to each of the above mechanisms. According to Kuczynski's calculations, the radius of the neck varies as the nth root of the sintering time, where $n=2$ for viscous flow, 3 for evaporation and condensation, 5 for volume diffusion, and 7 for surface migration. Although these exponents cannot be far from the truth if the assumptions used in the present paper are correct, uncertainties in geometrical details of the calculations could perhaps affect the values of n by as much as 0.5. The exponents in the present scaling laws, on the other hand, are subject to no such uncertainty.

A Resonant Bar Method for Determining the Elastic Properties of Thin Lamina

A. W. Nolle and P. J. Westervelt
Acoustics Laboratory, Massachusetts Institute of Technology, Cambridge, Massachusetts
(Received September 9, 1949)

A resonant bar method for obtaining the dynamic elastic properties of a thin cement layer is discussed. Formulas are deduced for the calculation of Young's modulus from the measured resonant frequency and band width of two similar steel bars, cemented end-to-end. The accuracy of the method is discussed.

I. INTRODUCTION

THE method to be described has proved useful in obtaining the effective elastic properties of a thin layer of cement. In this application two cylindrical steel bars (see Fig. 1) of equal length $l/2$ are cemented end-to-end forming a single bar. By suitable means the frequency and Q of the fundamental resonance of the cemented bar are measured and compared with similar quantities measured for a continuous bar of length l. From this comparison it is possible to obtain an effective complex Young's modulus for the thin cement film.

For a discussion of the concept of a complex modulus the reader is referred to a recent paper by Nolle.[1] Briefly, the complex modulus is defined as the stress-to-strain ratio for sinusoidal displacements. Provided the displacements are proportional to $e^{-i\omega t}$, the complex modulus E can be expressed as $E=E_1-iE_2$ where E_1 is the ordinary Young's elastic modulus, and $E_2=\omega\gamma$ (γ=normal viscosity coefficient).

The moduli are termed "effective" for two reasons. In the first place, E_1 and γ are presumed to vary with frequency, whereas for a true modulus, E_1 and γ would be independent of frequency. Secondly, in laterally constrained lamina, the measured modulus might lie between that of a Young's modulus and a bulk modulus.

Approximate formulae will first be derived for E_1 and E_2 under the assumption that the resonant frequency of the cemented bar does not differ much from the value for the continuous bar.

II. APPROXIMATE FORMULA FOR E_1

The fundamental resonant frequency ν_0 of a bar of length l is given by

$$l\nu_0=c/2, \tag{1}$$

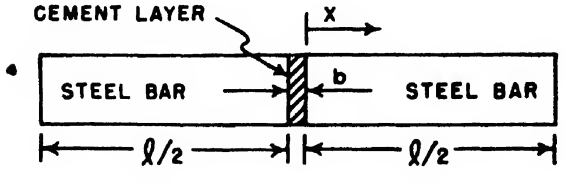

FIG. 1. Sketch of cemented bars.

where the velocity of sound $c=(E/\rho)^{\frac{1}{2}}$ (E=Young's modulus; ρ=density for the bar).

Increasing the length of the bar by δl will result in a decrease $\delta\nu$ of the resonant frequency, given by:

$$\delta\nu/\nu_0=\delta l/l, \tag{2}$$

as can be verified by differentiating Eq. (1). Next, suppose the element $\delta l \ll l$ lies in the middle of the rod. The effect of δl can be visualized as that of a spring, coupling the two halves of the rod together. If the element had a Young's modulus E_1 instead of the modulus E of the bar, its length would have to be $(E_1/E)\delta l$ in order to give the same fractional change in frequency; thus the fractional change due to an element b with modulus E_1 is:

$$\delta\nu/\nu_0=(E/E_1)(b/l). \tag{3}$$

From Eqs. (1), (3) and the expression $E=\rho c^2$, we obtain an expression for the real part of the complex Young's modulus, E_1, of a lamina of thickness b:

$$E_1=4\rho l b\nu_0^2(\nu_0/\delta\nu). \tag{4}$$

It can be shown that Eq. (4) is valid to within 10 percent provided the band width $\Delta\nu$ of the resonance of the cemented bar is small enough to satisfy $(\Delta\nu)^2 \ll(\delta\nu)^2$, and provided $(\delta\nu/\nu_0)<0.1$. These restrictions are met in many cases. Formulas that hold when the first restriction does not apply will be given in the Appendix.

In the event that $\delta\nu/\nu_0$ is not small with respect to unity but that $(\Delta\nu)^2\ll(\delta\nu)^2$ and $b\ll l$, it can be shown that a more precise value of E_1 is obtained by multiplying the value given by Eq. (4) by the function $F(\delta\nu/\nu_0)$:

$$F\left(\frac{\delta\nu}{\nu_0}\right)=\frac{\pi}{2}\left(1-\frac{\delta\nu}{\nu_0}\right)\left(\frac{\delta\nu}{\nu_0}\right)\cot\frac{\pi\delta\nu}{\nu_0}. \tag{5}$$

From Eq. (5), $F(0.1)=0.90$. Hence, when $\delta\nu/\nu_0=0.1$, the value of E_1 obtained from Eq. (4) will be too high by 10 percent.

Another approximate form results from expanding the cotangent in Eq. (5) and retaining the first term in the expansion. This leads to the following expression which is accurate to within 10 percent, provided $\delta\nu/\nu_0<0.3$:

$$E_1=4\rho l b\nu_0^2\left(\frac{\nu_0}{\delta\nu}-1\right), \tag{6}$$

[1] A. W. Nolle, "Method for measuring dynamic mechanical properties of rubber-like materials," J. App. Phys. 19, 753 (1948).

which may be written:

$$E_1 = 4\rho l b \nu_0^2 (\nu/\delta\nu), \tag{7}$$

where $\nu = \nu_0 - \delta\nu$, the resonant frequency of the cemented bars.

III. APPROXIMATE FORMULA FOR E_2

We shall look for a relation between E_2 (which is a measure of the damping of the lamina), the resonant frequency of the cemented bar ν and the band width $\Delta\nu$ of the resonance peak. The quantity E_2 can be expressed in terms of the mechanical resistance, R, of the lamina which is supposed to have a thickness $b \ll l$ and the same area S as that of the bar:

$$E_2 = (2\pi\nu R b)/S. \tag{8}$$

Provided that the Q of the fundamental mode is at all times large compared with unity, the band width $\Delta\nu$ is given by:[2]

$$\Delta\nu = \frac{\nu}{2\pi} \times \frac{\text{Decrease of Energy of Free Vibration per Cycle}}{\text{Total Energy of Vibration}}. \tag{9}$$

The total energy of vibration in the bar is the maximum kinetic energy, or:

$$\text{total energy} = (MV_0^2)/2, \tag{10}$$

where M is the equivalent mass of the bar, vibrating in its first mode

$$M = (\rho l S)/2, \tag{11}$$

and V_0 is the amplitude of the velocity configuration $V(x)$ at a point $x < l/2$ along the bar, measured from the plane joining the bar and the sample:

$$V(x) = V_0 \cos\left[\left(1 - \frac{\delta\nu}{\nu_0}\right)\left(\frac{\pi x}{l} - \frac{\pi}{2}\right)\right].$$

The energy loss per cycle in the lamina is given by:

$$\text{loss per cycle} = \frac{1}{2}\frac{R 2 V(x - l/2)^2}{\nu},$$

or, for $\delta\nu/\nu_0 \ll 1$:

$$\text{loss per cycle} = \pi^2 V_0^2 \frac{R}{2\nu_0}\left(\frac{\delta\nu}{\nu_0}\right)^2. \tag{12}$$

Introducing Eqs. (10) and (12) into (9) we obtain:

$$\Delta\nu = \frac{\pi}{2}\frac{R}{M}\left(\frac{\delta\nu}{\nu_0}\right)^2,$$

then, solving for R and using Eq. (11)

$$R = \frac{\rho l S}{\pi}\left(\frac{\nu_0}{\delta\nu}\right)^2 \Delta\nu.$$

Introducing the above expression into Eq. (8):

$$E_2 = 2\rho l b \nu_0 (\nu_0/\delta\nu)^2 \Delta\nu,$$

or in terms of E_1, given in Eq. (4):

$$E_2 = (E_1/2)\Delta\nu/\delta\nu. \tag{13}$$

Any loss inherent in the continuous unloaded bar is effectively added to the loss introduced by the sample. Therefore, if the band width of the unloaded rod is not negligible in comparison to the band width observed with the sample in place, the quantity $\Delta\nu$ to be used in Eq. (12) should be obtained from the relation:

$$\Delta\nu = \Delta\nu_{\text{loaded}} - \Delta\nu_{\text{unloaded}}. \tag{14}$$

The term "band width" as used above denotes the difference between the two frequencies for which the displacement amplitude of the system is $\frac{1}{2}\sqrt{2}$ times the value found at resonance, under the condition that the system is excited by a sinusoidal force whose amplitude is independent of frequency.

IV. APPLICATIONS

The method described here may be employed successfully in conjunction with any of the known techniques for measuring the fundamental resonant frequency and the band width of a rod with free ends. A technique that is suitable when the rod is made of magnetostrictive metal has been described in a previous publication.[1] The completely electrostatic technique of Bordoni[3] is also well suited to this application. This method is being used by a group at M.I.T. for the study of deterioration of adhesives.*

In general, this method is suitable for investigating the elastic properties of thin samples whose mechanical impedance per unit area is large compared to the specific acoustic impedance, ρc, of the rod material, provided of course that the samples can be bonded suitably to the rod metal. For the study of samples whose mechanical impedance per unit area is small compared to the specific acoustic impedance of the rod material, it is necessary to place the sample at a position of low impedance (that is, at an antinode of displacement) with respect to the wave pattern in the rod. This case has been discussed in connection with the magnetostriction technique to which reference has already been made.[1]

APPENDIX

More Rigorous Treatment of the Vibration of a Split Rod

It is assumed that the Q of the vibrating system is at least of the order of 10 to 100. The motion, then, is closely symmetrical about a plane normal to the rod and through the center of the viscoelastic sample. This plane of symmetry contains a displacement node which may be replaced by a termination of infinite impedance. The problem resolves into the treatment of a rod whose length is that of one-half of the actual rod, terminated by a rigidly backed viscoelastic sample whose thickness is half that of the actual sample. The analysis is easily performed by the hyperbolic tangent method of Morse[4] and is given below in the terminology established by him.

In the plane joining the sample and the metal rod ($x=0$), the specific acoustic impedance $2(E_2+iE_1)/b\omega$ of the half-thickness viscoelastic sample must equal the transmission-line impedance at this location as given by the function

$$z=\rho c \tanh\pi(\alpha-i\beta_0). \tag{15}$$

Here β_0 represents the value at $x=0$ of the phase parameter β which obeys the relation

$$\beta_{l/2}=\beta_0+l/\lambda. \tag{16}$$

Evidently the dynamic modulus, E_1-iE_2, can be calculated from a knowledge of the quantities α and β_0.

It will be shown that these quantities may be evaluated by measurement of the resonant frequency and the band width of the system.

Let $K\omega$ represent the amplitude of an alternating pressure whose magnitude is proportional to frequency, applied to the free end of the rod at $x=l/2$. The displacement amplitude at $x=l/2$ is $K/z_{l/2}$. Expansion of the hyperbolic tangent Eq. (15) shows that the square of this displacement amplitude is proportional to

$$\frac{A\cos^2\pi\beta_{l/2}+B\sin^2\pi\beta_{l/2}}{B\cos^2\pi\beta_{l/2}+A\sin^2\pi\beta_{l/2}} \tag{17}$$

where $A=\cosh^2\pi\alpha$, $B=\sinh^2\pi\alpha$. It may be verified by differentiation that this squared amplitude is maximum for $\beta_{l/2}=0$. Thus the parameter β_0 is given immediately as

$$\beta_0=-\nu l/c=-\nu/2\nu_0=-\tfrac{1}{2}\left(1+\frac{\delta\nu}{\nu_0}\right), \tag{18}$$

where ν and ν_0 are the frequencies of maximum amplitude for the compound rod and for an unmodified rod of length l respectively.

At the amplitude maximum, the quantity (17) has the value A/B, but this value must reduce to $A/2B$ at either of the two frequencies which define the band width. By setting the expression (17) equal to $A/2B$, we obtain

$$\tan\beta'_{l/2}=\pm(AB/(A^2-2B^2))^{\frac{1}{2}}, \tag{19}$$

where $\tan\beta'_{l/2}$, which equals $\pm l\Delta\nu/2c$, denotes the values of $\beta_{l/2}$ obtaining at the limits of the "pass band." This expression results in the following transcendental equation for α:

$$\tanh^2\pi\alpha/(1-2\tanh^2\pi\alpha)=\tan^2(\pi\Delta\nu/4\nu_0). \tag{20}$$

By means of Eqs. (15), (18), and (20) it is possible to compute the specific acoustic impedance or the complex modulus of the cement layer from measurements of the resonance frequency and the band width of the compound rod.

Since the above equations are unwieldy for purposes of calculation, it is convenient to introduce approximations. Suppose that the fractional frequency change $\delta\nu/\nu_0$ and the fractional band width $\Delta\nu/\nu_0$ are each small compared to unity. In this case the equations reduce to

$$E_1=4\rho l b\nu_0^2(1+\delta\nu/\nu_0)(\delta\nu/\nu_0)/[(\delta\nu/\nu_0)^2+(\Delta\nu/2\nu_0)^2], \tag{21}$$

$$E_2/E_1=\tfrac{1}{2}(\Delta\nu/\delta\nu). \tag{22}$$

These equations are valid for any ratio E_2/E_1. Where this ratio is small compared to unity, as is the case for many cements, Eq. (21) may be replaced by Eq. (7), obtained in the simpler derivation.

The assumption that the driving-force amplitude is proportional to frequency, made in the derivation leading to Eqs. (21) and (22), is introduced solely to achieve a considerable simplification in the derivation and in the results. This condition can be achieved easily in the design of the apparatus, but the distinction involved is unimportant when the resonance is sharp, as will be the case for hard cements. Results identical to Eqs. (21) and (22) are also obtained if it is assumed that the driving-force amplitude is independent of frequency and that the detection device responds to velocity rather than to amplitude.

The Electronic Isograph for Roots of Polynomials

BYRON O. MARSHALL, JR.
Air Force Cambridge Research Laboratories, Cambridge, Massachusetts
(Received August 10, 1949)

An electronic apparatus which assists in the finding of the roots of polynomials is described. The device accepts the coefficients of polynomials of degree 10 or less and yields the absolute magnitude of the roots to a precision of 0.01 relative to the largest coefficient in the polynomial and an angular accuracy of 0.3 degree on the angle of the root.

The method used is the electronic analog of the expression

$$\omega = \Sigma a_n z^n$$
$$= \Sigma a_n r^n \cos n\theta + j \Sigma a_n r^n \sin n\theta.$$

$\sin n\theta$ and $\cos n\theta$ are generated by a motor-driven commutator. The radius r is controlled manually. Hence a plot of ω is placed on the oscilloscope for a fixed r as a function of θ. To find the root r is manipulated until ω crosses the origin in the ω-plane. The value of θ is found by inserting a pip on the intensity of the oscilloscope under a variable phase control. When this pip is moved to the origin of the ω-plane the phase meter indicates the angle of the root in the z plane.

I. INTRODUCTION

THE great interest in the location of the roots of polynomials is partly evidenced by the great number of methods that have been devised for the process. The most common "pencil and paper" methods include the binomial formula for quadratics, the rather awkward formulas for cubics and quartics, Graffe's root squaring method, the various methods of successive approximation (Newton's Birge-Vieta, etc.[1]) and several more complicated procedures. These methods, however useful for low degree polynomials, are laborious and time consuming for greater than fourth or fifth degree. A convenient process for finding the roots of polynomials of perhaps tenth degree or so would have several fold applications: (1) for the solution to the great variety of engineering problems that may be expressed as functions of polynomials, (2) as an aid to large-scale computing machines for which the roots of a polynomials must be isolated before further calculation can be performed, (3) possibly to give new approaches to problems difficult by other mathematical procedures, since any analytic function may be expressed as a power series, many of which converge rapidly, (4) as an adjunct to other mathematical processes: complementary solution to differential equations, the study of transforms, the determination of latent roots of a matrix, and the like.

Several electrical and mechanical methods have been developed for finding the roots of polynomials, some of which are: the Bell Laboratories isograph,[2] the Stibitz electrolytic isograph,[3] and the University of Texas[4] mechanical synthesizer. The system herein described will possess the advantages: (a) of being able to evaluate a polynomial to three significant figures for all values of the complex variables in a matter of minutes, (b) of being extendable to operation with automatic computers, and (c) of allowing additional operations such as Fourier synthesis.

II. THEORY OF OPERATION

Given the polynomial

$$a_n z^n + a_{n-1} z^{n-1} \cdots a_0 = f(z),$$

it is desired to find the values of complex z for which $f(z)=0$. That is, $f(z)$ will have one value for each point $z=x+jy$ of the complex plane. In particular, $f(z)$ will be zero for some values of z (the roots) and the number of roots will equal the degree of the polynomial. By de Moivre's theorem we can set

$$z = re^{j\theta} = r(\cos\theta + j \sin\theta) \quad r, \theta \text{ real}, \ \geq 0$$

and the polynomial becomes

$$\sum_0^n a_k r^k e^{jk\theta} = f(z).$$

Let θ now be varied periodically from 0 to 2π at a frequency $\omega/2\pi$ cycles per second. It can be seen that the kth term may be represented by a sinusoid of frequency $k\omega/2\pi$ amplified or attenuated by the amount $a_k r^k$. It is possible to investigate $f(z)$ for all values of z by summing these weighted sinusoids and varying r from zero to infinity continuously. Also

$$f(z) = \sum_{k=0}^{n} a_k r^k \cos k\omega t + j \sum_{k=0}^{n} a_k r^k \sin k\omega t,$$

and a root will obtain when both

$$\sum_{k=0}^{n} a_k r^k \cos k\omega t = 0$$

$$\sum_{k=0}^{n} a_k r^k \sin k\omega t = 0.$$

[3] G. R. Stibitz, "An electric root finder," Memo., Burlington, Vermont.
[4] S. Leroy Brown and R. G. Packard, Phys. Rev. 73, 646 (1948).

In other words, both real and imaginary components must be zero simultaneously. This situation and the value of $f(z)$ for all z are indicated by the isograph.

Physically, then, the method of solution consists of (1) generating the required sinusoids, constant in phase relationships and amplitude, (2) multiplying the amplitude of each sinusoid by its corresponding coefficient, a_k, (3) multiplying each of these quantities by the appropriate r^k, r being continuously variable from zero to infinity, (4) presentation of the sum by some convenient means.

There are many existing techniques for performing each of the above operations; those for the isograph were chosen for ease of operation, reliability and accuracy of circuits.

III. PHYSICAL DESIGN

Although it would be possible to introduce complex coefficients through phase shifting of each frequency, the present model operates with real coefficients only, since a method exists (described in a later paragraph) for obtaining a polynomial with real coefficients from one with complex ones. Let this polynomial be divided through by its largest coefficient. All the remaining coefficients are now one or smaller and so may be obtained electrically with potentiometers. Coefficients are inverted in sign by reversing the phase of the corresponding sinusoid.

Again, it will be shown possible to construct an equivalent polynomial

$$\sum_{k=0}^{n} a_k' r'^k e^{jk\omega} = f(z),$$

such that $r=1/r'$. We can investigate $f(z)$ from 0 to 1 and $f'(z')$ in the same range, covering the whole z plane. If R designates r when $|z|\leq 1$, and r' when $|z|\geq 1$, then R will be everywhere less than one and may also be obtained with potential dividers. The value of R^n may be formed by the ganged potentiometers shown in Fig. 1. Each potentiometer is separated from the following one by buffing amplifiers of gain one. One could use a gang of k potentiometers for the kth frequency, $k+1$ for the $(k+1)$th frequency, and so on, but a more convenient method is to produce d.c. voltages proportional to R^k, k between 0 and n, with a gang of n potentiometers. It then remains to control the amplitude of each voltage of frequency $k\omega$ with the d.c. voltage R^k.

As to the number of frequencies to be generated, or the degree of polynomial that may be generated, ten has been chosen for the electronic isograph, since most frequent polynomials are of this degree or less. Also, as will be shown, the roots of polynomials of higher degree may be found if the roots are sufficiently removed from 1. It is necessary, then to produce the first ten harmonics of the base frequency in constant phase relationships and of controlled amplitude. Some of the many methods of this generation are:

1. Mixing and remixing of the base frequency.
2. Synchronized oscillators or trigger circuits.
3. Magnetic pick up from revolving gears.
4. The photoelectric analogy of (3).
5. The electrostatic analogy of (3).
6. Square wave generators using commutators.

The commutators (6) possess the unique property of having a large output that is a linear function of the applied d.c. voltage, since the d.c. voltage is the amplitude of the square wave output. Other types of generators must be followed by a linear modulator for multiplication of their output by the d.c. voltage, R^k. This consideration eliminated 30 vacuum tubes from the first design of the isograph. Operation using method (2) is being considered for another model.

The ten commutators, Fig. 1, being driven by a 3600 r.p.m. synchronous motor, have been found to have optimum operation with from one to ten segments.

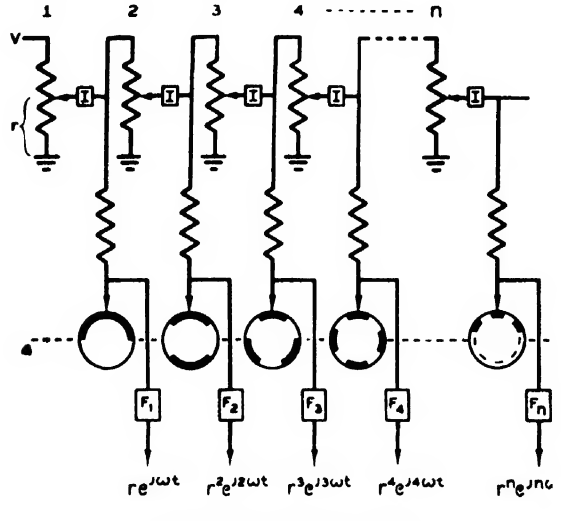

FIG. 1. Generation of terms.

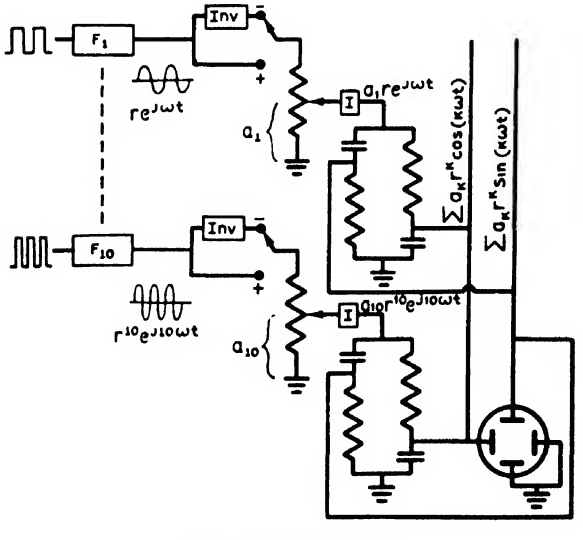

FIG. 2. Block diagram.

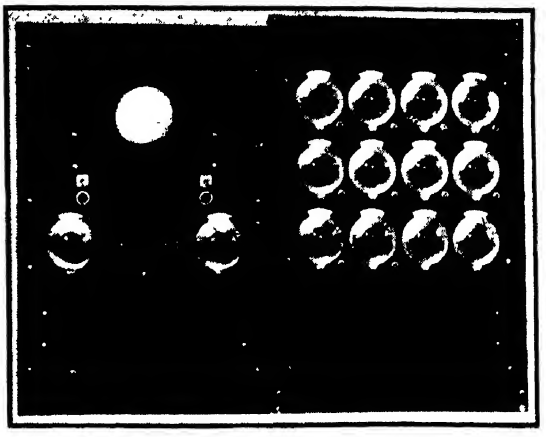
The output frequencies are therefore 60,120 · · · 540 and 600 cycles, each of which will be at least as constant as the line frequency and will have permanent relative phase. The d.c. voltages from the ganged potentiometer are applied to the commutators and each output square wave, proportional to R^k, is filtered to obtain a sinusoidal voltage with harmonics less than 0.1 percent. The potentiometer for multiplication by the fractional a_n may be introduced at a convenient point in the subsequent circuit.

In view of the range of frequencies employed, the type of presentation that immediately suggests itself is an oscilloscope. It is convenient to separate the polynomial into:

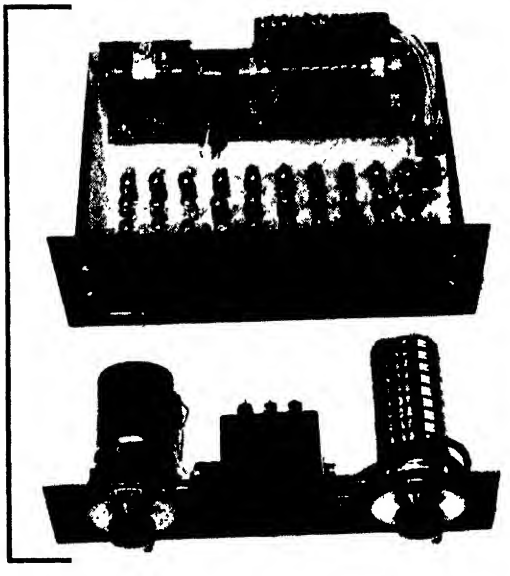
$$f(z)=\sum^{n} a_k R^k e^{jk\omega t}=\sum^{n} a_k R^k \cos k\omega t+j\sum^{n} a_k R^k \sin k\omega t,$$

which may be achieved electrically by splitting each frequency into $\sin k\omega t$ and $\cos k\omega t$ and summing the ten of each in linear mixers. If the sum of the cosine voltages is supplied to the horizontal deflection circuit of the oscilloscope and the sines to the vertical, it is seen that a root of the polynomial will occur when the trace of $f(z)$ crosses the zero point of the oscilloscope. Such a representation has the convenient properties that: (a) The complex value of $f(z)$ is the vector from the origin to that particular point of the trace, (b) the region of greatest interest occurs at the center of the scope face, and hence the presentation may be greatly amplified for greater precision, and (c) since the parameter of the presentation is θ, varying periodically, a particular θ may be indicated by a marker in the proper phase relationship to the fundamental frequency. In the isograph, this marker is produced with a differential selsyn to shift the phase of the fundamental by any given angle, a clipper and peaker and then intensity modulation of the trace with the peaked pulse. In addition, the vector from the origin of the oscilloscope face to a point of the trace is the value of $f(z)$ at that setting of R and the indicated θ.

Using the elements described above, the electronic isograph appears as shown in the block diagram, Fig. 2. It can be seen that the channel for each frequency consists of rather elementary circuits, linear throughout. The zero degree term, the constant in the polynomial, is introduced by horizontal and vertical displacements of the oscilloscope pattern relative to the etched axes. Since all potentiometers have errors of less than 0.07 percent and all circuits are linear, it is possible to align the channels to evaluate a tenth degree polynomial with a constant term to three significant digits. Figure 3(a) shows the physical appearance of the isograph.



(a)



(b)

FIG. 3. Appearance of isograph

IV. OPERATION

Basic Function—Zeros of Tenth Degree Polynomial With Real Coefficients

The only operation that must be performed externally is to divide the polynomial by its largest coefficient, the new polynomial having the same roots as the original. These coefficients are now entered on the vernier coefficient dials, which can be set with an accuracy of one part in two thousand. The values of $f(z)$ for $|z|$ from zero to one are investigated by the R potentiometer through this range. The oscilloscope presentation gives at once a trace representing the values complex $f(z)$ for all z lying on the circle $|z|=R$ for the particular R entered on that dial. A root will be indicated by the trace crossing the origin of the presentation, the magnitude of the root being the R setting when this situation obtains. The argument, or phase angle, of the root may be read from the θ-scale after the θ-marker has been placed on the portion of the trace at the origin. The precision of the root magnitude measurement is 0.05 percent and of the argument, 0.1 degree, which, of course, is one limit of the attainable accuracy.

To investigate the polynomial for $|z|$ greater than one, a slightly different procedure is employed. If the transformation

$$z = 1/Z = 1/(re^{j\theta})$$

is made, the polynomial becomes

$$\sum_{k=0}^{n} a_k z^k = \sum_{k=0}^{n} a_k Z^k = \sum_{k=0}^{n} a_k (r^k e^{jk\theta})$$

which may be multiplied by $r^n e^{jn\theta}$ to give

$$\sum_{k=0}^{n} a_k r^{n-k} e^{j(n-k)\theta} = a_n + a_{n-1} r e^{j\theta} + \cdots + a_0 r^n e^{jn\theta}.$$

This transformation is performed simply by inverting the order of the coefficients, allowing the completion of the investigation of the z plane from 1 to ∞. The reciprocal of r, r', and the argument are again read from the R and θ scales, respectively.

Since the figure traversed in the z plane is a circle with a radius r (determined by the ganged potentiometer setting), the figure on the oscilloscope face (the w plane) is the transform of the circle. From complex variable theory, a line through a branch point of a function is transformed into a cusp. The branch points are the roots of the derivative, and another method of finding roots presents itself. It is merely necessary to integrate the polynomial (a simple multiplication by integers) and observe the occurrence of cusps on the w plane, as shown by the seven simultaneous roots of Fig. 4.

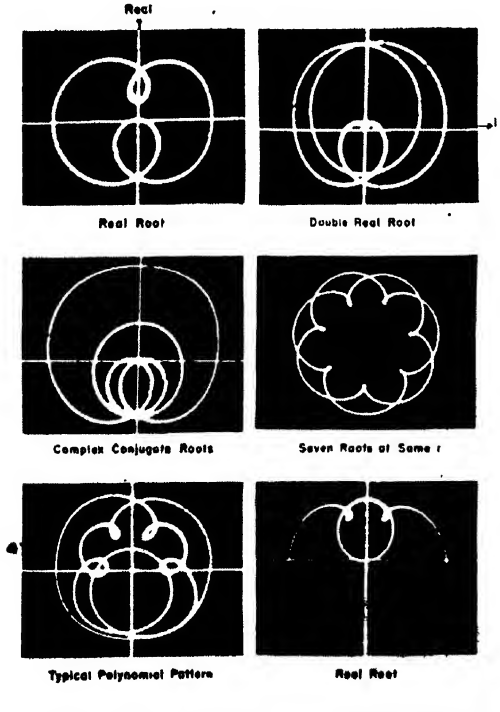


FIG. 4 Real, complex conjugate, double roots, etc.

The accuracy of the isograph is greater near $(z)=1$, so that large or small roots should be brought to this neighborhood by constructing a polynomial in z', z' being defined as Mz when M is some large (or small) real number.

Many of the properties of the polynomial may be observed on the $f(z)$ presentation. The investigation of $f(z)$ is carried out over circles about the origin in the z plane, since r is constant at any instant and θ is being scanned. Any polynomial, $P_n(z)$, may be expressed as the product

$$P_n(z) = A(z-p_1)(z-p_2)\cdots(z-p_n),$$

where $p_1 \cdots p_n$ are the roots of $P_n(z)$. The quantity $(z-p_k)$ will change its argument by 2π as z moves around a circle enclosing p_k. If the circle C encloses m roots, the argument of $P_n(z)$ will change by $2m\pi$ for each circuit or z on C, or the trace of $P_n(z)$ will enclose the origin m times. In other words, the number of loops made by the trace of $P_n(z)$ about the origin of the oscilloscope is equal to the number of roots of absolute value less than the r then entered in the isograph.

The character of each root may also be determined from the presentation. Real, complex conjugate, double roots, etc., have the characteristic appearance shown in Fig. 4. It is also possible to determine some of the properties of the derivative at the root from the presentation.

If it is desired to obtain greater accuracy, the polynomial may be differentiated and the resulting $f'(z)$ entered in the isograph as a new polynomial to be evaluated at the R and θ of the root's approximation given by the first process. One can then apply Newton's formula:

$$z_1 = z_0 - [f(z_0)/f'(z_0)],$$

where z_0 is the first approximation, z_1 a better value. It is necessary to calculate the value of $f(z_0)$ by some auxiliary means; but since each application of Newton's formula usually doubles the number of significant figures, the additional calculation is efficient.

Roots of Polynomials with Complex Coefficients

A necessary and sufficient condition for a polynomial to have real coefficients is that its roots be distributed symmetrically about the real axis in the z plane. A polynomial with complex coefficients may be changed to one with real coefficients by introducing the conjugates of the roots of the original. Since it may be shown that

$$f(\bar{z}) = \langle f(z) \rangle_{Av}$$

the conjugate roots may be introduced by forming the product

$$F(z) = f(z) \cdot \langle f(z) \rangle_{Av}.$$

The new polynomial will in general be of twice the degree of the original and have twice the number of roots. The additional roots are the conjugates of the

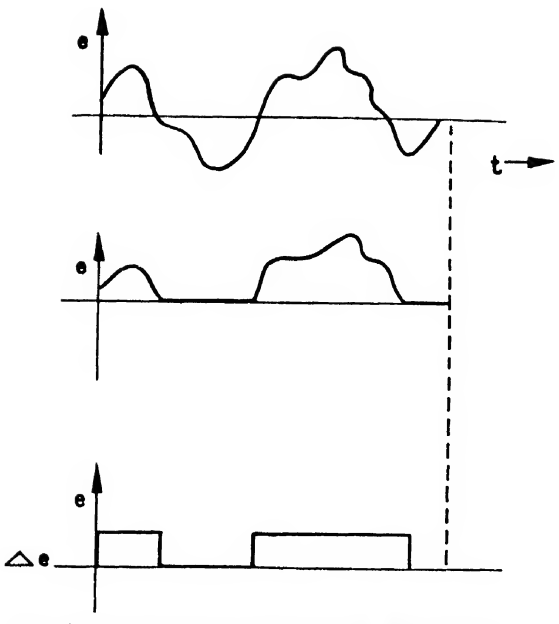

FIG. 5.

desired ones and may be eliminated by substitutions in the original polynomial. The roots of $F(z)$ are found by as described in the first paragraphs of Section IV.

Polynomials of Degree Higher Than Ten

A polynomial of degree $10+n$ may have all of its roots found by the isograph if n of its roots are sufficiently removed from one. The upper ten terms will give perhaps ten of the roots correct to three places if the roots are greater than 1.6 or less than 0.6, assuming reasonable coefficients. The terms neglected will contribute little to the root determination since $(1.6)^{10}$ is greater than 1000 and $(0.6)^{10}$ is less than 1/1000, meaning that the lower terms' contributions are outside the accuracy of the instrument. The larger roots, discovered by using the upper ten terms, may be divided out of the original polynomial, resulting in one of lower degree which may then be solved by the isograph for the remaining roots.

Again, if the roots are too close to one for the above conditions to obtain, it is possible to remove them from this neighborhood by defining a new variable or by using Horner's method

V. EXTENSIONS

It is possible to give a presentation much easier to interpret by mapping the polynomial over the z plane. This is a familiar type of representation and would be much more recognizable by mathematicians and engineers. It is difficult to accomplish but a method which would indicate the important points of the map would be valuable. One way of doing this, which it is believed will give considerable information to the engineer, would be as follows.

The previously mentioned oscilloscope presentation was developed by having a voltage on the horizontal plates proportional to the sum of the cosines of the various terms of the polynomial and was some periodic voltage centered about 0. The voltage on the vertical plates is the same type representing the sum of the sines. If each voltage were clipped at zero and at some small voltage above zero (see Fig. 5), and the resulting rectangular wave form were placed on the z axis of an oscilloscope while at the same time tracing on the face of the oscilloscope the circle corresponding to z magnitude$=r$ (r the setting of the r potentiometer), then this intensity modulation defines the regions of positive real (or imaginary) $P_n(z)$. This means that as r is varied from 0 to 1 there is obtained on the face of the oscilloscope a set of zones corresponding roughly to the surface of real (or imaginary) $P_n(z)$. The edges of these zones, of course, represent the lines real $P_n(z)=0$ (or imaginary $P_n(z)=0$). Although this is an approximation to the surface $P_n(z)$ mapped above the z plane, the significant points, roots, and branch points are given accurately. It is possible to put both surfaces on the face of the oscilloscope by simply adding the two intensity modulating voltages. There are then displayed on the z plane, intersections of the zero lines indicating the roots, and other shapes, the branch points of the

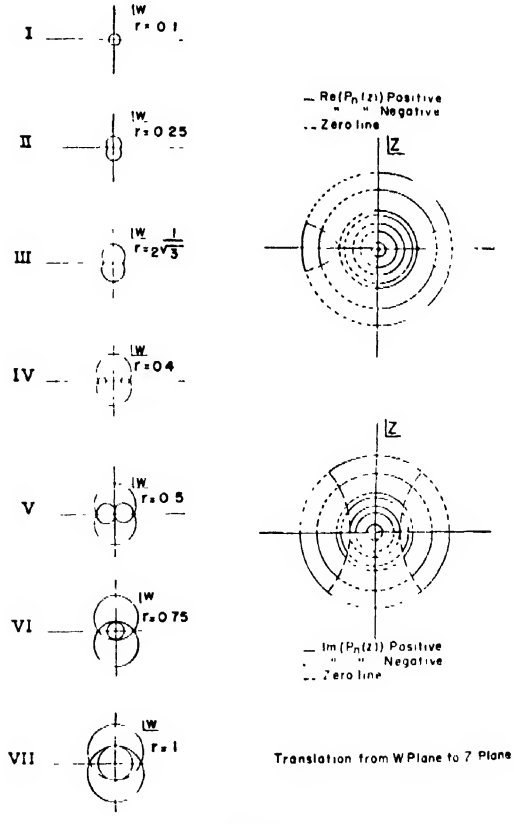

FIG. 6

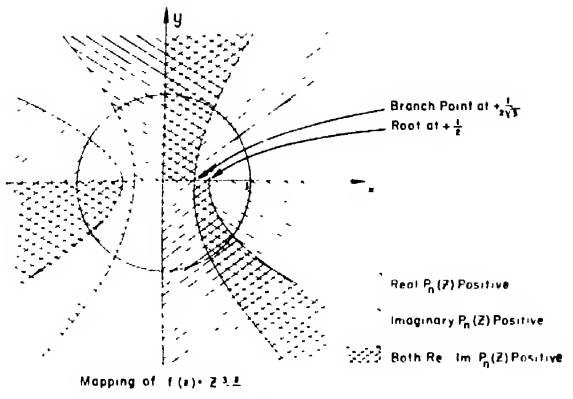

FIG. 7

polynomial, and it will be possible to trace the behavior of these significant points as coefficients of the input polynomial are varied. Figure 6 is an illustration of what would be obtained using this presentation on the polynomial $z^3-z/4$. On the left are the series of illustrations representing the transforms of circles in the z plane to the w plane which are the usual isograph presentation. To the right are the two presentations representing the surface real $P_n(z)$ and imaginary $P_n(z)$ and Fig. 7 is the sum of the two upon which may be seen the roots and the branch points of this function. It is believed that this is the first attempt at mapping a function electronically. Instrumentation of this presentation is presently being completed.

Also, the coincidences of zeros in both real and imaginary parts of $P_n(z)$ may be detected electronically and presented on the z axis of the oscilloscope representing the z plane. The horizontal and vertical voltages again sweep the oscilloscope beam in a circle of $r=z$. The trace is brightened at the roots and the presentation is one in which the roots are indicated by bright spots on the z plane.[5] Again it will be possible to trace the movement of the roots as coefficients are varied.

VI. CONCLUSION

The electronic isograph can give rapid solutions to reasonably well-behaved polynomials to three places. With the addition of a small amount of paper work it is possible to find the zeros of all but a very small number of polynomials. It is hoped that the isograph will prove extremely valuable in servomechanism and other fields where the problem may be represented as a polynomial and that theoretical analysis of engineering problems will be furthered by its use.

VII. ACKNOWLEDGMENTS

The Cadmium Sulfide X-Ray Detector*

RUDOLF FRERICHS
Department of Physics, Northwestern University, Evanston, Illinois
(Received September 12, 1949)

The CdS x ray detector is compared with the photo-multiplier x-ray detector. Reduced to the same solid angle the sensitivity of the CdS x-ray detector is of the same order of magnitude as the sensitivity of the photo-multiplier x-ray detector. As the internal amplification of the primarily released electron currents in CdS is of the order 10^3 to 10^4 compared with the amplification in the multiplier tube of $\frac{1}{2}\times10^6$ the conversion process of x-ray quanta in slow electrons in CdS must be more efficient than the corresponding processes in the combination crystal phosphor screen photo-multipher. Calibration curves show a linear relation between photo-current and intensity of x-rays at low irradiation levels. At high irradiation saturation effects occur. Oscilloscope curves of the response at 60 x-ray pulses per second are given. At strong irradiation the photo-current over a long time increases in a completely reversible way. X-ray intensities as low as 150 quanta CuK_α per second are registered with a circuit employing a WL 759 trigger tube.

INTRODUCTION

THE measurement of x-rays with a combination of a crystal phosphor screen and a photoelectric cell has been introduced by Herz in 1936.[1] Since this time every progress in the development of new phosphor screens or photo-cells has increased the sensitivity of this method. A great step was achieved in 1941, when Hodges and Morgan[2] introduced the photo-multiplier tube x-ray detector. Subsequently this combination

* This investigation was sponsored by the U. S. Navy, Bureau of Ships.

[1] R. H. Herz, Fortschr. Gebiete Röntgenstrahlen 54, 6 (1936). It is interesting to note that in his first papers Röntgen tried to determine the distribution in space of the x-rays around the tube by photometrie of barium platino cyanide screens. Now the expensive and unstable barium platino cyanide screens have generally been replaced by crystal phosphors.

[2] R. H. Morgan, Am. J. Roent. Rad. Ther. 47, 777 (1942).

has been thoroughly investigated[3] and the photo-multiplier x-ray detector is now a sensitive and reliable x-ray measuring device.

On the other hand, it was shown in 1946 by the author that synthetic CdS crystals show a large photo-conductivity under irradiation with x-rays.[4] In the photo-multiplier x-ray detector the energy of the absorbed x-rays is transformed at first in energy of slow electrons of a few ev. These electrons raised into the conduction band, subsequently recombine with the activating impurities and produce photons. A part of these photons is absorbed in the photo-cathode of the multiplier and releases a small yield of photo-electrons. These in turn release increasing cascades of secondary electrons at the consecutive stages of the multiplier. One photo-electron, liberated from the cathode, yields up to $\frac{1}{2}\times10^6$ electrons in the anode circuit. In the CdS crystal the same primary process of raising a number of slow electrons into the conduction band takes place. But in contradistinction to the man-made photo-multiplier arrangement the nature of the crystal provides the subsequent amplification of these electron currents.[5]

While in the photo-multiplier the rate of amplification in the different stages can be easily investigated, in CdS the amplification factor is only approximately known. Estimates made under rather plausible assumptions yield values of 10^3 to 10^4. Exact figures could be obtained by a simultaneous study of the light emission and the photo-conductivity of the irradiated CdS crystal. The light emission is determined by the number of electrons in the conduction band which recombine with the activating impurities. The photo-conductivity is related to the lifetime of the positive stationary space charges at the activating impurities. They make the presence of an additional electron in the conduction band possible.[6] As their lifetime is large, compared with the time one electron needs for passing through the crystal, a chain of up to 10^4 electrons cross the crystal, until the positive charge is neutralized by recombination. This amplification of the primary photo-current appears to be less favorable in the CdS crystal than in the multiplier tube. The primary processes, however, are simpler and are apparently connected with smaller losses than the corresponding processes in the combination phosphor screen photo-multiplier.

The purpose of this investigation to compare the two devices under identical conditions in order to find out for which purpose the one or the other might be best applied.

D.C. MEASUREMENTS OF THE PHOTO-CURRENT

Measurements were performed with copper target tubes provided with beryllium windows.[7] The tubes were used with half-wave and with full wave rectification but without condensors. They furnished 60 (half-wave), 120 (full wave) x-ray pulses per second.

For a comparison at higher intensities the crystal, as well as the photo-multiplier x-ray detector, were placed in the beam at a distance of 50 cm from the target. For this informatory experiment no filtering other than 1.5-mm beryllium window was used. The photo-multiplier tube was used with 102 volts across each dynode corresponding to an over-all amplification of the electron current by a factor of 1.3×10^6. The d.c. currents were measured with a sensitive micro-amperemeter (full scale 5, 50, 500, 5000×10^{-6} amp.). The photo-multiplier tube was shielded in a brass container, and a fluoroscopic screen, Patterson Type B, was attached at the tube surface behind a black, paper window. The dark current of the tube was about 1×10^{-7} amp. When the multiplier was irradiated without the phosphor screen at 24 kv and 10 ma, the current rose to $3.8\pm0.2\times10^{-6}$ amp. The crystals to be investigated have sensitive areas of the order of 1 mm^2. Accordingly, a comparable size of the phosphor screen was used. The phosphor layer was scratched from the supporting cardboard leaving an area of 1×5 mm. Under these conditions the current obtained under x-ray irradiation amounted to 12.5×10^{-6} amp., but quickly dropped to 9×10^{-6} amp. because of the fatigue effects extensively discussed by Marshall, Coltman, and Hunter.[3]

The CdS crystal showed a bright red luminescence under irradiation with filtered ultraviolet. It is known

[5] Natural amplification phenomena will play a more important role as the number of electronic devices applied in complicated mechanism (electronic calculators, electronic brains) reaches values which make it necessary to reduce the size and the labor involved in the individual device. An example is the recently developed transistor, which can replace complicated electron tubes. See furthermore: V. K. Zworykin and E. G. Ramberg, *Photoelectricity*, p. 469.

(0.5 mm Cu filter)

that luminescent CdS crystals yield large amplification.[8] The sensitive area between the Aquadag electrodes was 0.3×1.5 mm^2. It was mounted in a brass tube with a black, paper window. The leads were well insulated and shielded. At an applied potential of 280 volts the dark current remained smaller than 1×10^{-8}; it could not be observed with the microamperemeter used. Within five seconds the current rose under irradiation to $27 \pm 1 \times 10^{-6}$ amp. The amount of energy absorbed in the phosphor layer or in the crystal was not determined. The thickness of the crystals was not uniform. These crystals show a ribbon-like structure. Therefore, exact measurements of the absorption are difficult to perform. It was observed, however, with a fluoroscopic screen that only a small amount of incident soft x-rays passed through the crystal at its average thickness of 0.2 mm. Table I shows the thickness which is necessary to absorb 99 or 99.9 percent of the incident irradiation at different wave-lengths. The values are calculated from the mass absorption coefficients of cadmium determined by Laubert and Biermann.[8a] In the range between 1 and 2A no data were available.

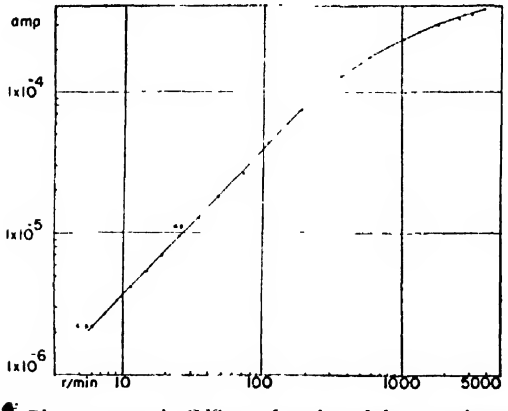

FIG. 1. Photo-current in CdS as a function of the x-ray intensity.

[8] This is to be expected from the theory outlined in reference 6. High luminescence proves that sufficient activating impurities are present which furnish the positive stationary space charges necessary for the compensation of the transported negative charges.

[8a] S. Laubert, Ann. d. Physik **40**, 553–578 (1941). H. H. Biermann, Ann. d. Physik **26**, 740 (1936).

It was not attempted to consider the influence of the scattering coefficient which is contained in these measurements but which is usually much smaller than the coefficient of true absorption. In contradistinction to other photo-conductors with larger dark currents, it is not necessary to chose the thinnest crystals. For short wave-lengths it is recommended to irradiate the ribbon-like crystals ($a > b > c$) through the surfaces $a \times c$ or even $b \times c$ in order to obtain high absorption. Thus, the effective area can be small, which is an advantage for measuring narrow bundles of x-rays.

From these experiments it follows that reduced to the same solid angle which corresponds to an effective area of 0.5 mm^2, the photo-currents obtained in CdS are one order of magnitude larger than those obtained with the multiplier.

The luminescent screen used (Patterson B) is not the most efficient. The photo-multiplier responds about three times better to the blue luminescent screen, Type C. It should be possible to use the entire light emitted by the phosphor. For instance, with a spherical mirror such as Coltman[3] used. Furthermore, the sensitive area of the phosphor screen generally should be larger (50 mm^2) in order to increase the solid angle without increasing the dark current.

On the other hand, the potential applied at the CdS crystal can be increased until the dark current reaches values comparable with the photo-multiplier dark current. Furthermore, it is possible to assemble different crystals in one plane and to connect the electrodes parallel.

In conclusion we might state that using d.c. currents the CdS crystal can be made one order of magnitude more sensitive per unit area than the photo-multiplier x-ray detector. The experiments show that the mechanism of transforming x-ray quanta into slow electrons in CdS is apparently much more effective than the transforming of x-rays→slow electrons→photons→photo-electrons at the photo-cathode since a deficiency in amplification of 10^{-2} to 10^{-3} is more than compensated.

THE PHOTO-CURRENT IN CdS AS A FUNCTION OF THE X-RAY IRRADIATION

A few measurements were made to study the photo-current in CdS as a function of the irradiation. It was previously observed by the author[6] that at high irradiation levels—for instance, with gamma-rays—the current produced in CdS crystals is proportional to the square root of the intensity of irradiation. This relation follows theoretically from the recombination processes involved in these secondary photo-currents. In equilibrium after prolonged and strong irradiation, the number n of the electrons in the conduction band and thus the current is determined by

$$dn/dt = aI - bn^2 = 0.$$

I is intensity of the impinging radiation; a is a factor which contains the absorption in the crystal and the

efficiency of conversing x-rays in slow electrons. The factor b determines the recombination rate between electrons in the conduction band and activating impurities in the lattice. At the first approximation trapping and releasing of electrons, which play such an important role in persistent phosphorescence, do not need to be considered in the equilibrium state. The number of the electrons which are trapped per second is equal to the number of electrons which are released from the traps into the conduction band per second. We make the assumption that first-order processes do not take part. Nail, Pearlman, and Urbach[9] recently pointed out that at low irradiation levels in crystal phosphors first-order processes such as energy transfer from trapped electrons to the lattice by direct transition can occur. Under certain circumstances a region of proportionality to the square root of the exciting intensity is situated between linear regions at low and extremely high intensities. Therefore, the dependence of the photo-current from the incident radiation should not be linear at high intensities. It might be pointed out here that the same is to be expected for the photo-multiplier x-ray detector if a crystal phosphor is used.[10] The combination with a fluorescent emitter, for instance, barium platino cyanide, yields a linear characteristic as fluorescent substances do not show any saturation effects.[11]

Some measurements were taken with the copper target tube at 40 kv and 20 ma. The crystal was used with 22.5 volts. The distance between crystal and target was varied from 8 to 147 cm. The results are plotted in the log-log diagram Fig. 1. The abscissa contains the true x-ray intensities. According to the manufacturer of the apparatus, at 40 kv and 20 ma the intensity of the unfiltered x-rays at 50-cm distance from the target amounts to 100 r per min. According to the measurements of Day and Taylor,[12] considerable corrections have to be applied at the simple distance square relation, if the tube potential is low and if no filters are interposed. The intensity values in Fig. 2 are corrected, using Fig. 4 of Day and Taylor, assuming a value of 40 kv and 1.5-mm beryllium window. The curve covers the range 10 r per min. up to 5000 r per min. It is straight at low values and becomes curved above 100 r per min. The tube used in our experiments with 40-kv peak current emits a spectrum, the distribution of which shifts periodically with the alternating voltage applied. In Fig. 1 the size of corrections is marked under the conservative assumption that the actual average voltage would be as low as 20 kv. Another possible correction, the slow change of the photo current with time, will be discussed later.

TABLE III. Current through crystal and multiplier at different filtering.

X ray tube Potential	X ray tube Current	Thickness of Al filter	Current ×10 ^{8} amp. Crystal	Current ×10 ^{8} amp. Photo multiplier

60	2.2	$\frac{1}{4}$ in	0.200	0.080
60	2.2	$\frac{1}{2}$ in	0.100	0.032
60	2.2	$\frac{3}{4}$ in	0.042	0.012
60	2.2	1 in	0.017	0.005
60	2.2	5/4 in.	0.005	0.002

Measurements at low intensity levels have been performed by Mr. J. E. Jacobs of the Department of Electrical Engineering, Northwestern Technological Institute.[13] The measurements were taken with a tungsten target tube. The x-rays in Table II are filtered by 0.5 mm Cu. The r values were determined by a Victoreen r meter. The crystal had a sensitive area of 3×1.5 mm^2; the field strength applied was low and equal 90 volts per 3 mm. The currents were measured with a d.c. amplifier. The photo-multiplier tube 931A was selected from a large number. The potential at the single dynodes was 105 volts. A Patterson E_2 industrial screen was used behind a lead aperture of 3×1.5 mm. This limited the solid angle to the value of the crystal.

With increasing potential the efficiency becomes smaller similarly as the efficiency of an ionization chamber decreases with increasing hardness or radiation. As the radiation was not homogeneous, it is not possible to construct a curve, sensitivity *versus* wave-length.[14] The general shape of such a curve should indicate that ionization in air and photo-conductivity in CdS are not parallel, if the hardness of the x-rays is changed.[15] Furthermore, the K absorption edge of cadmium at 0.460A should produce a discontinuity in this curve analogous to the discontinuity produced in the photographic plate due to the silver K edge. Similar

[13] The author is much indebted to Mr. Jacobs for the facility of using these values in the present investigation.

[14] It might be useful to determine this dependency, for instance, with the powerful filter method developed by H. Kustner, Zeits. f. Physik 70, 324 (1931). According to his measurements monochromatic radiations $\Delta\lambda=0.005$A with intensities from 5×10^{-4} to 27×10^{-3} r per min. can be produced in the wave-length region 0.128 to 2.50A.

[15] For a comparison of the effects produced by x-rays of different wave-lengths at ionization in air, at fluorescent screens and at the photographic plate see: G. L. Clark, *Applied X-Rays* (New York, 1940), p. 68, Fig. 48.

discontinuities are to be expected with the crystal phosphor photo-multiplier x-ray detector at the zinc and cadmium K absorption edges.

Table III contains further measurements with the photo-multiplier and the CdS crystal obtained by Mr. Jacobs. The potential was constant, and different thicknesses of aluminum filtering were applied. Crystal and photo-multiplier were used in 150-cm distance from the tungsten target tube.

THE SPEED OF RESPONSE

As the photo-multiplier can follow light pulses of the order of 10^{-8} sec. the speed of the photo-multiplier x-ray detector is determined by the properties of the screen used. Fast responding phosphors (calcium tungstate) show, according to Marshall, Coltman, and Hunter, a fast and exponential decline of the photo-current, after irradiation with x-ray pulses of 1 μsec. duration. The somewhat persistent sulfide screens, Patterson B and C, are slower. According to their oscillograms the response of the phosphor screen does not match the short x-ray pulse applied. It is not possible to determine its exact shape from such measurements.

Identical experiments could not be performed with the CdS crystal, as the necessary radar pulsing equipment was not available. However, the usual chopping of the x-ray output with 60, respectively, 120 pulses per second, which is obtained by one way or two way rectifiers is very useful for the oscilloscopic observation of the currents in CdS.

A comparison was made of the current *versus* time curves obtained with the photo-multiplier x-ray detector and the CdS crystal at the half-wave tube. The comparison of Figs. 2 and 3 shows that the reproduction of the x-ray intensity curve obtained with these two devices is nearly identical. The declining branch in the photo-multiplier curve approaches the ideal curve more perfectly,[16] but also at these low frequencies the slow decline of the phosphor in the photo-multiplier can be observed. According to Marshall, Coltman, and Hunter, the screens, Type B and C, are somewhat persistent. This dissymmetry is to be attributed to the afterglow of the phosphor. The curves show that at these rather low frequencies the CdS crystal follows the x-ray intensity distribution with good approximation. Figure 4 has been taken with the CdS crystal connected directly to the input resistance of the oscilloscope without battery. In the polar crystal the x-rays produce a small e.m.f., which can be observed with the oscilloscope, if the irradiation is strong enough.[16a]

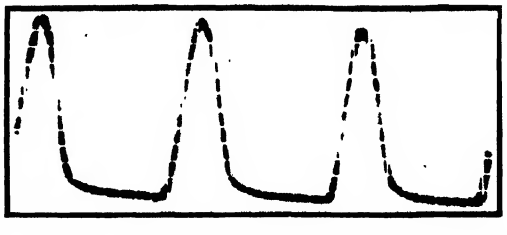

FIG. 3. 30 kv, 8 ma, distance 50 cm, photo-multiplier x-ray detector, screen size = 1 mm², Patterson Type B, dynode potential = 123 volts, current amplitude = 1.3×10^{-7} amp.

[16] The intensity of the afterglow of the phosphor is proportional to the number of recombination processes bn^2. The photo-current is proportional to the number n of electrons in the conduction band. Hence the optical decay is faster than the decay of the photo-current. Verified by L. Gildart and A. W. Ewald in a paper given at the Oak Ridge meeting of the Physical Society (March, 1950).

Curve 4 shows the current in the crystal under weak irradiation. As it has been observed with the luminescence of crystal phosphors, the slope of the raising and declining branch of these curves depends upon the intensity of irradiation. At low intensities the current rises and declines slowly, and the x-ray curve is badly reproduced. One should expect that at low intensities the curve of the photo-multiplier x-ray detector should show some similar shape.

From these experiments it can be concluded that for x-ray pulses of 60 per sec. the CdS crystal can replace the photo-multiplier x-ray detector.

FIG. 4. 40 kv, 20 ma, 17 cm distance, CdS crystal without potential applied, crystal photo-current amplitude = 4.8×10^{-9} amp.

EFFECTS DUE TO PROLONGED IRRADIATION

The fatigue effects observed in photo-multiplier x-ray detectors are due to the multiplier tube. With sufficiently low levels of irradiation they can be greatly reduced. The phosphor screen used with the photo-multiplier shows no change in its sensitivity with prolonged irradiation. An experiment was made to find out whether small changes in the brightness of the phosphor screen take place at prolonged irradiation with intense x-rays. The detector was irradiated with 36,000 r at 60 pulses per sec. In order to avoid fatigue of the multiplier the potential at the dynodes was interrupted during this irradiation. The currents observed at the beginning and at the end of this irradiation agreed within 0.6 percent. This proves that the Patterson B screen does not undergo any observable changes in its luminosity. Such effects could be due to a slow rearrangement of the electrons in the traps of different depths.

A CdS crystal was adjusted so that it showed a photo-current of 85×10^{-6} amp., after a few seconds of irradiation. This current slowly increased during 11 hr. of continuous irradiation until it finally reached 182×10^{-6} amp. The irradiation during this period amounted to 2.5×10^{5} r. The x-rays were pulsed (60 per sec.) and the potential at the crystal was kept constant. The dark current remained throughout this experiment below 10^{-8} amp. After about 12 hr. recovery the crystal

[16a] T. Broser and R. Warminsky, Zeits. f. Naturforschung 5A, 63 (1950).

FIG. 5. 40 kv, 20 ma, 130 cm distance, CdS crystal, potential applied at crystal = 45 volts, current amplitude = 1.2×10^{-8} amp.

reassumed its original value, corresponding to 85×10^{-6} amp. at that particular level of irradiation; and no permanent changes remained. This slow change of the resistance has been investigated with gamma-rays.[6] It is attributed to a rearrangement in the occupancy of deep and shallow traps during prolonged and intermittent irradiation.

The slow increase in the final current has to be considered at all d.c. measurements with these crystals. In the measurements of Fig. 1 the currents were always read after 5 sec. irradiation.

It has been shown by the author that the original high dark resistance can be quickly restored by irradiation with infra-red light.

MEASURING OF SMALL X-RAY INTENSITIES WITH CdS CRYSTALS

Measurements of very weak x-rays were made using a trigger tube (Westinghouse WL759) in a circuit developed by Dr. R. J. Cashman.[17] The current in the crystals (active area 0.5×6 mm^2) charges a well-insulated condensor. As soon as the potential across the condensor reaches a defined value, the trigger tube starts, and the resultant impulse is counted by a suitable amplifier and an electromagnetic counting device. The frequency of this periodic discharging is a scale for the intensity of the impinging radiation and currents of the order of 10^{-11} amp. can easily be measured.

The copper target x-ray tube, used in a full wave rectifier circuit, was applied with reduced heating current. The number of quanta emitted by the tube were determined by a Geiger-Müller counter with a measured efficiency of 40 percent for the copper K_α line monochromatized by a simple rocksalt spectrometer. The exit slit in front of the Geiger-Müller tube of 3 mm^2 defined the same bundle of x-rays with the crystal and with the counter.

With 1900 quanta hitting the crystal the condensor was charged within 12 to 13 sec. to the starting potential of the trigger tube. With this irradiation (about 150 quanta per sec.) a periodical trigging every 12 to 13 sec. is produced. This state is reached three minutes after the irradiation of the crystal has started. However, 20 min. after the x-ray irradiation was interrupted the crystal was still counting with a rate of one triggering in 55 to 59 sec. This persistent conductivity can be quickly reduced to zero, if a small amount of infra-red simultaneously illuminates the crystal during the irradiation with x-rays. The conductivity reached under x-ray irradiation is lowered somewhat by the simultaneous infra-red irradiation. 2300 quanta are necessary to charge the smallest capacity so that the trigger tube starts every 11 sec. Under the additional infra-red irradiation the trigger tube stops after counting two or three more counts (equivalent to 2300 quanta each), as soon as the x-ray irradiation is interrupted. No more counts were observed in the following 10 hr. The additional infra-red irradiation can also be applied between the different triggerings. It should be possible to design a circuit where each triggering flashes a small infra-red lamp (for instance, a xenon discharge), which reduces the persistent conductivity.

Thus, the trigger circuit is quite promising for the measuring of small numbers of x-ray quanta. Further experiments have to be made to find the actual limit of this method. As the current at 150 x-ray quanta per sec. is of the order of 1×10^{-11} amp. $=6.3\times10^7$ electron charges per sec. the efficiency in this case is 4.2×10^5 electrons per x-ray quantum.

CONCLUSIONS

The measurements show that the sensitivity of the CdS crystal can be compared directly with the sensitivity of the photo-multiplier x-ray detector. The crystal has in its present form the disadvantage that the response to x-ray pulses is apparently slower and that the current reaches a final value only after long irradiation. As the persistence in the original zinc sulfide screens has been greatly reduced by "killers," it might be possible to reduce the inertial of CdS by suitable impurities. On the other hand, the crystals do not show the fatigue effects observed with multiplier tubes. Their small size is a further advantage in some applications. As the crystal size defines the sensitive volume, it is not necessary to screen the receiver with lead slits.

The crystals can be grown in large numbers. They afford no treatment but a suitable mounting, for instance on a polystyrene strip, and the application of the Aquadag electrodes. As the crystal current is proportional to the first power of the potential applied no power of supply of extreme constancy is necessary.

The present measurements deal with such intensities that the effects of single x-ray quanta have not been considered. The regularities of electron pulses produced in these crystals afford further detailed investigations.[18]

[18] S. G. Zizzo and J. B. Platt, Phys. Rev. 76, 704 (1949) studied the pulses due to x-ray quanta as well as the continuous photocurrent in CdS crystals obtained from the author.

Note added in proof: Measurements of the efficiency of the photocurrents produced in CdS crystals by irradiation with x-rays have been recently published by Y. Fassbender and O. Hachenberg, Ann. d. Physik (6) 6, 229 (1949). They confirm our results regarding the amplification factor in CdS.

Diffraction by a Cylindrical Obstacle*

CHARLES H. PAPAS
Cruft Laboratory, Harvard University, Cambridge, Massachusetts
(Received September 23, 1949)

The diffraction of a plane electromagnetic wave by an infinitely long, perfectly conducting cylinder has been treated by a variational method (see the two papers by H. Levine and J. Schwinger). The incident field is assumed to be polarized in the direction of the cylinder axis, and thus the entire field is of two-dimensional nature. This formulation yields an expression for the diffracted cylindrical wave amplitude, at distances from the cylinder large compared to its transverse dimension and the wave-length, which is stationary relative to small independent variations of the surface currents arising from plane-wave excitation along a pair of directions in space; furthermore, the stationary form of the diffracted amplitude is independent of the scale of the surface currents. In accordance with a theorem of Levine and Schwinger, the total plane-wave scattering cross section is simply related to the diffracted cylindrical wave amplitude in the direction of incidence. To examine the high frequency behavior of the cross section, the surface current induced by a plane wave is taken different from zero only on the illuminated part of the cylinder, where its value is derived from the tangential component of the incident magnetic field. The resulting cross section is obtained and is shown to approach $4a$ when ka approaches infinity ($k=2\pi\div$wave length, a equals the radius of cylinder).

I. INTRODUCTION

THE theoretical examination of the diffraction of a steady-state plane electromagnetic wave by a cylindrical obstacle has interested many investigators. One of the earliest treatments proceeds according to the Fourier-Lamé eigenfunction method. The incident electromagnetic wave is assumed to be polarized parallel to the axis of the perfectly conducting, circular cylinder. The axis of the cylinder lies along the x axis, and the incident wave has only an x component of the electric field, $E_x^{\text{inc}}(\rho,\phi)$, and a y component of the magnetic field, $H_y^{\text{inc}}(\rho,\phi)$ (Fig. 1). For an incident wave whose electric field is of unit amplitude and propagating in the direction ϕ_1, i.e., $E_x^{\text{inc}}=\exp[ik\rho\cos(\phi-\phi_1)]$, the corresponding scattered electric field is given by

$$E_x^{sc}(\rho,\phi-\phi_1)=-\sum_{-\infty}^{\infty}(i)^m\frac{J_m(ka)}{H_m^{(1)}(ka)}H_m^{(1)}(k\rho)\cos m(\phi-\phi_1), \quad (1)$$

where $J_m(x)$ are the Bessel functions, and $H_m^{(1)}(x)$ are the Hankel functions of the first kind, and $k=2\pi\div$wave-length.

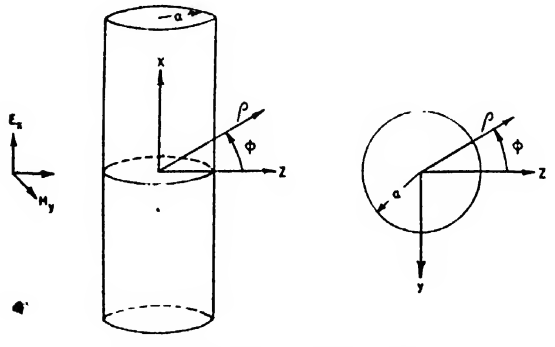

FIG. 1. Diffracting circular cylinder.

* The research reported in this document was made possible through support extended Cruft Laboratory, Harvard University, jointly by the Navy Department (ONR), the Signal Corps of the U. S. Army, and the U. S. Air Force, under ONR Contract N5ori-76, T. O. I.

The inadequacy of the rigorous representation (1) stems from the fact that its convergence becomes slower with increasing values of ka, i.e., at high frequencies. To avoid this difficulty, Debye[1] represented the scattered field by a Fourier integral in the following manner. Let

$$f(m)=\frac{H_m^{(1)}(k\rho)}{H_m^{(1)}(ka)}\cos m(\phi-\phi_1),$$

where m can be considered to be a continuous real variable. According to the Fourier integral theorem,

$$f(m)=\frac{1}{2\pi}\int_{-\infty}^{\infty}d\mu\int_{\infty}^{\infty}f(\alpha)\exp[i\mu(m-\alpha)]d\alpha$$

$$=\frac{1}{\pi}\int_{-\infty}^{\infty}d\mu\exp(i\mu m)\int_0^{\infty}f(\alpha)\cdot\cos\mu\alpha\cdot d\alpha$$

$$=\frac{1}{\pi}\int_{-\infty}^{\infty}d\mu\exp(i\mu m)\int_0^{\infty}\frac{H_\alpha^{(1)}(k\rho)}{H_\alpha^{(1)}(ka)}\cdot\cos\alpha(\phi-\phi_1)\cdot\cos\mu\alpha\cdot d\alpha.$$

Then,

$$E_x^{sc}(\rho,\phi-\phi_1)=\frac{1}{\pi}\sum_{m=-\infty}^{\infty}(i)^mJ_m(ka)\cdot\int_{-\infty}^{\infty}d\mu\exp(i\mu m)\int_0^{\infty}\frac{H_\alpha^{(1)}(k\rho)}{H_\alpha^{(1)}(ka)}\cos\alpha(\phi-\phi_1)\cdot\cos\mu\alpha\cdot d\alpha.$$

Since

$$\sum_{m=-\infty}^{\infty}(i)^mJ_m(ka)\exp(im\mu)=\exp(ika\cos\mu),$$

by interchanging the order of summation and integra-

[1] P. Debye, "Das electromagnetische Feld um einem Zylinder und die Theorie des Regenbogens," Physik. Zeits. 9, 775–778 (1908).

tion Debye's integral representation is obtained:

$$E_x^{sc}(\rho,\phi-\phi_1)=-\frac{1}{\pi}\int_{-\infty}^{\infty}\exp(ika\cos\mu)d\mu \times\int_0^{\infty}\frac{H_\alpha^{(1)}(k\rho)}{H_\alpha^{(1)}(ka)}\cos\alpha(\phi-\phi_1)\cdot\cos\mu\alpha\cdot d\alpha. \quad (2)$$

By an approximate evaluation of (2) for large ka, he obtained

$$E_x^{sc}(\rho,\phi)=-\left(\frac{ka\cos(\phi/2)}{2k\rho}\right)^{\frac{1}{2}}\exp\left[ik\left(\rho-2a\cos\frac{\phi}{2}\right)\right] \quad (3)$$

for the scattered electric field resulting from a plane wave incident in the direction $\phi_1=0$.

Up to the present we have had the rigorous eigenfunction expansion of the scattered field (1) which suffers from convergence difficulties for large ka, and the Debye summation scheme yielding the expression (3) for the high frequency far-zone scattered field, valid for directions not in the neighborhood of $\phi=\pi$. Consequently (3) cannot be used to calculate the total scattering cross section of the cylinder; (1) can be used, however, even for large values of ka, i.e., at high frequencies, but only with considerable heuristic manipulation of the slowly convergent eigenfunction expansion.

It is the purpose of this paper to show that the aforementioned difficulties can be avoided if the problem is formulated from the start using a variational principle in the manner of Levine and Schwinger.[2,3] This formulation yields an expression for the diffracted cylindrical wave amplitude, at distances from the cylinder large compared to its transverse dimension and the wavelength, which is stationary relative to small independent variations of the surface currents arising from plane-wave excitation along a pair of directions in space. Furthermore, the stationary form of the diffracted amplitude is independent of the scale of the surface currents. The total plane-wave scattering cross section is simply related to the diffracted cylindrical wave amplitude in the direction of incidence. To examine the high frequency behavior of the cross section ($ka\gg1$), the surface current induced by a plane wave is taken different from zero only on the illuminated part of the cylinder, where its value is derived from the tengential component of the incident magnetic field.

II. INTEGRAL EQUATION FORMULATION

Consider a plane electromagnetic wave incident upon a perfectly conducting circular cylinder of radius a, whose axis lies along the x axis of a rectangular coordinate system, Fig. 1. The incident wave is polarized parallel to the axis of this cylinder, its electric field

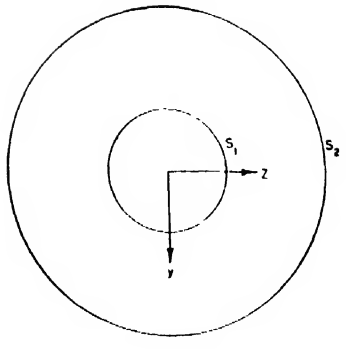

FIG. 2. Integration domain.

being given by

$$E_x^{inc}(\rho,\phi)=\exp[ik\rho\cos(\phi-\phi_1)], \quad (1)$$

where ρ,ϕ are cylindrical coordinates, $k=2\pi\div$ wavelength, and ϕ_1 is the direction of propagation. The scattered electric field, $E_x^{sc}(\rho,\phi)$, is also polarized parallel to the cylinder axis. The electric field at any point r, r being a two-dimensional vector from the origin to any point (ρ,ϕ), is the sum of the incident and scattered fields, $E_x(r)=E_x^{inc}(r)+E_x^{sc}(r)$. The problem is formulated in terms of these electric fields. To emphasize their two-dimensional scalar nature, denote them by $\psi(r)\equiv E_x(r)$, $\psi^{inc}(r)\equiv E_x^{inc}(r)$, and $\psi^{sc}(r)\equiv E_x^{sc}(r)$.

Note that $\psi(r)$ satisfies the scalar wave equation

$$(\nabla^2+k^2)\psi(r)=0, \quad (2)$$

and the two-dimensional scalar Green's function $G(r,r')$ satisfies the inhomogeneous scalar wave equation

$$(\nabla^2+k^2)G(r,r')=-\delta(r-r'), \quad (3)$$

where the inhomogeneous term is the two-dimensional Dirac delta-function. Applying Green's second scalar identity to $\psi(r)$ and $G(r,r')$, we obtain

$$\int_v[G(r',r)(\nabla'^2+k^2)\psi(r')-\psi(r')(\nabla'^2+k^2)G(r',r)]d\tau = \int_{s_1+s_2}\left[G(r',r)\frac{\partial}{\partial n'}\psi(r')-\psi(r')\frac{\partial}{\partial n'}G(r',r)\right]ds', \quad (4)$$

where the derivative in the surface integral is taken in the direction of the outward normal (Fig. 2). The surface integral extends over the surface of the scattering cylinder, s_1, and a concentric cylinder, s_2, of very large radius. In view of (2) and (3) the volume integral becomes $\psi(r)$, and since $\psi(r)=0$ when r lies on the scattering cylinder, it follows that

$$\psi(r)=\int_{s_1}G(r',r)\frac{\partial}{\partial n'}\psi(r')ds' + \int_{s_2}\left[G(r',r)\frac{\partial}{\partial n'}\psi(r')-\psi(r')\frac{\partial}{\partial n'}G(r',r)\right]ds'. \quad (5)$$

Recalling that $\psi(r)=\psi^{inc}(r)+\psi^{sc}(r)$, the integral over s_2

[2] H. Levine and J. Schwinger, "On the theory of diffraction by an aperture in an infinite plane screen, I," Phys. Rev. 74, 958–974 (1948).

[3] H. Levine and J. Schwinger, "On the theory of diffraction by an aperture in an infinite plane screen, II," Phys. Rev. 75, 1423–1432 (1949).

in (5) becomes

$$\int_{s_0}\left[G(r',r)\frac{\partial}{\partial n'}\psi^{\mathrm{inc}}(r')-\psi^{\mathrm{inc}}(r')\frac{\partial}{\partial n'}G(r',r)\right]ds'$$

$$+\int_{s_2}\left[G(r',r)\frac{\partial}{\partial n'}\psi^{s}(r')-\psi^{s}(r')\frac{\partial}{\partial n'}G(r',r)\right]ds'.$$

The first integral yields $\psi^{\mathrm{inc}}(r)$ and the second disappears due to the asymptotic behavior of the integrand for $r'\to\infty$, and (5) takes the form

$$\psi(r)=\psi^{\mathrm{inc}}(r)+\int_{s_1}G(r',r)\frac{\partial}{\partial n'}\psi(r')ds'. \tag{6}$$

Since $(\partial/\partial n')\psi(r')=-(\partial/\partial\rho')E_z(\rho',\phi')=i\omega\mu H_\phi(\rho',\phi')$ and $ds'=ad\phi'$, (6) becomes

$$\psi(\rho,\phi)=\psi^{\mathrm{inc}}(\rho,\phi)+\int_0^{2\pi}i\omega\mu H_\phi(a,\phi')G(a,\phi';\rho,\phi)\cdot ad\phi'. \tag{7}$$

$H_\phi(a,\phi')$ is numerically equal to the surface-current density at the point (a,ϕ') on the cylinder. Let $I_{\phi_1}(\phi')=i\omega\mu a H_\phi(a,\phi')$, where $I_{\phi_1}(\phi')$ is proportional to the current density at the point (a,ϕ') due to the incident wave (1) propagating in the direction ϕ_1. With this notation, (7) becomes

$$\psi(\rho,\phi)=\psi^{\mathrm{inc}}(\rho,\phi)+\int_0^{2\pi}I_{\phi_1}(\phi')G(a,\phi';\rho,\phi)d\phi'. \tag{8}$$

Since $\psi(a,\phi)=0$, i.e., E_z must disappear at the surface of the cylinder, the following integral equation is obtained by placing $\rho=a$ in (8):

$$0=\psi^{\mathrm{inc}}(\rho,\phi)+\int_0^{2\pi}I_{\phi_1}(\phi')G(a,\phi';a,\phi)d\phi'$$

or

$$-\exp[ika\cos(\phi-\phi_1)]=\int_0^{2\pi}I_{\phi_1}(\phi')G(a,\phi';a,\phi)d\phi' \tag{9}$$

The solution of this integral equation would yield $I_{\phi_1}(\phi)$, i.e., the current except for a numerical factor, produced by a plane incident wave traveling in the direction ϕ_1. By substituting this solution back into (8) and carrying out the indicated integration, the diffracted field $\psi(\rho,\phi)$ could be determined. Two objections are immediately apparent, the first is the difficult problem of solving (9) for $I_{\phi_1}(\phi')$, the second is the evaluation of the integral in (8) once $I_{\phi_1}(\phi')$ is determined. Moreover, to obtain the total scattering cross section, still another integration would have to be performed. Use will be made of the integral equation (9) to formulate a variational principle for the scattered wave amplitude.

III. VARIATIONAL PRINCIPLE FOR SCATTERED WAVE AMPLITUDE

Since the two-dimensional Green's function, $G(r,r')$, has to satisfy the inhomogeneous wave equation (3) and the radiation condition, i.e., it must represent at large distances from the cylinder outwardly propagating cylindrical waves, it follows that $G(r,r')=(i/4)H_0\times(k|r-r'|)$. For large r, the leading term of the asymptotic expansion is

$$r\to\infty:\quad G(r,r')\sim\frac{i}{4}\left(\frac{2}{\pi k|r-r'|}\right)^{\frac{1}{2}}\exp(ik)|r-r'|\exp\left(-i\frac{\pi}{4}\right),$$

where

$$|r-r'|=[\rho^2+\rho'^2-2\rho\rho'\cos(\phi-\phi')]\sim\rho\left(1-\frac{\rho'}{\rho}\cos(\phi-\phi')\right).$$

With these asymptotic values the scattered field, which is given by the integral in (8), at large distances becomes

$$\psi^{sc}(\rho,\phi)\sim\frac{i}{4}\left(\frac{2}{\pi ik\rho}\right)^{\frac{1}{2}}\exp(ik\rho)\times\left[\int_0^{2\pi}\exp[-ika\cos(\phi-\phi')]I_{\phi_1}(\phi')d\phi'\right].$$

The scattered wave amplitude is represented by the quantity in square brackets. We denote it by $A(\phi,\phi_1)$:

$$A(\phi,\phi_1)=\int_0^{2\pi}\exp[-ika\cos(\phi-\phi')]I_{\phi_1}(\phi')d\phi'. \tag{10}$$

As the notation explicitly denotes, $A(\phi,\phi_1)$ is the scattered wave amplitude in the direction ϕ for an incident wave traveling in the direction ϕ_1.

Multiplication of the integral equation (9) by $I_{\phi_2}(\phi)$ and integration with respect to ϕ (in accordance with the notation that $I_{\phi_2}(\phi)$ is $i\omega\mu a$ times the surface-current density at the point (a,ϕ) due to an incident plane wave traveling in the direction ϕ_2) leads to

$$-\int_0^{2\pi}\exp[ika\cos(\phi-\phi_1)]I_{\phi_2}(\phi)d\phi=\int_0^{2\pi}\int_0^{2\pi}d\phi I_{\phi_2}(\phi)G(a,\phi';a,\phi)I_{\phi_1}(\phi')d\phi'. \tag{11}$$

But according to (10),

$$\int_0^{2\pi}\exp[ika\cos(\phi-\phi_1)]I_{\phi_2}(\phi)d\phi=\int_0^{2\pi}\exp[-ika\cos(\pi+\phi_1-\phi)]I_{\phi_2}(\phi)d\phi=A(\pi+\phi_1,\phi_2). \tag{12}$$

$A(\pi+\phi_1,\phi_2)$ represents the scattered wave amplitude in the direction of $\pi+\phi_1$ due to an incident wave traveling in the direction ϕ_2, and it is clear that it must equal the scattered wave amplitude in the direction $\pi+\phi_2$ due to an incident wave traveling in the direction ϕ_1. This reciprocity relation is given by the equality,

$$A(\pi+\phi_1,\phi_2)=A(\pi+\phi_2,\phi_1). \tag{13}$$

Dividing (11) by

$$\int_0^{2\pi}\exp[ika\cos(\phi-\phi_1)]I_{\phi_2}(\phi)d\phi \times\int_0^{2\pi}\exp[ika\cos(\phi-\phi_2)]I_{\phi_1}(\phi)d\phi,$$

and taking into consideration (12) and (13),

$$\frac{1}{A(\pi+\phi_2,\phi_1)}=\frac{1}{A(\pi+\phi_1,\phi_2)}\frac{\int_0^{2\pi}\int_0^{2\pi}d\phi I_{\phi_2}(\phi)G(a,\phi';a,\phi)I_{\phi_1}(\phi')d\phi'}{\int_0^{2\pi}\exp[ika\cos(\phi-\phi_1)]I_{\phi_2}(\phi)d\phi\int_0^{2\pi}\exp[ika\cos(\phi-\phi_2)]I_{\phi_1}(\phi)d\phi} \tag{14}$$

The expression (14) is homogeneous in $I_{\phi_1}(\phi)$, $I_{\phi_2}(\phi)$ and stationary with respect to independent first-order variations about their correct values (determined by integral equations of the form (9)). The property of homogeneity is clear. To show the stationary property of (14), proceed as follows. Clearing fractions in (14),

$$\int_0^{2\pi}\exp[ika\cos(\phi-\phi_1)]I_{\phi_2}(\phi)d\phi \times\int_0^{2\pi}\exp[ika\cos(\phi-\phi_2)]I_{\phi_1}(\phi)d\phi = -A\int_0^{2\pi}\int_0^{2\pi}d\phi I_{\phi_2}(\phi)G(\phi,\phi')I_{\phi_1}(\phi')d\phi',$$

where $A\equiv A(\pi+\phi_1,\phi_2)$, $G(\phi',\phi)\equiv G(a,\phi';a,\phi)$. Now take the variations of $I_{\phi_2}(\phi)$, $I_{\phi_1}(\phi)$, and A.

$$\begin{aligned}&\int_0^{2\pi}\exp[ika\cos(\phi-\phi_1)]\delta I_{\phi_2}(\phi)d\phi \times\int_0^{2\pi}\exp[ika\cos(\phi-\phi_2)]I_{\phi_1}(\phi)d\phi\\ &+\int_0^{2\pi}\exp[ika\cos(\phi-\phi_1)]I_{\phi_2}(\phi)d\phi \times\int_0^{2\pi}\exp[ika\cos(\phi-\phi_2)]\delta I_{\phi_1}(\phi)d\phi_1\\ &=-\delta A\int_0^{2\pi}\int_0^{2\pi}d\phi I_{\phi_2}(\phi)G(\phi,\phi')I_{\phi_1}(\phi')d\phi'\\ &-A\int_0^{2\pi}\int_0^{2\pi}d\phi\delta I_{\phi_2}(\phi)G(\phi,\phi')I_{\phi_1}(\phi')d\phi'\\ &-A\int_0^{2\pi}\int_0^{2\pi}d\phi I_{\phi_2}(\phi)G(\phi,\phi')\delta I_{\phi_1}(\phi')d\phi'.\end{aligned}$$

Using (12) and (13) this can be written in the form

$$\begin{aligned}&A\int_0^{2\pi}\exp[ika\cos(\phi-\phi_1)]\delta I_{\phi_2}(\phi)d\phi\\ &+A\int_0^{2\pi}\exp[ika\cos(\phi-\phi_2)]\delta I_{\phi_1}(\phi)d\phi\\ &=-\delta A\int_0^{2\pi}\int_0^{2\pi}d\phi I_{\phi_2}(\phi)G(\phi,\phi')I_{\phi_1}(\phi')d\phi'\\ &-A\int_0^{2\pi}\int_0^{2\pi}d\phi\delta I_{\phi_2}(\phi)G(\phi,\phi')I_{\phi_1}(\phi')d\phi'\\ &-A\int_0^{2\pi}\int_0^{2\pi}d\phi I_{\phi_2}(\phi)G(\phi,\phi')\delta I_{\phi_1}(\phi')d\phi'.\end{aligned}$$

Combining terms, this equation becomes

$$\begin{aligned}&\delta A\int_0^{2\pi}\int_0^{2\pi}d\phi I_{\phi_2}(\phi)G(\phi,\phi')I_{\phi_1}(\phi')d\phi'\\ &=-A\int_0^{2\pi}d\phi\delta I_{\phi_2}(\phi)\Big[\int_0^{2\pi}d\phi'G(\phi,\phi')I_{\phi_1}(\phi')\\ &+\exp[ika\cos(\phi-\phi_1)]\Big]-A\int_0^{2\pi}d\phi'\delta I_{\phi_1}(\phi')\\ &\Big[\int_0^{2\pi}d\phi G(\phi,\phi')I_{\phi_2}(\phi)\\ &+\exp[ika\cos(\phi'-\phi_2)]\Big].\end{aligned} \tag{15}$$

If $I_{\phi_1}(\phi)$ and $I_{\phi_2}(\phi)$ satisfy integral equations of the form (9), then the square-bracket terms in (15) vanish identically. Hence A is stationary with respect to first-order independent variations of $I_{\phi_1}(\phi)$ and $I_{\phi_2}(\phi)$.

IV. A THEOREM CONCERNING THE TOTAL SCATTERING CROSS SECTION AND SCATTERED WAVE AMPLITUDE

The total scattering cross section is defined by the ratio of the total scattered power per unit length of

cylinder to the incident power per unit area. The time-average incident power per unit area, $\bar{S}^{\text{inc}}$, is given by $\frac{1}{2}\,\text{Re}E\times H^*=\frac{1}{2}\,\text{Re}E^*\times H$, where the asterisk indicates the conjugate complex and Re the real part. Since

$$E_x^{\text{inc}}=\exp(ikz)$$

and

$$H_y^{\text{inc}}=\frac{1}{i\omega\mu}\frac{\partial}{\partial z}E_x^{\text{inc}}=\frac{k}{\omega\mu}\exp(ikz),$$

then

$$\bar{S}^{\text{inc}}=\tfrac{1}{2}\,\text{Re}E_x^{*\text{inc}}H_y^{\text{inc}}=\frac{k}{2\omega\mu}.$$

The time-average scattered power, $\bar{P}^{sc}$, passing through a cylinder s_2 of large radius is equal to the time-average power leaving the cylindrical surface s_1, i.e.,

$$\bar{P}^{sc}=\text{Re}\int_{s_2}\tfrac{1}{2}(E_x^{sc}(\rho,\phi))(-H_\phi^{sc}(\rho,\phi))\rho d\phi$$

$$=\text{Re}\int_{s_1}\tfrac{1}{2}(E_x^{sc}(a,\phi))(-H_\phi^{sc}(a,\phi))ad\phi.$$

The total scattering cross section, σ, is then given by the expression

$$\sigma=\frac{\bar{P}^{sc}}{\bar{S}^{\text{inc}}}=\frac{1}{k}\,\text{Re}\frac{1}{i}\int_0^{2\pi}E_x^{*sc}(a,\phi)\frac{\partial}{\partial\rho}E_x^{sc}(a,\phi)ad\phi. \quad (16)$$

At the surface of the cylinder, $E_x^{*sc}(a,\phi)=-E_x^{*\text{inc}}(a,\phi)$; hence

$$\sigma=\frac{1}{k}\,\text{Re}\frac{1}{i}\int_0^{2\pi}-E_x^{*\text{inc}}(a,\phi)\frac{\partial}{\partial\rho}[E_x(a,\phi)-E_x^{\text{inc}}(a,\phi)]ad\phi.$$

But

$$\int_0^{2\pi}E_x^{*\text{inc}}(a,\phi)\frac{\partial}{\partial\rho}E_x^{\text{inc}}(a,\phi)ad\phi=0,$$

and consequently

$$\sigma=\frac{1}{k}\,\text{Re}\frac{1}{i}\int_0^{2\pi}\exp[-ika\cos(\phi-\phi_1)]I_{\phi_1}(\phi)d\phi, \quad (17)$$

where use has been made of $a(\partial/\partial\rho)E_x(a,\phi)=-i\omega\mu aH_\phi\times(a,\phi)=-I_{\phi_1}(\phi)$. In view of (10) and (17) σ can be represented in terms of the scattered wave amplitude:

$$\sigma=\frac{1}{k}\,\text{Re}\frac{1}{i}A(\phi_1,\phi_1)=\frac{1}{k}\,\text{Im}A(\phi_1,\phi_1), \quad (18)$$

where Im means imaginary part.

V. LOW FREQUENCY SCATTERING CROSS SECTION

To find the total scattering cross section it is necessary first to compute $A(\phi_1,\phi_1)$ from (14) and then to use (18). Let $\phi_1=0$ and $\phi_2=\pi$ in (14); then

$$\frac{1}{A(\pi,\pi)}=\frac{\int_0^{2\pi}\int_0^{2\pi}d\phi I_\pi(\phi)G(a,\phi';a,\phi)I_0(\phi')d\phi'}{\int_0^{2\pi}\exp(ika\cos\phi)I_\pi(\phi)d\phi\int_0^{2\pi}\exp(-ika\cos\phi)I_0(\phi)d\phi}. \quad (19)$$

At low frequencies $ka\ll1$; also choose $I_\pi(\phi)=I_0(\phi)=1$. The numerator then becomes

$$\int_0^{2\pi}\int_0^{2\pi}d\phi G(a,\phi';a,\phi)d\phi'=\frac{i}{4}\int_0^{2\pi}\int_0^{2\pi}d\phi d\phi' H_0(k|r-r'|)$$

$$=\frac{i}{4}\int_0^{2\pi}\int_0^{2\pi}d\phi d\phi'\sum_{m=0}'\epsilon_m J_m(ka)H_m^{(1)}(ka)\cos m(\phi-\phi')$$

$$=i\pi^2J_0(ka)H_0(ka).$$

and

$$\int_0^{2\pi}\exp(ika\cos\phi)d\phi=2\pi J_0(ka),$$

$$\int_0^{2\pi}\exp(-ika\cos\phi)d\phi=2\pi J_0(ka).$$

Consequently

$$\frac{1}{A(\pi,\pi)}=\frac{i\pi^2J_0(ka)H_0(ka)}{[2\pi J_0(ka)]^2}=\frac{i}{4}\frac{H_0(ka)}{J_0(ka)},$$

and

$$\sigma=\frac{4}{k}\frac{J_0^2(ka)}{J_0^2(ka)+N_0^2(ka)}. \quad (20)$$

Suppose, instead of taking $I_\pi(\phi)=I_0(\phi)=1$, the following more general representation is used:

$$I_0(\phi)=\sum_0^\infty A_m\cos m\phi,$$

$$I_\pi(\phi)=\sum_0^\infty A_m\cos m(\phi-\pi)=\sum_0^\infty A_m(-1)^m\cos m\phi,$$

where the A_m's are constants. Substitution in (19) gives for the numerator:

$$\int_0^{2\pi}\int_0^{2\pi}d\phi I_\pi(\phi)G(a,\phi';a,\phi)I_0(\phi')d\phi'$$

$$=\frac{i}{4}\int_0^{2\pi}\int_0^{2\pi}d\phi d\phi'\left(\sum_{m=0}^\infty A_m(-1)^m\cos m\phi\right)$$

$$\times\left(\sum_{p=0}^\infty\epsilon_pJ_p(ka)H_p^{(1)}(ka)\cos p(\phi-\phi')\right)$$

$$\times\left(\sum_{n=0}^\infty A_n\cos n\phi'\right).$$

Let

$$C_{mn}=(-1)^m\frac{i}{4}\int_0^{2\pi}\int_0^{2\pi}d\phi d\phi'\cos m\phi \times\left(\sum_{p=0}^{\infty}\epsilon_p J_p(ka)H_p^{(1)}(ka)\cos p(\phi-\phi')\right)\cos n\phi'.$$

But

$$\int_0^{2\pi}\int_0^{2\pi}d\phi d\phi'\cos m\phi\cos p(\phi-\phi')\cos n\phi'=\frac{4\pi^2\delta_p{}^n\delta_p{}^m}{\epsilon_p{}^2},$$

where

$$\delta_n{}^m=\begin{cases}1 & m=n\\ 0 & m\neq n\end{cases}\quad\text{and}\quad\epsilon_m=\begin{cases}1 & m=0\\ 2 & m\geq 1\end{cases},$$

and hence

$$C_{mn}=\frac{(-1)^m i\pi^2}{(\epsilon_m)}\delta_n{}^m J_m(ka)H_m^{(1)}(ka).$$

The numerator becomes the double series,

$$\sum_{m=0}^{\infty}\sum_{n=0}^{\infty}A_m C_{mn}A_n.$$

For the denominator the following is obtained:

$$\int_0^{2\pi}\exp(ika\cos\phi)I_\pi(\phi)d\phi\int_0^{2\pi}\exp(-ika\cos\phi)I_0(\phi)d\phi$$

$$=\int_0^{2\pi}\exp(ika\cos)\phi\sum_{m=0}^{\infty}A_m(-1)^m\cos m\phi d\phi \times\int_0^{2\pi}\exp(-ika\cos)\phi\sum_{n=0}^{\infty}A_n\cos n\phi d\phi$$

$$=\left(\sum_{m=0}^{\infty}A_m(-1)^m 2\pi(i)^m J_m(ka)\right)\times\left(\sum_{n=0}^{\infty}A_n 2\pi(-i)^m J_n(ka)\right).$$

By setting $B_m=2\pi(-i)^m J_m(ka)$, it follows that

$$\frac{1}{A(\pi,\pi)}=\frac{\sum_{m=0}^{\infty}\sum_{n=0}^{\infty}A_m C_{mn}A_n}{\left(\sum_{l=0}^{\infty}A_l B_l\right)^2}. \tag{21}$$

In view of the stationary character of $A(\pi,\pi)$, differentiation of (21) with respect to A_m gives

$$A(\pi,\pi)\sum_{n=0}^{\infty}A_n C_{mn}=-B_m\sum_{n=0}^{\infty}A_n B_n,\quad m=0,1,2,\cdots \tag{22}$$

To simplify (22) the coefficients D_n are introduced so that

$$A(\pi,\pi)=-\sum_{n=0}^{\infty}B_n D_n, \tag{23}$$

where the D_n's are determined by the simultaneous equations

$$\sum_{n=0}^{\infty}C_{mn}D_n=B_m,\quad m=0,1,2,\cdots \tag{24}$$

Since $C_{mn}=0$ when $m\neq n$ only the diagonal terms of (24) are different from zero, i.e., $D_n=B_n/C_{nn}$, and hence

$$A(\pi,\pi)=-\sum_{n=0}^{\infty}\frac{B_n{}^2}{C_{nn}}=\sum_{n=0}^{\infty}\frac{(\epsilon_n 2\pi(-i)^n J_n(ka))^2}{i\pi^2(-1)^n J_n(ka)H_n^{(1)}(ka)}=4i\sum_{n=0}^{\infty}\epsilon_n\frac{J_n(ka)}{H_n^{(1)}(ka)}. \tag{25}$$

Applying the theorem (18) to (25) the total scattering cross section is obtained. It is

$$\sigma=\frac{4}{k}\sum_{n=0}^{\infty}\frac{\epsilon_n J_n{}^2(ka)}{J_n{}^2(ka)+N_n{}^2(ka)}, \tag{26}$$

where use has been made of the form $H_n^{(1)}(ka)=J_n(ka)+iN_n(ka)$. Since $ka\ll 1$, only the first term of (26) contributes appreciably to the value of σ. Therefore

$$\sigma=\frac{4}{k}\frac{J_0{}^2(ka)}{J_0{}^2(ka)+N_0{}^2(ka)}. \tag{27}$$

Comparing (20) with (27) it is seen that the expressions are identical. It appears that for low frequencies ($ka\ll 1$) very accurate results are obtained by taking the current on the cylinder to be independent of ϕ.

VI. HIGH FREQUENCY SCATTERING CROSS SECTION

Now consider the frequency of the incident wave to be high, i.e., $ka\gg 1$. In (14) let $\phi_1=3\pi/2$, $\phi_2=\pi/2$, and for this choice the following result is obtained:

$$\frac{1}{A\left(\pi+\frac{3\pi}{2},\frac{\pi}{2}\right)}=\frac{\int_0^{2\pi}\int_0^{2\pi}d\phi I_{\pi/2}(\phi)G(a,\phi';a,\phi)I_{3\pi/2}(\phi')d\phi'}{\int_0^{2\pi}\exp\left[ika\cos\left(\phi-\frac{3\pi}{2}\right)\right]I_{\pi/2}(\phi)d\phi\int_0^{2\pi}\exp\left[ika\cos\left(\phi-\frac{\pi}{2}\right)\right]I_{3\pi/2}(\phi)d\phi}. \tag{28}$$

In accordance with the assumed convention, $I_{\pi/2}(\phi)$ and $I_{3\pi/2}(\phi)$ are proportional to the surface currents induced by incident waves propagating in the directions $\pi/2$ and $3\pi/2$ respectively. For an incident wave propagating in the direction ϕ_1, $H_\phi^{inc}(\rho,\phi)=-(k/\omega\mu)\times\cos(\phi-\phi_1)\exp[ik\rho\cos(\phi-\phi_1)]$. It is assumed that the high frequency current induced by a plane wave is different from zero only on the illuminated half of the cylinder, where its value is numerically equal to the tangential component of the incident magnetic field. That is, for a trial function we take

$$I_{\phi_1}(\phi)=\text{const.}\cos(\phi-\phi_1)\exp[ika\cos(\phi-\phi_1)]. \quad (29)$$

Hence,

$$I_{\pi/2}(\phi)=\text{const.}\sin\phi\exp[ika\sin\phi] \text{ for } \pi\leq\phi\leq 2\pi$$
$$=0 \text{ for } 0\leq\phi\leq\pi,$$

and

$$I_{3\pi/2}(\phi)=-\text{const.}\sin\phi\exp[-ika\sin\phi] \text{ for } 0\leq\phi\leq\pi$$
$$=0 \text{ for } \pi\leq\phi\leq 2\pi.$$

Substituting these trial functions in (28) and noting that $A(\pi+3\pi/2,\pi/2)=A(\pi/2,\pi/2)$, we get

$$\frac{1}{A\left(\frac{\pi}{2},\frac{\pi}{2}\right)}=\frac{\int_0^{\pi}d\phi'\sin\phi'\exp[-ika\sin\phi']\int_{\pi}^{2\pi}\sin\phi\exp(ika\sin\phi)G(a,\phi';a,\phi)}{\int_{\pi}^{2\pi}\sin\phi d\phi\int_0^{\pi}\sin\phi d\phi}$$

Since

$$G(a,\phi',a,\phi)=\frac{i}{4}H_0^{(1)}\left(2ka\left|\sin\left(\frac{\phi-\phi'}{2}\right)\right|\right),$$

then

$$\frac{1}{A\left(\frac{\pi}{2},\frac{\pi}{2}\right)}=\frac{i}{16}\int_0^{\pi}d\phi'\int_{\pi}^{2\pi}d\phi\sin\phi'\sin\phi\exp[-ika(\sin\phi'-\sin\phi)]H_0^{(1)}\left(2ka\left|\sin\left(\frac{\phi-\phi'}{2}\right)\right|\right). \quad (30)$$

Let $\phi=2\pi-\xi$. Then $\sin\phi=-\sin\xi$, $d\phi=-d\xi$, and

$$\left|\sin\left(\frac{\phi-\phi'}{2}\right)\right|=\left|\sin\left(\frac{\xi+\phi'}{2}\right)\right|.$$

With this change of variables (30) becomes*

$$\frac{1}{A\left(\frac{\pi}{2},\frac{\pi}{2}\right)}=-\frac{i}{16}\int_0^{\pi}d\phi'\int_0^{\pi}d\xi\sin\phi'\sin\xi$$
$$\times\exp[-ika(\sin\phi'+\sin\xi)]H_0^{(1)}\left(2ka\left|\sin\left(\frac{\xi+\phi'}{2}\right)\right|\right).$$

Let the variables be changed again according to the following transformation

$$(\phi'+\xi^2)/2=\beta+\pi/2, \quad (\phi'-\xi)/2=\alpha.$$

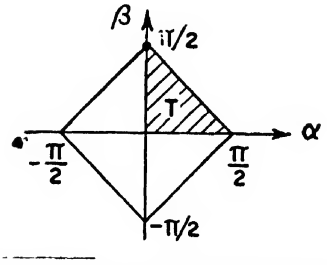

FIG. 3. Integration domain.

Then

$$\sin\phi'\sin\xi=\tfrac{1}{2}(\cos 2\alpha+\cos 2\beta), \quad \sin\phi'+\sin\xi=2\cos\alpha\cos\beta,$$
$$\frac{\partial(\phi',\xi)}{\partial(\alpha,\beta)}=2, \quad \text{and} \quad \left|\sin((\xi+\phi')/2)\right|=\cos\beta.$$

It follows that in terms of α and β,

$$\frac{1}{A\left(\frac{\pi}{2},\frac{\pi}{2}\right)}=-\frac{i}{16}\int\int_Q\exp(-2ika\cos\alpha\cos\beta)$$
$$\times(\cos^2\alpha+\cos 2\beta)H_0^{(1)}(2ka\cos\beta), \quad (31)$$

where Q is the square region in the α, β plane shown in Fig. 3. In view of the symmetry in α and β about $\alpha=\beta=0$, we can confine the integration to the triangular region T, Consequently,

$$\frac{1}{A\left(\frac{\pi}{2},\frac{\pi}{2}\right)}=-\frac{i}{4}\int_0^{\pi/2}d\beta\int_0^{\pi/2-\beta}d\alpha\exp(-2ika\cos\alpha\cos\beta)$$
$$\times(\cos 2\alpha+\cos 2\beta)H_0^{(1)}(2kR\cos\beta). \quad (32)$$

Consider first the integration with respect to α. Since $ka\gg 1$, the main contribution to the value of this integral occurs in the neighborhood of $\alpha=0$ (provided $\beta\neq\pi/2$). An approximate evaluation is obtained by

* The author received enlightening discussions on integrals of this class from Professor F. Tricomi.

the method of stationary phase:

$$\int_0^{\pi/2-\beta} d\alpha \exp(-2ika\cos\alpha\cos\beta)(\cos 2\alpha+\cos 2\beta)$$
$$=\left(\frac{\pi}{ka}\right)^{\frac{1}{2}}\frac{\cos^2\beta}{(\cos\beta)^{\frac{1}{2}}}\exp(-2ika\cos\beta)\exp\left(i\frac{\pi}{4}\right).$$

There remains the task of evaluating the following integral:

$$\frac{1}{A\left(\frac{\pi}{2},\frac{\pi}{2}\right)}=-\frac{i}{4}\left(\frac{\pi}{ka}\right)^{\frac{1}{2}}\exp\left(i\frac{\pi}{4}\right)\int_0^{\pi/2}d\beta\frac{\cos^2\beta}{(\cos\beta)^{\frac{1}{2}}}$$
$$\times\exp[-2ika\cos\beta]H_0^{(1)}(2ka\cos\beta). \quad (33)$$

As $\beta\to\pi/2$ the integrand disappears, and hence the contribution to the integral in the neighborhood of $\beta=\pi/2$ is very small. When $\beta\neq\pi/2$ and $ka\to\infty$,

$$H_0^{(1)}(2ka\cos\beta)$$
$$\sim\left(\frac{2}{2\pi ka\cos\beta}\right)^{\frac{1}{2}}\exp(2ika\cos\beta)\exp(-i\pi/4). \quad (34)$$

After substituting this asymptotic form into (33) and changing the upper limit from $\pi/2$ to β_0, the result is

$$\frac{1}{A(\pi/2,\pi/2)}\sim-\frac{i}{4}\frac{1}{ka}\int_0^{\beta_0}d\beta\cos\beta=-\frac{i}{4ka}\sin\beta_0 \quad (35)$$

for the leading term of the asymptotic development of $[1/A(\pi/2,\pi/2)]$ in reciprocal powers of ka. Application of the theorem (18) to (35) gives for the total scattering cross section

$$\sigma=\frac{1}{k}\mathrm{Im}A\left(\frac{\pi}{2},\frac{\pi}{2}\right)\sim\frac{4a}{\sin\beta_0}=\frac{4a}{(1-(4/ka)^2)^{\frac{1}{2}}}. \quad (36)$$

Choose β_0 such that $\cos\beta_0=4/ka$. This choice guarantees the argument of the Hankel function to be equal to or greater than 8 for the entire range of values from $\beta=0$ to $\beta=\beta_0$, and thereby allows the replacement of the Hankel function by the first term of its asymptotic development. It is seen that as $ka\to\infty$, $\sigma\to 4a$ which is the geometric optics scattering cross section and physically equal to twice the projected area of a unit length of the scattering cylinder. Figure 4 shows a plot of σk *versus* ka. For values of ka less than 10, Eq. (26) was used to compute σk; for ka larger than 8, Eq. (36) was used. In the region $8<ka<10$ the broken and solid curves overlap.

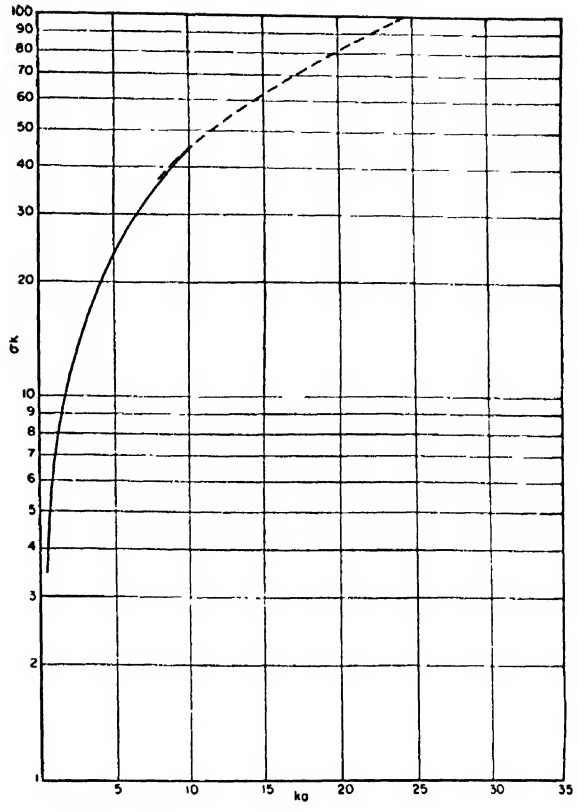

FIG. 4. σk *versus* ka. Solid curve computed fr
Broken curve computed from (36).

Air Temperature Modification by Vertical Transport*

ROBERT G. FLEAGLE
University of Washington, Seattle, Washington
(Received October 3, 1949)

It is suggested that when the air temperature increases upward an efficient and economical method for modifying low temperatures near the ground is to force air downward through vertical stacks from the relatively warm air aloft. Theory is developed which shows that the necessary power per unit mass is mainly a function of the air velocity in the stack. The energy required by this method is compared with the energy required to heat the air originally near the ground, and it is shown that under a strong temperature inversion the power method requires considerably less energy than the heating method.

INTRODUCTION

TEMPERATURE modification by a combination of radiational cooling and direct application of heat (both accomplished by smudge pots) is the standard method used by fruit growers in avoiding low nocturnal temperatures near the ground. Under conditions requiring the use of smudge pots the temperature of the air usually increases rapidly with height; at 100–200 feet above the ground the temperature may be 5 to 10° C higher than the temperature near the ground. Recently, this normal temperature inversion has been utilized in modifying the temperatures near the ground; large fans have been set up above the trees to mix the cold and warm air.[1] It appears that a more effective and better controlled method would be to conduct the warm air downward through vertical stacks and exhaust it within the orchard. It is proposed to investigate the energy required for this process and to compare it with the energy required by direct heating. The application to maintenance of outdoor temperature sensitive installations, machinery, and supplies is obvious.

THEORY

Consider the energy required to force a unit mass of air through a vertical stack at a speed, v_2. Some energy is converted into kinetic energy, some is lost in friction at the sides of the stack, and some is required to overcome the buoyant force experienced by the warm air in being displaced downward into colder air. Where M represents the energy per gram supplied by the fan; F_r, the energy per gram dissipated by friction; and W, the energy per gram required to overcome atmospheric stability, the principle of conservation of energy requires that,

$$M=\tfrac{1}{2}v_2^2+F_r+W. \tag{1}$$

The mass of air passing through the stack per second is given by $\pi r^2\rho v_2$, where ρ represents air density and r represents radius of the stack. We therefore have for the power required of the motor,

$$P(\text{ergs/sec.})=\pi r^2\rho v_2\{\tfrac{1}{2}v_2^2+F_r+W\}. \tag{2}$$

The frictional loss of energy per unit mass in fundamental c.g.s. units is given by the empirical expression,

$$F_r=\frac{fhv_2^2}{4r}, \tag{3}$$

where f represents a dimensionless coefficient depending upon roughness of conduit and the Reynolds number and h represents length of the conduit.[2] Several values of f are shown in Table I below.[3] Table I shows that f is not sensitive to changes in r or v_2 within the ranges applicable to this problem. The single value of 0.02 will be used in future computations.

The work required to bring air down the stack against the buoyant force due to atmospheric stability remains to be computed. Where F represents the net upward

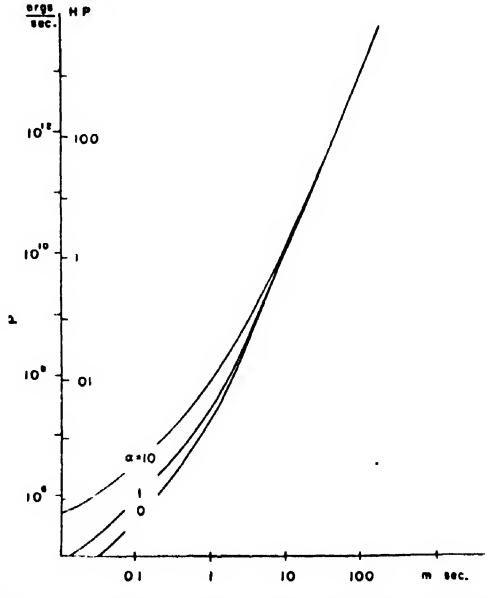

FIG. 1. Power required by fan as function of velocity for $\alpha=0$, 1, $10K/(100\ m)$ as computed from Eq. (12).

[3] Computed from (3) using data supplied in Am. Soc. Heating and Ventilating Eng. (see reference 2).

force per gram on the displaced air, we have,

$$W=-\int_h^0 F\,dz. \tag{4}$$

The net force per gram is given by,

$$F=\frac{\rho-\rho'}{\rho'}g=\frac{(p/RT)-(p/RT')}{p/RT'}g=\frac{T'-T}{T}g, \tag{5}$$

where the prime indicates a property of the moving air, p represents pressure; T, absolute temperature; and R, the gas constant for air. Substitution of (5) in (4) gives,

$$W=-g\int_h^0 \frac{T'-T}{T}\,dz. \tag{6}$$

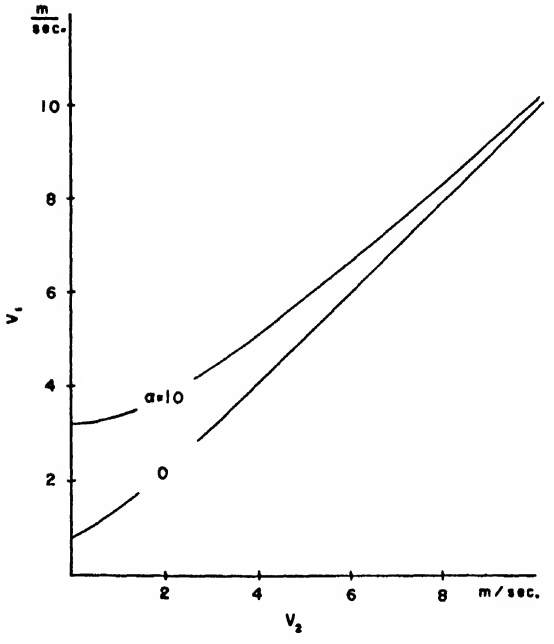

FIG. 2. Air speed within stack, (v_2), as a function of horizontal wind speed at the top of the stack, (v_1) for $\alpha=0$ and $10K/(100\text{ m})$ as computed from Eq. (13).

We shall assume that the temperature in the undisturbed air may be expressed by a linear function of elevation and that the disturbed air neither gains nor loses heat to the stack walls. Thus, the descending air increases in temperature at the adiabatic rate. We may express these assumptions by the following:

$$T=T_0+\alpha z \tag{7}$$

$$T'=T_0+\alpha h+\frac{g}{c_p}(h-z). \tag{8}$$

Equation (6) now may be written, for $\alpha\neq 0$

$$W=-\frac{g(\alpha+(g/c_p))}{\alpha}\int_h^0 \frac{(h-z)\partial z}{(T_0/\alpha)+z}. \tag{9}$$

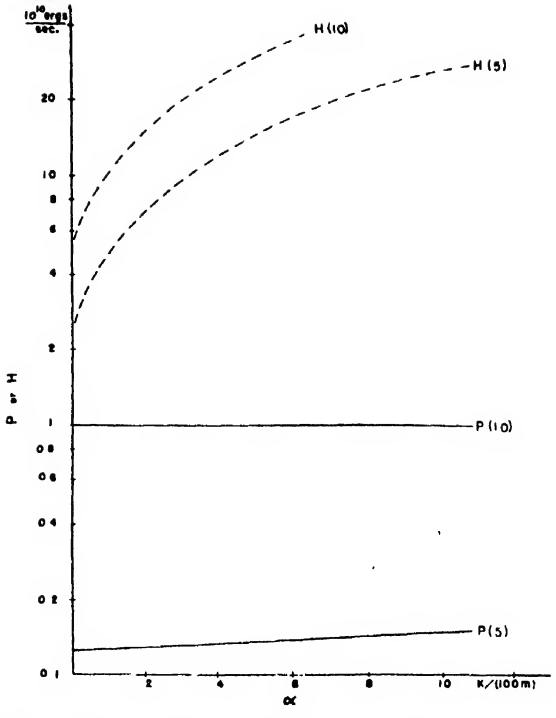

FIG. 3. Power required by fan compared with rate of energy required for heating (H) as function of rate of temperature increase with height (α). The bracketed numbers indicate the air speed within the stack in m/sec.

Integration gives,

$$W=-g\left(1+\frac{g}{\alpha c_p}\right)\left\{-\left(h+\frac{T_0}{\alpha}\right)\log_e\frac{T_h}{T_0}+h\right\}, \tag{10}$$

where T_h represents the temperature at the height of the top of the stack. For purposes of computation it is sufficiently accurate to replace $T_0+\alpha z$ by T_0 in the denominator of (9). This leads to,

$$W=gh^2/2T_0(\alpha+(g/c_p)). \tag{11}$$

Equation (11) holds for $\alpha=0$ since division by α is not required in the integration.

Finally, substituting (3) and (11) in (2) results in,

$$P=\pi r^2\rho v_2\left\{0.5v_2^2(1+0.01h/r)+\frac{gh^2}{2T_0}\left(\alpha+\frac{g}{c_p}\right)\right\}. \tag{12}$$

In order to visualize the relative importance of the individual terms in this rather cumbersome equation, P is plotted as a function of v_2 and α in Fig. 1 using the following arbitrary values:

$r=0.5$ meter
$h=50$ meters
$T_0=270°$ K

Figure 1 shows that within the power range between 0.1 and 100 horsepower the lapse rate does not affect seriously the air speed within the stack.

TABLE I.

r(cm)	v_1(m/sec.)	f
15	2.5	0.022
15	5.1	0.021
15	50.8	0.018
46	2.5	0.019
46	5.1	0.016
46	50.8	0.013

It is of interest to investigate the speed within the stack which is possible without the use of a fan. A horizontal opening at the top of the stack free to rotate so that it always faces the wind stream is assumed. For this case, the kinetic energy of the moving air must be added to the left side of (1) and M set equal to zero. Equation (12) then becomes,

$$0.5v_2^2\left(1+0.01\frac{h}{r}\right)+\frac{gh^2}{2T_0}\left(\alpha+\frac{g}{c_p}\right)=0.5v_1^2. \quad (13)$$

In Fig. 2, v_2 is plotted as a function of v_1 and α using the same arbitrary values listed above. Figure 2 indicates that the air speed within the stack is of the same order of magnitude as the wind speed. It appears that where only a small quantity of air is required, the kinetic energy of the wind at the height of the top of the stack might be sufficient to do the job alone. However, it should be realized that when the wind speed at the top of the stack exceeds about 5 m.p.sec. the resulting mechanical turbulence is likely to prevent the creation of a large temperature inversion. In other words, at high wind speeds the warm air is conducted to the ground without the assistance of fan and stack.

POWER COMPARISON

It is important to compare the energy required to produce at the ground a certain temperature increase by the method described here with the energy required to heat the original air through the same temperature interval. The rate of expenditure of heat required by the latter process may be written,

$$H=\pi r^2\rho v_2 c_p[T_h+(gh/c_p)-T_0]. \quad (14)$$

Substitution of $T_0+\alpha h$ for T_h leads to,

$$H=\pi r^2\rho v_2 c_p h(\alpha+(g/c_p)). \quad (15)$$

This energy requirement may be compared with P by plotting P and H as functions of α for certain arbitrary values of v_2, say 5 and 10 m/sec. In Fig. 3 P and H have been computed for air at sea level using the same values of r, h, and T_0 used before. Inspection of Fig. 3 shows that economy of the power method over the heating method ranges from a factor of about 5 to a factor of about 100. The relative economy varies in a direct sense with the strength of the temperature inversion. Economy of power is greater at the lower velocity (5 m/sec.) than at the higher velocity (10 m/sec.). It follows that maximum efficiency would be attained with fans operating at slow speed in stacks of large radius. Of course the economy in energy expended by the power method must be balanced against the greater cost of mechanical energy. Also, the greater efficiency attained with large stacks must be balanced against the greater initial cost of large stacks. Determination of the economy of cost of installation and operation depends upon local factors beyond the scope of this paper.

Aside from the question of economy, advantages of the power method over the heating method include: greater uniformity in temperature, absence of smoke, gas, and dirt, less attention required, and the possibility of utilizing the kinetic energy of the wind. Disadvantages include: more critical dependence on a large temperature inversion, greater initial expense (unless existing stacks may be used).

Mode Conversion Losses in Transmission of Circular Electric Waves through Slightly Non-Cylindrical Guides

SAMUEL P. MORGAN, JR.
Bell Telephone Laboratories, Murray Hill, New Jersey
(Received July 8, 1949)

A general expression is derived for the effective attenuation of circular electric (TE_{01}) waves owing to mode conversions in a section of wave guide whose shape deviates slightly in any specified manner from a perfect circular cylinder. Numerical predictions are in good agreement with experiment for the special case of transmission through an elliptically deformed section of pipe. The effect of random distortions in a long wave guide line is analyzed in terms of the mean-square values of the Fourier coefficients describing the distortions; and from the general formulas it appears that the mode conversion losses depend in large measure upon the statistical distribution of the various types of distortion. Under certain rather arbitrary simplifying assumptions about this distribution, it is calculated that mode conversions in a 4.732-inch copper pipe whose radius deviates by 1 mil r.m.s. from that of an average cylinder will increase the attenuation of the TE_{01} mode at 3.2 cm by an amount equal to 8 percent of the theoretical copper losses. The dependence on frequency of mode conversion losses in such a guide is discussed.

I. INTRODUCTION

THE propagation of electromagnetic energy through a perfectly conducting cylindrical guide may take place at sufficiently high frequencies in any one of a number of independent transmission modes, the field pattern for a given mode being the same, up to phase, at every cross section of the guide. The natural modes in circular and rectangular guides are well known, and it has been shown[1,2] that for a cylindrical guide whose uniform cross section deviates but slightly from circular, the natural modes are only slightly different in field configuration from the corresponding modes for a circular cylinder. If however the size or shape of the cross section varies slightly from point to point, so that the guide is not strictly cylindrical, then although one may still represent the field at any given section by an expansion in terms of the natural modes of a circular cylinder, these modes are no longer independent but coupled to each other by the distortion. Electromagnetic energy in any mode will, on passing through a distorted section of guide, be partially converted into other modes, of which those above cut-off can be expected to propagate through the guide with different phase velocities from the original mode and, in the case of a physical guide, with different attenuations due to the finite conductivity of the walls. Thus the original mode exhibits an increase in effective attenuation owing to mode conversions in the distorted section, provided of course that no other mode is present at a sufficiently high level to return an appreciable amount of energy by reconversion.

Mode conversion losses become of practical importance when one attempts to transmit a mode which has intrinsically low copper loss, such as the lowest order circular electric (TE_{01}) wave in a round pipe, through a guide so large that many other modes are freely propagated at the chosen frequency. It is easy to imagine that in transmission of the TE_{01} mode through commercial copper pipe of diameter several times the wave-length, mode conversion losses might under some conditions be an appreciable fraction of the total loss; and it seems desirable to have a theoretical estimate of the magnitude of this effect. In the present paper we treat the following problem:

A pure TE_{01} wave propagating in the forward direction through a perfectly conducting circular pipe passes through a distorted section, the only restrictions on the form of the distortion being that the deviation from perfect circularity is small compared to the pipe radius, and there are no discontinuities in the surface of the pipe. No real generality is lost by the assumption of infinite conductivity, since to first approximation the losses from the TE_{01} mode due to finite conductivity and due to mode conversions are additive.* The distorted section will in general couple an infinite number of other modes to the circular electric mode; but if this section is of finite length then at sufficient distances on each side of it we shall find only those modes which propagate freely in the original circular pipe, and the power carried in each direction by these propagating modes can be calculated. The power which has been abstracted from the incident TE_{01} mode can be expressed in terms of an effective attenuation or, if desired, in terms of an average attenuation per unit length caused by mode conversions in the distorted section. In the present analysis the mode conversions are supposed to take place either in an infinitely long pipe or in one where each undesired mode is terminated

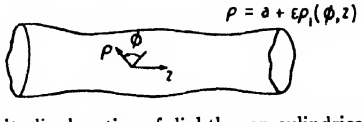

FIG. 1. Longitudinal section of slightly non-cylindrical wave guide.

[1] S. A. Schelkunoff, J. App. Phys. 9, 484 (1938).
[2] M. Jouguet, Comptes Rendus 266, 1436 (1948).

* Inhomogeneity in the conductivity of the inner wall of the guide would couple the TE_{01} mode to other modes even if the walls were perfectly smooth and circular; but an order-of-magnitude calculation has shown that for such variations in conductivity as are likely to occur in practice the coupling would be far smaller than the anticipated geometrical mode coupling effects.

whose deviation from perfect circularity is given by:

$$\epsilon\rho_1(\varphi,z)=\epsilon a f(z)\cos 2\varphi, \tag{14}$$

$$f(z)=\begin{cases}1, & 0\le|z|\le\frac{1}{2}s;\\ (l-2|z|)/(l-s), & \frac{1}{2}s\le|z|\le\frac{1}{2}l;\\ 0, & |z|\ge\frac{1}{2}l.\end{cases} \tag{15}$$

These equations represent a section of pipe, of length l, which is held with circular pipe clamps at each end and whose center section, of length s, is squeezed into an approximately elliptical shape of the same perimeter as the original pipe, the transition between the clamped ends and the distorted center section being linear. Measurements of the section of pipe used in the experiments showed that this transition was in fact very nearly linear. Of course a real pipe would not have the discontinuities in slope exhibited by (15) at $z=\pm\frac{1}{2}s$ and $z=\pm\frac{1}{2}l$; but in view of the other idealizations present in our formulation of the problem we do not feel that much would be gained by choosing a more complicated shape function with continuous slope.

In order to obtain the mode conversion losses in a pipe whose deformation is given by (14), we have to calculate the coefficients $C_{nm}^{\pm}$ and $S_{nm}^{\pm}$ defined by (8) of the preceding section. It is easily seen that all of these quantities vanish except

$$C_{2m}^{\pm}=\frac{1}{2\pi a}\int_0^{2\pi}\int_{-\frac{1}{2}l}^{\frac{1}{2}l} f(z')\exp(-i(h_{01}\mp h_{2m})z')\cos^2 2\varphi'\,dz'\,d\varphi'$$

$$=\frac{1}{a}\int_0^{\frac{1}{2}l} f(z')\cos(h_{01}\mp h_{2m})z'\,dz'$$

$$=\frac{2[\cos\frac{1}{2}(h_{01}\mp h_{2m})s-\cos\frac{1}{2}(h_{01}\mp h_{2m})l]}{(h_{01}\mp h_{2m})^2 a(l-s)}.$$

As might have been anticipated, an elliptical deformation couples only TE_{2m} modes to the TE_{01} wave. The attenuation of the circular electric mode by a single passage through the distorted section is, using Eqs. (9) to (12) of Section II,

$$N=4.343\epsilon^2\sum_m D_{2m}[|C_{2m}^{+}|^2+|C_{2m}^{-}|^2]\ \text{db}, \tag{16}$$

where the summation includes all TE_{2m} modes which are above cut-off in the circular pipe.

Using the numerical values which prevailed in the experimental work, namely

$$\lambda=3.20\ \text{cm},\quad a=2.366\ \text{in.}=6.010\ \text{cm},$$
$$l=77\ \text{cm},\quad s=17\ \text{cm},$$

we find that the only TE_{2m} waves which are above cut-off are TE_{21}, TE_{22}, and TE_{23}. A calculation the details of which will be omitted gives for the value of the sum on the right side of (16):

$$\sum_{m=1}^{3} D_{2m}[|C_{2m}^{+}|^2+|C_{2m}^{-}|^2]=38.12,$$

of which the TE_{21}^{+} mode contributes over 99.9 percent and the TE_{22}^{+} about 0.09 percent, while the TE_{23}^{+} and the three "backward" waves contribute entirely negligible amounts. Thus from (16) the attenuation per one-way trip through the elliptical section is

$$N=165.6\epsilon^2\ \text{db}. \tag{17}$$

If the distortion of the pipe is given by (14) and (15), then the parameter ϵ is related to the major and minor axes $d_{\max}$ and $d_{\min}$ of the center section by

$$\epsilon=\frac{d_{\max}-d_{\min}}{d_{\max}+d_{\min}}. \tag{18}$$

When ϵ has been determined* by (18), the theoretical attenuation is easily calculated from (17). The comparison between the values so calculated and representative experimental values, for a total of 30 round trips through the distorted section, is set forth in Table I. We regard the agreement between theory and experiment as quite satisfactory.

IV. RANDOM DISTORTIONS IN CIRCULAR GUIDE

A complete specification of the inner surface of a given section of pipe by means of the function $\epsilon\rho_1(\varphi,z)$ would allow us, at least in principle, to calculate by the formulas of Section II the mode conversion losses in that particular pipe. To obtain such detailed knowledge of $\epsilon\rho_1(\varphi,z)$ by actual measurement would, however, be highly impracticable, and at any rate we are not likely to be so interested in the properties of a single section of pipe as in the average properties of a line composed of many sections of pipe whose deviations from circularity will be more or less random. In the following paragraphs we shall calculate, for sections of pipe having a certain degree of randomness in shape, the average mode conversion loss per unit length in terms of the root-mean-square departure of the pipe from a perfect circular cylinder.

We shall begin by describing the deformation of a specific section of pipe in terms of a double Fourier series in the circumferential variable φ and the axial distance z. The deformation is thus characterized by its Fourier coefficients, which for an arbitrary continuous distortion will be a doubly infinite set of constants. In the subsequent numerical calculations, however, it will be necessary to deal with only a finite number of Fourier components; this will essentially restrict us to sections of pipe which exhibit only gradual changes in shape and no very closely spaced "ripples".

We shall proceed to express the mode conversion losses associated with the given pipe in terms of the Fourier coefficients of the distortion. We then consider

* The sample of pipe squeezed by Beck and King evidently had a radius $a=\frac{1}{4}(d_{\max}+d_{\min})$ smaller by about 0.005 in. than the nominal radius, namely 2.366 in., of the wave guide line from which it was taken. Our results should not be appreciably affected by the fact that we used the latter value of a in the calculations leading to (17).

a large number of different sections of pipe (all of equal length for simplicity), whose shapes are defined by different sets of Fourier amplitudes. We suppose that any particular Fourier coefficient is as likely to be negative as positive, so that the mean value of each coefficient, averaged over all the sections of pipe, is zero. It is also assumed that the various coefficients describing an individual section of pipe are uncorrelated, i.e., that the mean value of the product of any two different coefficients, averaged over all sections, is zero. These assumptions enable us to express the average attenuation per unit length caused by mode conversions in a wave guide line composed of many such sections in terms of the r.m.s. values of the Fourier coefficients used to describe the departure of the individual sections from perfect circularity. By making specific assumptions about the r.m.s. values of the amplitudes of the various harmonic components of distortion, we can calculate numerically the theoretical mode conversion losses in a long line.

Let us therefore consider a section of pipe whose deformation is given by a finite Fourier series:

$$\epsilon\rho_1(\varphi,z)=\tfrac{1}{4}\epsilon\sum_{s=0}^{S}\sum_{t=0}^{T}\epsilon_s\epsilon_t\left[\left(a_{st}\cos\frac{2\pi tz}{l}+b_{st}\sin\frac{2\pi tz}{l}\right)\cos s\varphi+\left(c_{st}\cos\frac{2\pi tz}{l}+d_{st}\sin\frac{2\pi tz}{l}\right)\sin s\varphi\right], \quad (19)$$

for $-\frac{1}{2}l\leq z\leq\frac{1}{2}l$ and $0\leq\varphi\leq 2\pi$. The coefficients a_{st}, b_{st}, c_{st}, and d_{st} are related to $\rho_1(\varphi,z)$ by the following scheme:

$$\begin{bmatrix}a_{st} & b_{st}\\ c_{st} & d_{st}\end{bmatrix}=\frac{2}{\pi l}\int_0^{2\pi}\int_{-\frac{1}{2}l}^{\frac{1}{2}l}\rho_1(\varphi,z)\begin{bmatrix}\cos\frac{2\pi tz}{l}\cos s\varphi & \sin\frac{2\pi tz}{l}\cos s\varphi\\ \cos\frac{2\pi tz}{l}\sin s\varphi & \sin\frac{2\pi tz}{l}\sin s\varphi\end{bmatrix}dzd\varphi. \quad (20)$$

The mean-square value of $\epsilon\rho_1(\varphi,z)$ is

$$\sigma^2=\frac{1}{2\pi l}\int_0^{2\pi}\int_{-\frac{1}{2}l}^{\frac{1}{2}l}\epsilon^2\rho_1^2(\varphi,z)dzd\varphi=\frac{\epsilon^2}{16}\left[\sum_{s=0}^{S}\sum_{t=0}^{T}\epsilon_s\epsilon_t a_{st}^2+2\sum_{s=0}^{S}\sum_{t=1}^{T}\epsilon_s b_{st}^2+2\sum_{s=1}^{S}\sum_{t=0}^{T}\epsilon_t c_{st}^2+4\sum_{s=1}^{S}\sum_{t=1}^{T}d_{st}^2\right]. \quad (21)$$

The quantities $C_{nm}^{\pm}$ and $S_{nm}^{\pm}$ which measure the mode conversion losses are given by (8) to be

$$C_{nm}^{\pm}=\frac{1}{4a^2}\sum_{t=0}^{T}\epsilon_t[a_{nt}f_{nmt}^{\pm}-ib_{nt}g_{nmt}^{\pm}],$$

$$S_{nm}^{\pm}=\frac{1}{4a^2}\sum_{t=0}^{T}\epsilon_t[c_{nt}f_{nmt}^{\pm}-id_{nt}g_{nmt}^{\pm}],$$

where

$$f_{nmt}^{\pm}=\int_{-\frac{1}{2}l}^{\frac{1}{2}l}\cos(h_{01}\mp h_{nm})z'\cos(2\pi tz'/l)dz'=\frac{(-)^t 2(h_{01}\mp h_{nm})l^2\sin\frac{1}{2}(h_{01}\mp h_{nm})l}{(h_{01}\mp h_{nm})^2l^2-4\pi^2t^2},$$

$$g_{nmt}^{\pm}=\int_{-\frac{1}{2}l}^{\frac{1}{2}l}\sin(h_{01}\mp h_{nm})z'\sin(2\pi tz'/l)dz'=\frac{(-)^t 4\pi tl\sin\frac{1}{2}(h_{01}\mp h_{nm})l}{(h_{01}\mp h_{nm})^2l^2-4\pi^2t^2}.$$

Hence

$$|C_{nm}^{\pm}|^2=\frac{1}{16a^4}\sum_{r=0}^{T}\sum_{t=0}^{T}\epsilon_r\epsilon_t[a_{nr}f_{nmr}^{\pm}-ib_{nr}g_{nmr}^{\pm}]\times[a_{nt}f_{nmt}^{\pm}+ib_{nt}g_{nmt}^{\pm}], \quad (22)$$

$$|S_{nm}^{\pm}|^2=\frac{1}{16a^4}\sum_{r=0}^{T}\sum_{t=0}^{T}\epsilon_r\epsilon_t[c_{nr}f_{nmr}^{\pm}-id_{nr}g_{nmr}^{\pm}]\times[c_{nt}f_{nmt}^{\pm}+id_{nt}g_{nmt}^{\pm}]. \quad (23)$$

On inserting these values into Eq. (9) and summing over n and m as in Eq. (11) we have an explicit expression for the total power converted into other modes, as a function of the Fourier coefficients a_{st}, b_{st}, c_{st}, and d_{st} describing the inner surface of the pipe.

Now let us imagine that we have a large number of sections of pipe, each of which will for the present be assumed to have the same length l. Let the kth section be represented by a finite Fourier series of the form (19), with coefficients

$$a_{st}^{(k)},\ b_{st}^{(k)},\ c_{st}^{(k)},\ d_{st}^{(k)}\quad(k=1,2,3,\cdots). \quad (24)$$

For all values of k, s, and t we may define, in accord with (20),

$$b_{s0}^{(k)}\equiv c_{0t}^{(k)}\equiv d_{s0}^{(k)}\equiv d_{0t}^{(k)}\equiv 0. \quad (25)$$

We assume that the coefficients (24) which define the various sections of pipe (excluding those which vanish identically by (25)) are *statistically independent random variables in k with mean zero and standard deviation* σ_{st}. In other words, using angular brackets to denote averages over k, so that

$$\langle f\rangle=\lim_{K\to\infty}(1/K)\sum_{k=1}^{K}f(k),$$

we assume that

$$\langle a\rangle_{st}=\langle b\rangle_{st}=\langle c\rangle_{st}=\langle d\rangle_{st}=0$$

and

$$\langle a_{st}^2\rangle=\langle b_{st}^2\rangle=\langle c_{st}^2\rangle=\langle d_{st}^2\rangle=\sigma_{st}^2, \quad (26)$$

while the average value of the product of any two coefficients with different subscripts is zero. We emphasize that these assumptions concerning the statistical behavior of the coefficients (24), while they may seem to possess a considerable degree of plausibility, are introduced at this stage as mathematical hypotheses;

TABLE II.

s \ t	0	1	σ_{st}/σ_0 2	3	4
0	25	20	15	10	5
1	20	16	12	8	4
2	15	12	9	6	3
3	10	8	6	4	2
4	5	4	3	2	1

we are not here concerned with proving their validity for any particular wave guide line.

It is easily seen from (21) and (26) that the average value of σ^2 taken over a large number of sections of pipe is given in terms of the quantities σ_{st}^2 by

$$\langle\sigma^2\rangle=\epsilon^2\left[\frac{1}{16}\sigma_{00}^2+\frac{1}{4}\sum_{t=1}^{S}\sigma_{s0}^2+\frac{1}{4}\sum_{s=1}^{T}\sigma_{0t}^2+\sum_{s=1}^{S}\sum_{t=1}^{T}\sigma_{st}^2\right], \quad (27)$$

provided that $\sigma_{st}=0$ for $s>S$ and/or $t>T$. In principle, of course, we may take S and T as large as desired.

If we add together Eqs. (22) and (23) and average the result over k, then using (25) and (26) and the assumed statistical independence of the different coefficients we obtain:

$$\langle|C_{nm}^{\pm}|^2+|S_{nm}^{\pm}|^2\rangle$$

$$=\frac{\epsilon_n}{16a^4}\left\{(f_{nm0}^{\pm})^2\sigma_{n0}^2+4\sum_{t=1}^{T}[(f_{nmt}^{\pm})^2+(g_{nmt}^{\pm})^2]\sigma_{nt}^2\right\}$$

$$=\frac{\epsilon_n l^2\sin^2\tfrac{1}{2}(h_{01}\mp h_{nm})l}{4a^4}\left\{\frac{\sigma_{n0}^2}{(h_{01}\mp h_{nm})^2l^2}\right.$$

$$\left.+4\sum_{t=1}^{T}\left[\frac{(h_{01}\mp h_{nm})^2l^2+4\pi^2t^2}{[(h_{01}\mp h_{nm})^2l^2-4\pi^2t^2]^2}\right]\sigma_{nt}^2\right\}. \quad (28)$$

Hence finally we get from (9), (11), and (13) the following expression for the average attenuation per unit length in a line composed of a great number of sections of pipe of length l, each deviating in a random way from a perfect circular cylinder:

$$\langle\alpha\rangle=\frac{4.343\epsilon^2}{l}\sum_{n=0}^{S}\sum_{m}D_{nm}[\langle|C_{nm}^{+}|^2+|S_{nm}^{+}|^2\rangle$$

$$+\langle|C_{nm}^{-}|^2+|S_{nm}^{-}|^2\rangle] \text{ db/unit length.} \quad (29)$$

In (29) the summation over m is taken to include all the modes which are above cut-off for a given value of n (except that the TE_{01}^{+} mode is omitted).

In view of the algebraic complexity of the final expression for $\langle\alpha\rangle$, it is worth while to point out some dimensional considerations which will permit us to introduce scale factors. If we fix our attention on the attenuation per wave-length $\langle\alpha\rangle\lambda$, it is not difficult to show that (29) may be written in the form

$$\langle\alpha\rangle\lambda=F(\lambda/a,\ l/\lambda;\ \sigma_{00}/a,\ \sigma_{10}/a,\ \sigma_{01}/a,\ \sigma_{20}/a,\ \cdots), \quad (30)$$

where the function F depends only on the indicated dimensionless ratios. In other words, if we multiply all linear dimensions of the wave guide line by a given scale factor and simultaneously multiply the frequency by the reciprocal of the same factor, the attenuation per wave-length due to mode conversion losses remains constant. We shall make use of this relationship presently.

The question may be raised here whether the function F which appears in (30) depends critically upon the assumed length (in wave-lengths) l/λ of the individual sections of pipe. Physically it seems very unlikely that the mode conversion losses in an extended line whose individual sections are hundreds of wave-lengths long would be much altered by moderate fractional changes in the lengths of these sections. On the other hand, it is easy to set up idealized configurations in which the theoretical mode conversion losses do depend markedly on phase relations determined by the length of the section in which the conversions take place, and it is perhaps not *a priori* clear by inspection of (29) that similar effects do not occur in this more complicated case. To settle the question it is possible to average the right side of (29) over a selected range of values of l. Thus we find that the average attenuation per unit length owing to mode conversions in a line composed of a great number of sections of pipe whose deviations from circularity are random in the sense defined above, and whose lengths are distributed uniformly between l_1 and l_2, is

$$\langle\alpha(l_1,l_2)\rangle=\frac{4.343\epsilon^2}{4a^2(l_2-l_1)}\sum_{n=0}^{S}\sum_{m}\epsilon_nD_{nm}$$

$$\times\left[\sum_{t=0}^{T}\epsilon_t^2(I_{nmt}^{+}+I_{nmt}^{-})\sigma_{nt}^2\right] \text{ db/unit length,} \quad (31)$$

where

$$I_{nmt}^{\pm}=\frac{1}{a^2}\int_{l_1}^{l_2}l\sin^2\tfrac{1}{2}(h_{01}\mp h_{nm})l\frac{(h_{01}\mp h_{nm})^2l^2+4\pi^2t^2}{[(h_{01}\mp h_{nm})^2l^2-4\pi^2t^2]^2}dl$$

$$=\frac{1}{4(h_{01}\mp h_{nm})^2a^2}\left\{\ln\tfrac{1}{4}|(h_{01}\mp h_{nm})^2l^2-4\pi^2t^2|\right.$$

$$-\mathrm{Ci}[|(h_{01}\mp h_{nm})l-2\pi t|]-\mathrm{Ci}[|(h_{01}\mp h_{nm})l+2\pi t|]$$

$$+2\pi t\,\mathrm{Si}[(h_{01}\mp h_{nm})l-2\pi t]-2\pi t\,\mathrm{Si}[(h_{01}\mp h_{nm})l+2\pi t]$$

$$\left.-\frac{4\pi^2t^2\sin^2\tfrac{1}{2}(h_{01}\mp h_{nm})l}{\tfrac{1}{4}[(h_{01}\mp h_{nm})^2l^2-4\pi^2t^2]}\right\}_{l_1}^{l_2}. \quad (32)$$

Before we can calculate numerical values of $\langle\alpha\rangle$, it is necessary to reduce considerably the number of parameters involved in the general expression (29). If we knew the relative magnitudes of the mean-square Fourier amplitudes σ_{nt}^2 occurring in (28), it would be a simple matter to express their absolute magnitudes in terms of $\langle\sigma^2\rangle$ by (27) and thus to express the mode con-

version losses in terms of the latter quantity. Unfortunately information about the individual σ_{st}'s is not at present available. It may be argued that in view of the structural rigidity of commercial copper pipe the amplitudes of the higher harmonics in the distortion must tend rapidly to zero, but this tells us little about the behavior of σ_{st} for the first few terms of the series. In the absence of more detailed information and for the purpose of obtaining a numerical result, we shall arbitrarily assume that only the constant term and the first four harmonics in both the circumferential and the axial directions occur in the expression (19) for the distortion of a typical section of pipe; and we shall further assume that the r.m.s. amplitudes of these harmonics are given by

$$\sigma_{st}=(5-s)(5-t)\sigma_0,\ 0\leq s,\ t\leq 4, \tag{33}$$

where σ_0 is a length proportional to the r.m.s. deviation of the wave guide line from an average circular cylinder. The relative magnitudes of the non-vanishing σ_{st}'s are thus assumed to be as shown in Table II:

It is easy to determine from (27) and (33) that the mean-square deviation of the wave guide line from an average cylinder is given by

$$\langle\sigma^2\rangle=1314.1\epsilon^2\sigma_0^2.$$

Numerical calculations have been carried out, under the assumptions just described, to obtain the mode conversion losses in transmission of TE_{01} power through a long wave guide composed of 20-foot sections of 5-inch (outside diameter) pipe at both X-band and K-band wave-lengths. For the X-band case we take

$$\lambda=3.20\text{ cm},\quad \lambda/a=0.532,$$
$$a=2.366\text{ in.},\quad l/\lambda=190.5.$$
$$l=20\text{ ft.},$$

Substitution of these values into (29) gives, after a lengthy calculation,

$$\langle\alpha\rangle=4.92\langle\sigma^2\rangle/a^2\text{ db/cm}, \tag{34}$$

where $\langle\sigma^2\rangle$ and a^2 are expressed in the same units. The numerical coefficient in (34) represents the combined effect of 14 forward modes (excluding TE_{01}^+) and 15 backward modes; but it turns out that the TE_{31}^+ and TE_{21}^+ modes together account for 97.6 percent of the total (TE_{31}^+, 85.8 percent; TE_{21}^+, 11.8 percent). It will in general be true that pipe deformations which are long compared to the wave-length convert power from the TE_{01} mode mostly into those (transverse electric) modes whose phase velocities are nearest the TE_{01}. Physically it is evident that unless the phase velocities of two modes are nearly equal, they will phase in and out so rapidly that over a distance of several wave-lengths the net power transfer will be small.*

If the r.m.s. deviation $\langle\sigma^2\rangle^{\frac{1}{2}}$ of the pipe from a perfect circular cylinder is expressed in mils, then since $a=2.366$ in., (34) becomes

$$\langle\alpha\rangle=0.879\times10^{-6}\langle\sigma^2_{\text{mils}}\rangle\text{ db/cm}. \tag{35}$$

This value may be compared with the theoretical attenuation α_0 due solely to heat losses. We find from the usual wave guide formulas[8] that for the TE_{01} mode at 3.2 cm in a copper pipe of diameter 4.732 in. and resistivity 1.72×10^{-6} ohm cm,[9]

$$\alpha_0=1.076\times10^{-5}\text{ db/cm}, \tag{36}$$

so that the ratio of mode conversion losses to theoretical heat losses, each expressed in db/cm, is

$$\langle\alpha\rangle/\alpha_0=0.0817\langle\sigma^2_{\text{mils}}\rangle. \tag{37}$$

A discrepancy of 8 percent of the theoretical copper losses could be accounted for by mode conversions, under the assumptions that led to (34), if the r.m.s. deviation of the pipe from perfect circularity were 1 mil. We may point out that if the circumferential variations in the pipe surface were sinusoidal, a 1-mil value of $\langle\sigma^2\rangle^{\frac{1}{2}}$ as here defined would correspond to a maximum variation of 2.83 mils in the radius, or, in the case of an even harmonic, to a difference of 5.66 mils between maximum and minimum internal diameters.

We should stress that the numbers just obtained depend rather strongly upon the assumptions which we made concerning the relative magnitudes of the various σ_{st}'s; in particular, the results are sentitive to variations in the relative amounts of second and third harmonics in the circumferential distortion, since these harmonics couple the two modes, TE_{21} and TE_{31}, whose phase velocities are closest to TE_{01}. It may be of interest to record the results of a calculation made under the assumption that all of the σ_{st}'s corresponding to harmonics of degree not greater than four are present in equal amounts; i.e.,

$$\sigma_{st}\begin{cases}=\sigma_1,\ 0\leq s,\ t\leq 4,\\ =0,\text{ otherwise.}\end{cases} \tag{38}$$

Then we find from (27) that

$$\langle\sigma^2\rangle=18.06\epsilon^2\sigma_1^2,$$

and from (29) and (36), after extensive computation,

$$\langle\alpha\rangle/\alpha_0=0.205\langle\sigma^2_{\text{mils}}\rangle,$$

which is two and one-half times the value of $\langle\alpha\rangle/\alpha_0$ given by (37). Although the "tapered" distribution of amplitudes (33) seems physically much more reason-

* On the other hand, unpublished calculations have indicated that the effect of a surface irregularity which is *short* compared to the wave-length is to couple the TE_{01} mode most strongly to those modes which are near cut-off. With such an irregularity one might expect pronounced resonance phenomena if the frequency were varied through the cut-off frequency of a particular higher mode.

[8] Reference 4, p. 390.

[9] The effective resistivity of metallic surfaces at centimeter wave-lengths is appreciably higher than the d.c. resistivity of the bulk metal, because of surface roughness and corrosion. See E. Maxwell, J. App. Phys. 18, 629 (1947), and S. P. Morgan, Jr., J. App. Phys. 20, 352 (1949). In estimating mode conversion losses from measurements of total line attenuation it is first necessary to take account of these augmented heat losses.

TABLE III. Values of the coefficients D_{nm} for $\lambda\ a=0.532$.

8	21.16	32.36	41.96	—	—

able than the "flat" distribution (38), it must be remembered, in view of our lack of experimental measurements, that the actual distribution in commercial copper pipe may be quite different from either of these assumed distributions.

In order to compare mode conversion losses in the same pipe at different frequencies, we turn now to K-band wave-lengths and take

$$\lambda=1.25\text{ cm},\quad \lambda/a=0.208,$$
$$a=2.366\text{ in.},\quad l/\lambda=488.$$
$$l=20\text{ ft.},$$

If we assume, as in obtaining (34), that the σ_{si}'s are given by (33), a calculation similar to the preceding one gives

$$\langle\alpha\rangle=2.94\langle\sigma^2\rangle/a^2\text{ db/cm},\qquad (39)$$

or, if $\langle\sigma^2\rangle^{\frac{1}{2}}$ is expressed in mils,

$$\langle\alpha\rangle=0.525\times10^{-6}\langle\sigma^2{}_{\text{mils}}\rangle\text{ db/cm}.\qquad (40)$$

In deriving the numerical coefficient of Eq. (39) contributions have been included from the 37 forward modes whose phase velocities are nearest to that of the TE_{01} mode; the contributions of the other modes would be too small to affect the third significant figure. It appears during the calculation that 98.2 percent of the mode converted power is carried by five modes (TE_{31}^+, 51.8 percent; TE_{21}^+, 27.3 percent; TE_{12}^+, 12.4 percent; TE_{11}^+, 4.7 percent; TE_{11}^+, 2.0 percent).

Equations (39) and (40) may be compared respectively with (34) and (35); we see that in absolute magnitude the mode conversion losses at 1.25 cm are only 0.597 times the losses due to mode conversions in the same pipe at 3.2 cm. But the copper losses for the TE_{01} mode diminish even more rapidly as the frequency is increased;* at 1.25 cm the theoretical attenuation of this mode in a 4.732-inch pipe is

$$\alpha_0=2.51\times10^{-6}\text{ db/cm}.$$

Hence the ratio of mode conversion loss to theoretical heat loss at 1.25 cm is

$$\langle\alpha\rangle/\alpha_0=0.209\langle\sigma^2{}_{\text{mils}}\rangle,\qquad (41)$$

and this is 2.56 times the relative mode conversion loss at 3.2 cm.

As a check on the preceding calculations, we have determined from (31) and (32) the average mode conversion power carried by the TE_{21}^+ and TE_{31}^+ modes at 3.2 cm for pipe sections ranging in length from 15 to 25 feet. Thus substituting

$$\lambda=3.20\text{ cm},\quad l_1=15\text{ ft.},$$
$$a=2.366\text{ in.},\quad l_2=25\text{ ft.},$$

we find that

$$\langle\alpha(l_1,l_2)\rangle\approx4.67\langle\sigma^2\rangle/a^2\text{ db/cm},\qquad (42)$$

where the right side is a very close lower limit to the actual value of $\langle\alpha(l_1,l_2)\rangle$. Similarly, taking

$$\lambda=1.25\text{ cm},\quad l_1=15\text{ ft.},$$
$$a=2.366\text{ in.},\quad l_2=25\text{ ft.},$$

and considering the five modes nearest in phase velocity to TE_{01}, we find

$$\langle\alpha(l_1,l_2)\rangle\approx3.03\langle\sigma^2\rangle/a^2\text{ db/cm}.\qquad (43)$$

On comparing (42) with (34) and (43) with (39) we see that the results obtained by considering 20-foot sections of pipe are within a few percent of the average results for lengths between 15 and 25 feet.

Finally we may inquire the effect of mode conversions on the TE_{01} wave at K-band in a smaller guide, say a 2-inch pipe instead of 5-inch. We get approximately this case if we scale down the results for X-band in a 5-inch pipe, using the dimensional relation (30) and the calculations which led to (34). The latter equation may be written

$$\langle\alpha\rangle\lambda=15.75\langle\sigma^2\rangle/a^2\text{ db/wave-length},\qquad (44)$$

and this relation holds for the values

$$\lambda=1.25\text{ cm},\quad a=0.924\text{ in.},\quad l=7.81\text{ ft.},$$

since the ratios λ/a and l/λ are the same as those for which it was derived. But at $\lambda=1.25$ cm, (44) gives

$$\langle\alpha\rangle=12.60\langle\sigma^2\rangle/a^2\text{ db/cm},$$

or, if $\langle\sigma^2\rangle^{\frac{1}{2}}$ is expressed in mils,

$$\langle\alpha\rangle=14.76\times10^{-6}\langle\sigma^2{}_{\text{mils}}\rangle\text{ db/cm}.$$

Since the theoretical copper losses for the TE_{01} mode at 1.25 cm in a guide of inside diameter 1.848 in. lead to an attenuation

$$\alpha_0=4.41\times10^{-5}\text{ db/cm},$$

we find for the ratio of mode conversion losses to heat losses,

$$\langle\alpha\rangle/\alpha_0=0.335\langle\sigma^2{}_{\text{mils}}\rangle.\qquad (45)$$

* In practice however surface roughness effects become more significant as the skin depth for eddy currents is reduced.

Comparing (45) with (41), we see that when we go from a 4.732-inch pipe to a 1.848-inch pipe at 1.25 cm, we increase the relative mode conversion losses, for a fixed value of $\langle\sigma^2_{\text{mils}}\rangle$, by a factor of 1.60.

ACKNOWLEDGMENTS

I wish to thank Mr. A. C. Beck and Mr. A. P. King for permission to quote certain of their unpublished experimental results. I am indebted to Dr. W. A. Tyrrell for helpful suggestions during the course of this work, and to Mrs. Jean A. Smith for carrying out most of the numerical calculations.

APPENDIX I

Excitation of Transverse Electric Modes by Tangential Electric Field at Boundary

Let the tangential components of the electric field vanish over the surface $\rho=a$ of a circular wave guide everywhere except in a finite region S where they are given by

$$E_\varphi=E(a,\varphi,z), \quad E_z=0. \tag{A1}$$

The stream function $\Psi(\rho,\varphi,z)$ corresponding to these assigned boundary values may be found by the following formal procedure:

Let the stream function giving the boundary value

$$E_\varphi=E_0(a,\varphi,z)=\delta(\varphi-\varphi')\delta(z-z'), \tag{A2}$$

where δ is the unit impulse-function, be

$$\Psi_0(\rho,\varphi,z;\varphi',z')$$
$$=\sum_{n=0}^{\infty}\left[\int_{(C)} A_n(\gamma)J_n[(\beta^2+\gamma^2)^{\frac{1}{2}}\rho]e^{\gamma z}d\gamma\right]\frac{\epsilon_n}{2\pi}\cos n(\varphi-\varphi'),$$

where the contour (C) in the γ plane will be specified presently and $A_n(\gamma)$ is a function to be determined. Now

$$E(a,\varphi,z)=[\partial\Psi_0/\partial\rho]_{\rho=a}=\sum_{n=0}^{\infty}\left[\int_{(C)} A_n(\gamma)(\beta^2+\gamma^2)^{\frac{1}{2}}J_n'[(\beta^2+\gamma^2)^{\frac{1}{2}}a]e^{\gamma z}d\gamma\right]\frac{\epsilon_n}{2\pi}\cos n(\varphi-\varphi'). \tag{A3}$$

But if we write $\delta(\varphi-\varphi')$ as a Fourier series in φ and $\delta(z-z')$ as a contour integral,[10] (A2) becomes

$$E_0(a,\varphi,z)=\lim_{\substack{s\to 0\\ t\to 0}}\sum_{n=0}^{\infty}\left[\frac{1}{2\pi i}\int_{(C)}\frac{\sinh\frac{1}{2}\gamma s}{\frac{1}{2}\gamma s}\right.$$
$$\left.\times\exp[\gamma(z-z')]d\gamma\right]\frac{\epsilon_n}{2\pi}\frac{\sin\frac{1}{2}nt}{\frac{1}{2}nt}\cos n(\varphi-\varphi'), \tag{A4}$$

the contour (C) in the γ-plane being along the imaginary axis indented to the right at the origin, as in Fig. 3. We determine $A_n(\gamma)$ by comparing (A3) and (A4), and obtain, on letting s and t pass to zero under the signs of summation and integration, the result

$$\Psi_0(\rho,\varphi,z;\varphi',z')$$
$$=\sum_{n=0}^{\infty}\left[\frac{1}{2\pi i}\int_{(C)}\frac{J_n[(\beta^2+\gamma^2)^{\frac{1}{2}}\rho]\exp[\gamma(z-z')]d\gamma}{(\beta^2+\gamma^2)^{\frac{1}{2}}J_n'[(\beta^2+\gamma^2)^{\frac{1}{2}}a]}\right]\frac{\epsilon_n}{2\pi}$$
$$\times\cos n(\varphi-\varphi')$$
$$=\sum_{n=0}^{\infty}\frac{\epsilon_n I_n}{2\pi}\cos n(\varphi-\varphi'),$$

where

$$I_n=\frac{1}{2\pi i}\int_{(C)}\frac{J_n[(\beta^2+\gamma^2)^{\frac{1}{2}}\rho]\exp[\gamma(z-z')]d\gamma}{(\beta^2+\gamma^2)^{\frac{1}{2}}J_n'[(\beta^2+\gamma^2)^{\frac{1}{2}}a]}. \tag{A5}$$

It is easily shown that the integrand in (A5) is a single-valued function of γ, so that I_n can be evaluated in terms of the residues at the poles of the integrand. These poles are at the points* $\gamma=\pm\Gamma_{nm}$, where $k_{nm}=(\beta^2+\Gamma_{nm}^2)^{\frac{1}{2}}a$ is the mth positive root of $J_n'(x)=0$ and Γ_{nm} is the corresponding natural propagation constant in the guide. The contour (C) is indented to the right of the poles on the negative imaginary γ-axis and to the left of the poles on the positive imaginary γ-axis; then if $z>z'$ it is closed with an infinite semi-circle in the left half-plane, thus including an infinite number of poles on the negative real axis. With the aid of l'Hospital's rule and Bessel's equation it is easy to show that

$$\lim_{\gamma\to-\Gamma_{nm}}\frac{\gamma+\Gamma_{nm}}{J_n'[(\beta^2+\gamma^2)^{\frac{1}{2}}a]}=\frac{k_{nm}^3}{\Gamma_{nm}a^2(k_{nm}^2-n^2)J_n(k_{nm})},$$

so that the contribution of the pole at $\gamma=-\Gamma_{mn}$ to the stream function $\Psi_0(\rho,\varphi,z;\varphi',z')$ is

$$\frac{k_{nm}^2\epsilon_n J_n(\chi_{nm}\rho)\cos n(\varphi-\varphi')\exp[-\Gamma_{nm}(z-z')]}{2\pi\Gamma_{nm}a(k_{nm}^2-n^2)J_n(k_{nm})} \tag{A6}$$

for $z>z'$. If $z<z'$ the contour (C) is to be closed with an infinite semicircle in the right half-plane; the end result

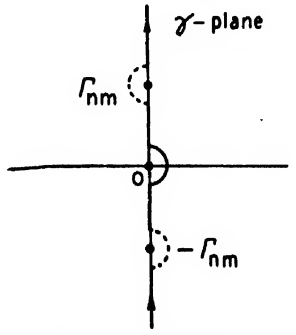

FIG. 3. The contour (C) in the γ-plane.

[10] Reference 4, pp. 34–35.

* For $n=0$ there are also poles at $\gamma=\pm i\beta$, but the contribution of these poles to the stream function is of the form constant $\times\exp(\pm i\beta z)$, which leads to no non-vanishing fields.

is to change the sign of the exponent in the last factor of (A6). Hence in general

$$\Psi_0(\rho,\varphi,z;\varphi',z')=\sum_{n=0}^{\infty}\sum_{m=1}^{\infty}\frac{\epsilon_n k_{nm}^2 J_n(\chi_{nm}\rho)\cos n(\varphi-\varphi')\exp[-\Gamma_{nm}|z-z'|]}{2\pi\Gamma_{nm}a(k_{nm}^2-n^2)J_n(k_{nm})}. \tag{A7}$$

Having the stream function which corresponds to an impulse-function boundary value of E_φ, we are able to write down at once the stream function for the general field given by (A1); it is

$$\Psi(\rho,\varphi,z)=\int\int_S F(a,\varphi',z')\Psi_0(\rho,\varphi,z;\varphi',z')dz'd\varphi',$$

which corresponds by (A7) to Eq. (5) of Section II.

APPENDIX II

Some values of the quantities D_{nm} defined by (10) have been calculated for particular choices of λ/a and are given in Tables III and IV.

Wettability, a Function of the Polarizability of the Surface Ions

L. R. Sonders, D. P. Enright, and W. A. Weyl
The Pennsylvania State College, School of Mineral Industries, State College, Pennsylvania
(Received October 28, 1949)

The wettability of crystals, glasses, and even of water itself can be temporarily decreased by bringing ions of high polarizability into their surfaces. Base exchange experiments are described where the hydrogen ions present in the surface layers of bentonite (a clay mineral of high exchange capacity) and of a soda-lime glass are replaced by different cations. This substitution seems to have no particular effect on the hydrophilic and rheological properties of the carriers as long as their surfaces are kept in contact with water. After drying, however, the surfaces which contain ions of high polarizability become hydrophobic, at least temporarily. A porous clay film will no longer absorb water instantaneously after having been treated with Ni^{2+}, Mn^{2+}, Hg^{2+}, or similar ions with incomplete outer electron shells. Contact angles with water up to 70° could be observed for a short period for Hg^{2+} and Pb^{2+} clays.

Glass capillary tubes which have been treated with non-noble gas-type ions show a capillary rise which is much smaller than that observed with the tubes which have been treated with HCl and water only. This depression of the capillary rise, too, is temporary and can be observed only if the glass wall has been thoroughly dried previous to the experiment and if the capillary rise is measured in the upward direction.

An explanation is presented for these and allied phenomena on the basis of the polarization of ions in the strongly asymmetrical forcefields of interfaces. The experiments are correlated with the hysteresis of the contact angle and with observations concerning adhesion phenomena and catalytic activities of heavy metal ions at interfaces.

I. INTRODUCTION

THE present difficulty in the understanding and in the correct interpretation of surface phenomena, such as heterogeneous catalysis, adhesion and wetting properties of solids, is partly the result of not being able to directly measure the surface forces emanating from a solid without changing the surface structure. For example, the forcefields emanating from the surfaces of alkali halides cannot be measured by bringing the salts onto a platinum surface and then determining their adhesion, because a metal surface in contact with NaCl is not identical with one in contact with KI. It is now well established that the electrical properties of metal films are changed if they are brought in contact with different gases or solids. The checkered forcefield of the cube face of NaCl or of a glass surface polarizes the metal surface by inducing higher electron densities opposite the cations and lower electron densities opposite the anions. The metals respond to the external forcefield by producing image forces and these in turn affect the surface structures of the alkali halides.

This uncertainty about the forcefields of surfaces and their change with the environment is not generally appreciated. A surface of galena (PbS), for example, exerts different forces upon its environment depending on its chemical composition. The galena surface undergoes a structural change if one medium, say air, is replaced by another, for example, water. The forcefields of the highly polarizable Pb^{2+} and S^{2-} ions can assume directional properties. This structural change in the galena surface affects its contact angle with a liquid and, as a result, the contact angle depends on whether the liquid is advancing over or receding from the solid surface. Adam[1] in his authoritative book writes on this hysteresis phenomenon as follows: ". . . mathematical works on Capillarity rarely mention it at all. It may, however, be observed without any apparatus with almost any rain drop traveling down an ordinarily dirty window pane. This difference between advancing and receding angles is often called the 'hysteresis' of

[1] N. K. Adam, *The Physics and Chemistry of Surfaces* (Oxford University Press, London, 1941), third edition, p. 180.

the contact angle. Early references to it in the literature are scarce; Rayleigh referred to it in 1890; Pockels measured it for several liquids; Sulman studied it in connection with the flotation of minerals. It is well known to those who have measured surface tension by the rise in a capillary tube, for the rise is often less if the liquid is pushing its way up from below than if it is falling from a point above its final equilibrium height.

"The cause of the 'hysteresis' of contact angles is still obscure. It looks superficially as if there was a frictional resistance to motion of the liquid edge over the solid."

It is the object of this paper to explain this hysteresis of the contact angle. Experiments with solid-liquid and liquid-gas interfaces are described and their explanation is based on the polarizability of ions and the effect which the asymmetrical forcefield of an interface exerts upon the direction of valency forces.

A note on this subject has been published as a Letter to the Editor.[1a]

II. THE POLARIZABILITY OF IONS AND SOME OF ITS MANIFESTATIONS

The polarizability of a molecule is frequently measured by its response to the alternating electromagnetic field of light. It can be easily computed from refractive index, molecular weight, and density. The polarizability is a measure for the change which takes place in the outer electronic orbits if an atom, molecule, or ion is exposed to an external electrical field. The polarizability of an ion depends on its size, charge, and on its electron configuration. The rules governing polarization of ions have been derived by Fajans[2] and his school.

Without going into details, some of these rules shall be mentioned.

(a) Anions are more polarizable than cations of the same configuration. For example, the ions which have the electron structure of the inert gas atom, neon, show polarizabilities which decrease with increasing nuclear charge.

$$O^{2-} > F^{-} > Ne > Na^{+} > Mg^{2+}.$$

(b) For ions of the same electrical charge and of comparable electron configuration, the polarizability increases with the size (Table I).

(c) The polarizability of cations of approximately equal size is larger for those of 18 outer electrons than for those of the noble gas type, but is greatest for those cations which have only one or two outer electrons.

Sr^{2+}(8 outer electrons) $< Cd^{2+}$(18 outer electrons) $< Pb^{2+}$(18+2 outer electrons).

The mercurous ion Hg^{+} has only one outer electron and its polarizability is, therefore, extremely high.

The polarizability of an ion can be described as its ability to adjust its own forcefield to that of the environment. This concept has been used by Weyl[3] for explaining adhesion phenomena and solubilities involving two incompatible media. A metal, for example, ordinarily is not soluble in a fused glass. Glasses, say soda-lime-silicates, consist only of noble gas-type ions having rather low polarizabilities. If a strongly polarizable cation such as Pb^{2+}, Bi^{3+}, Sn^{2+}, or Tl^{+} is introduced into the glass, a metal such as gold or copper becomes soluble to a certain extent. These ions act as "metallophilic groups" comparable with hydrotropic substances or with emulsifiers. In the asymmetrical forcefield, which exists between the neutral metal atom and the negatively charged O^{2-} ion, metallophilic ions are strongly polarized. Their electron density no longer possesses the spherical symmetry of the ion in the gaseous state, but has become strongly asymmetrical as far as the outer or valency electrons are concerned.

The deformation of a strongly polarizable ion, such as a Pb^{2+} ion, can be described in the language of the chemist as a disproportionation. Its inner shells (*K* to *O* shell) are not directly affected by chemical changes. It is the *P* shell of a lead atom with its four 6*s* electrons which is primarily responsible for its chemical properties. The four outer electrons of the *P* shell can be donated to electron acceptors. The result of this electron transfer is the formation of the fourfold positively charged Pb^{4+} ion. If only two of the four valence electrons are surrendered to an electron acceptor a Pb^{2+} ion is formed. Outside of the 18 electrons of the *O* shell, such a Pb^{2+} ion, has still two 6*s* electrons. On approach of a negatively charged oxygen ion these two outer electrons are repelled. As a result, the electrical or valence forces of the Pb^{2+} ion are no longer equally distributed in space. The one side of the Pb^{2+} from which the two electrons are repelled has a lower electron density and resembles in its structure the Pb^{4+} ion (18 outer electrons). The

Ni^{2+}	62	55	49	48	12.2	20.2	21.8
Hg^{2+}	60	46	40	40	24.1	32.8	32.8
Pb^{2+}	61	44	39	37	29.0	38.1	40.8

[a] The value for the blank (H^+ glass) varied between 60 and 64 mm depending on the diameter of the tube. All data presented are averages of several experiments carried out with different tubes.

other side characterized by a higher electron density resembles the neutral Pb atom.

One can describe this deformation or polarization of the lead ion by the scheme:

$$Pb^{2+} = \tfrac{1}{2}Pb^{4+} + \tfrac{1}{2}Pb.$$

This is analogous to other "internal oxidation-reduction" reactions such as:

$$2Sn^{2+} = Sn^{4+} + Sn \quad \text{or} \quad Hg_2Cl_2 = HgCl_2 + Hg.$$

The strongly polarized Pb^{2+} ion, therefore, exerts strong ionic forces toward the oxygen ion at its one side but is "neutral" at the opposite side. The side to which the two 6*s* electrons have been repelled has the property of atomic lead and, as a result of its high electron density at this side, it may form a "metallic bond" with a metal atom and, thus, keep atomic Au or Cu in solution.

A similar state of polarization was found to exist for Pb^{2+} and other strongly polarizable cations in surface layers. The polarization of surface ions affects the surface tension, hygroscopicity, catalytic properties, as well as adhesion forces.

Summarizing, we may say that polarizable ions change their electron distribution and with it their "chemical affinities" when brought into the asymmetrical forcefield of a surface or of an interface. In contrast to the gaseous ion or to the hydrated ion which has an electron density function of spherical symmetry, the polarized surface ion exerts directional valence forces because its electron density distribution has become asymmetrical.

III. WETTABILITY OF A SOLID SURFACE

Whether or not a solid brought into a liquid goes into solution depends on its lattice energy and the heat of solvation. Solubility is an equilibrium phenomenon and, as such, it is fairly well understood. There seems to be no relationship, however, between the solubility of a crystal and its wettability by the solvent. Anhydrous chromium chloride may be cited as a typical example. This compound is soluble in water and forms several hydrates, when allowed to crystallize from its aqueous solutions. Nevertheless, it is not easily wet by water and one cannot obtain a reproducible contact angle between $CrCl_3$, H_2O, and air. Even the uncontaminated freshly sublimed anhydrous $CrCl_3$ will float on water for hours without being wet. This phenomenon is due to the state of polarization of the large Cl^- ions in the surface layer where they are exposed to the positive forcefields of Cr^{3+} ions on one side only. The Coulomb forces of these polarized surface Cl^- ions are directed only toward the interior and, therefore, they are not available for hydration. The air film covering the $CrCl_3$ is gradually replaced by water, and the presence of "contrapolarizing" cations is required in order to make the $CrCl_3$ crystal hydrophilic. Addition of HCl accelerates this process because now the Cl^- ions come into a more symmetrical forcefield; they have a Cr^{3+} ion on the one side and a H^+ ion on the other.

Just as striking is the behavior of freshly precipitated mercuric iodide HgI_2. This compound contains the two very polarizable ions Hg^{2+} and I^-. When precipitated from aqueous solution the iodide behaves like any other hydrophilic precipitate, for example, $BaSO_4$, AgCl, etc. However, on filtering, the HgI_2 changes into a hydrophobic material as soon as it comes in contact with air. In the asymmetrical forcefield crystal-air, the polarizable ions adjust their own forcefields to that of the interface by directing their valence forces primarily toward the interior of the crystal. This structural change causes the surface-free energy of the crystal to be lowered.

The low surface-free energy or the lack of strong attraction forces of glasses containing some strongly polarizable heavy metal ions causes them to be less hygroscopic than others which contain only noble gas-type ions of low polarizability. This phenomenon was discovered by Hubbard.[4]

When developing a more logical test for optical glasses which correspond to actual service conditions instead of treating a lens with hot nitric acid, Hubbard found that the hygroscopicity of otherwise "chemically poor" glasses can be much lower than that of a bottle glass of known high chemical resistivity as can be seen from Table II. Glasses containing only noble gas-type ions exert strong surface forces because their low polarizability makes it impossible for them to adjust their Coulomb forces to the asymmetrical forcefield of the

[4] D. Hubbard, J. Research Nat. Bur. Stand. 36, 365–375 (1946).

surface. A surface ion of such a glass has incomplete coordination and extends unsaturated valence forces into space. As a result, oncoming water molecules have a greater chance to be attracted and chemisorbed at such a glass surface: the glass is hygroscopic. However, a glass containing Pb^{2-} ions does not extend strong forces toward the atmosphere and, as a result, only a smaller number of collisions with oncoming H_2O molecules will lead to adsorption.

The difference between a lead glass and a soda-lime glass is not very convincing evidence that it is the polarizability of the surface ions which determines primarily the wettability of a solid and, as such, is responsible for the hysteresis of the contact angle. Experiments were carried out, therefore, with a soda-lime silicate glass and a clay of high base exchange capacity, both of which can be easily changed in respect to surface forces by bringing different cations into their surfaces.

IV. CAPILLARY RISE IN GLASS TUBES CONTAINING DIFFERENT CATIONS AT THEIR INNER SURFACE

The surface of a soft (soda-lime-silicate) glass in contact with water consists of OH^- groups. These hydroxy-groups extend hydrogen bonds toward any liquid containing one or more OH^- groups (water, glycerol, sulfuric acid) so that these liquids completely wet the glass and give a zero contact angle. The importance of the OH^- groups for the wettability of a glass surface can be easily demonstrated.

Concentrated sulfuric acid to which a trace of potassium dichromate has been added is heated in a test tube. The chromate oxidizes organic impurities and produces a clean glass surface which is completely wetted by the liquid. Sulfuric acid molecules can attach themselves to this surface by hydrogen bonds. Adding a trace of sodium fluoride to the sulfuric acid causes the OH^- groups to be replaced by F^- ions according to the equation:

$$-\overset{|}{\underset{|}{Si}}-OH+HF=-\overset{|}{\underset{|}{Si}}-F+H_2O.$$

The dehydrating effect of the concentrated sulfuric acid causes this reaction to proceed to completion. After a few seconds, the inner surface of the test tube has become depleted of OH^- groups and is now covered with fluorine ions. With the OH^- groups missing, the surface lacks the ability to form hydrogen bonds with the H_2SO_4 molecules and, as a result, the sulfuric acid forms little droplets on the glass surface and behaves like water in a greasy container. The substitution of F^- for OH^- has completely changed the interfacial forces between glass and sulfuric acid, because the fluorine ion under the strongly polarizing influence of the silicon ion cannot exert a Coulomb force upon the H_2SO_4 molecules which is sufficiently strong to overcome the cohesion forces of the liquid and to produce wetting.

TABLE IV. Temporary hydrophobicity imparted to a clay film by adsorbed ions.

Cation	Approximate contact angle	Average time for spreading
H^+	0°	Immediate spreading
Li^+	0°	Immediate spreading
Na^+	0°	Immediate spreading
K^+	0°	Immediate spreading
Mg^{2+}	20°	1–3 min.
Ca^{2+}	20°	1–3 min.
Sr^{2+}	20°	1–3 min.
Be^{2+}	20°	1–3 min.
Al^{3+}	20°	1–3 min.
Ba^{2+}	40°	5–10 min.
Tl^+	40°	5–10 min.
Zn^{2+}	40°	5–10 min.
Cd^{2+}	40°	5–10 min.
Cu^{2+}	40°	5–10 min.
Co^{2+}	40°	5–10 min.
Cr^{3+}	40°	5–10 min.
Ni^{2+}	60°	10–12 min.
Mn^{2+}	60°	10–12 min.
Pb^{2+}	70°	15–30 min.
Hg^{2+}	70°	15–30 min.
Laurylamine	80°	No spreading after 120 min.

In the absence of water the silicon fluoride layer is stable and, if the glass tube with the sulfuric acid is sealed, the inner surface retains its repellency indefinitely. However, in the presence of water, hydrolysis takes place and the OH^- groups are restored. The glass surface again is completely wet by water; that means it has a zero contact angle.

In contact with the aqueous solution of a salt some of the H^+ ions of the glass surface can be replaced by other cations; for example, Hg^{2+} or Pb^{2+}. This base exchange is accomplished by treating glass capillaries of about 0.3-mm inner diameter first with diluted HCl and, after rinsing them with water, exposing them to a salt solution for several days. After rinsing with distilled water and drying at 110°C, the glass surface was modified by adsorbed cations. The number of ions adsorbed on the glass depends on the time of exposure, the nature of the compounds, its concentration, and on the temperature. Rinsing of the glass after the adsorption is necessary in order to remove the excess salt and the loosely adsorbed anions. Unfortunately, this procedure introduces a certain error because the substitution of H^+ by other cations is a reversible reaction.

The capillary rise was then determined by carefully inserting the treated glass tubes into water and measuring the rise in the *upward direction.*

The salts containing cations of the noble gas-type did not exert a measurable effect on the capillary rise, namely, the nitrates of Li^+, Na^+, K^+, Be^{2+}, Mg^{2+}, Ca^{2+}, Sr^{2+} and Al^{3+}. The effect of other cations can be seen from Table III.

The experiments on the capillary rise of water in glass tubes which had been treated with various cations

shows how the polarizability of the cation determines the temporary interfacial tension value. With the exception of the large and, therefore, polarizable Ba^{2+} ion, all cations with eight outer electrons (noble gas-type ions) did not affect the wettability of the surface to a noticeable extent. As the capillaries were allowed to stand in the water a gradual rise was observed and the time required for reaching the equilibrium value varied from one ion to another. It was greatest for Hg^{2+} (144 hr.) and Pb^{2+} (120 hr.), less for Ni^{2+} (72 hr.) and Cd^{2+} (48 hr.).

As water molecules distill from the meniscus onto the glass surface, the forcefield of the polarized surface ions gradually becomes more symmetrical and with increasing symmetry the strength of attraction forces emanating from the surface ions increases. As a result the liquid rises, replaces the gas film as well as the adsorbed cations and gradually the original glass surface (OH^- groups) is restored.

V. WETTABILITY OF CLAY SURFACES

The same phenomenon of "temporary hydrophobicity" can be observed for clay minerals. Because of its high base exchange capacity, Wyoming bentonite was selected for these experiments. The clay was purified by electrodialysis and allowed to stand with the electrolyte for 48 hr. under occasional agitation by a mechanical stirrer. The concentration of the electrolyte was chosen so as to provide 200 milliequivalents of the cation per 100 grams of the dry clay.

The homogeneous clay suspensions containing the various cations adsorbed at their surface were then sprayed onto porous ceramic tiles by means of a DeVilbiss spray gun. This method produced smooth clay films of controlled thickness. The porosity of the tile removes both the excess electrolyte and water from the clay film.

The clay-covered tiles were then dried at 110°C for 24 hr. Their wettability was tested by dropping freshly distilled water upon the clay, estimating the contact angle of the water droplet right after its application and determining the time necessary for its complete disappearance.

As the bentonite shows practically no anion exchange capacity it was immaterial which salt was used for introducing the cations. The experiments showed that no significant difference exists between nitrates, chlorides, and sulfates. Nitrates were chosen for the base exchange experiments.

Table IV summarizes the results. The cations are divided into several groups according to their increasing effectiveness based on the contact angle. Table IV brings out the parallelism which exists between the effect of these ions on the wettability of a clay film and on the capillary rise in glass tubes.

In order to show the effect of a long chain hydrocarbon group on the wettability and the spreading time, a clay was treated with a solution of the organic base, laurylamine. As far as the contact angle is concerned, Pb^{2+} and Hg^{2+} ions come very close to this substance. However, in contrast to the temporary hydrophobicity imparted by the polarized cation, the lauryl group causes the clay surface to become permanently water repellent.*

VI. WETTABILITY OF A WATER SURFACE

The phenomenon that a drop of a liquid, for example, one falling from a reflux condenser onto the surface of a boiling liquid, does not immediately unite, but may be seen floating for several seconds, is well known to every chemist and has been described in the textbooks on surface chemistry. It can be explained on the basis that gas films or vapor films are present at the surface. The removal of adsorbed gas molecules or the rearrangement of adsorbed vapor molecules so that they fit into the structure of the liquid are time consuming processes.

We have found that polarizable cations, such as Pb^{2+} or Hg^{2+} dissolved in water affect its surface properties in a manner similar to surface active agents, such as sodium stearate or laurylamine. It can be demonstrated that there is no basic difference between the effects of mercuric acetate and sodium stearate upon the forcefield emanating from a water surface. However, the long chains of the stearic acid molecules cannot turn around very rapidly, but the state of polarization of the Hg^{2+} ions change instantaneously with the symmetry of the forcefield. As a result, the similarity between the effects of the two compounds can be demonstrated best by a dynamic rather than by a static method.

The influence of polarizable cations on the surface forces of water affects the tendency of a stream of water flowing out of an orifice to trap air bubbles. Distilled and degassed water was allowed to flow from a burette into a glass container. Both burette and container were equipped with overflow tubes which ensured constancy of the two water levels. By a screw attachment the container could be gradually lowered or raised and the variable distance between the orifice of the burette and the water level could be measured. As long as the tip of the burette was kept close to the water level of the container a steady flow could be observed and no gas bubbles were trapped. By gradually increasing the distance between the tip of the burette and the water level of the container, one reaches a point where gas bubbles become entrapped and carried under the water surface. It was found that for one and the same apparatus and orifice this critical height, H, could be reproduced with fair accuracy. Taking the essential precautions, such as using boiled and degassed water, avoiding contamination and using degreased glass ware (no stopcock grease), the values for H were reproducible within one percent.

* Viscosity measurements of the different clay suspensions did not reveal any unusual features for those clays which contained Pb^{2+} or Hg^{2+} at their surfaces.

The phenomenon can be explained as follows. Depending on the height and on the speed of the flowing water a surface film is formed which has its own characteristic structure. Its structure is the result of two antagonistic effects, namely, the tendency of the system to assume a molecular arrangement which decreases its surface-free energy and the thermal motion favoring a random orientation.

Gas molecules are being adsorbed at the water surface and their desorption is a time consuming process. The desorption of the gas film, however, is essential before the surface of the streaming water can unite with that of the stagnant water. For slowly flowing water the rate of combination of the two water surfaces is slower than the gas desorption. However, as H and with it the time of exposure of the water to air and the velocity of the falling water is increased, a point is reached where the speed of the uniting water surfaces exceeds the rate of desorption. As a result the gas film is carried below the water level where it assumes spherical shape under the influence of the surface tension: gas bubbles are formed.

The addition of sodium stearate to the flowing or to the stagnant water or to both causes their surface structures to change, the surface tension of the water is lowered. In other words, the ratio of attraction forces toward air to attraction forces toward the liquid is increased if a surface active compound such as sodium stearate is added to the water. A one-tenth molal sodium stearate solution was found to trap the airfilm at a height which was nearly 20 percent lower than that for the pure water. A solution of laurylamine (two percent by volume) decreased the value of H nearly 15 percent.

This method of studying the surface forcefields of solutions was found to be very sensitive as can be seen from Table V which shows the effects of a 0.5 molal and a 1.0 molal salt solution on the critical height, i.e., the one above which a gas film is trapped and carried under the water surface. In contrast to the experiments on the wettability of glass and of clay, it was found that even the Na^+ and K^+ ions showed some influence on the wettability of water. In addition, it was found that the nature of the anion is not without influence as can be seen from a comparison between the values for a sodium nitrate and a sodium acetate solution.

A 1.0 molar solution of $NaNO_3$ causes H to decrease 1.2 percent due to the weak polarizability of the hydrated sodium ion. The NO_3^- ion has no effect as can be seen from the addition of HNO_3. The sodium acetate in 1.0 molal solution was found to decrease the value of H by 2.4 percent which means that the acetate group must have about the same effect as the Na^+ ion.

The response of this method to changes in the constitution of aqueous solutions makes it an interesting tool for studying complex formation and related phenomena. For example: depression of H for 0.25 molar mercuric chloride, 9.1 percent; depression of H for 0.25 molar potassium chloride, 0; depression of H for 0.25 molar KCl+0.25 m $HgCl_2$, 4.8 percent.

TABLE V. Effect of dissolved salts on trapping of airfilm by flowing water.

Cation	Salt Anion	0.5 molal solution H mm	0.5 molal solution Percent decrease	1.0 molal solution H mm	1.0 molal solution Percent decrease
H^+	NO_3^-	83	0	83	0
Li^+	NO_3^-	83	0	83	0
Na^+	NO_3^-	83	0	82	1.2
K^+	NO_3^-	82	1.2	79.5	4.2
Be^{2+}	NO_3^-	83	0	83	0
Mg^{2+}	NO_3^-	83	0	83	0
Ca^{2+}	NO_3^-	82.5	0.6	80.5	3.0
Sr^{2+}	NO_3^-	81.5	1.8	79	4.8
Ba^{2+}	Br^-	80	3.6	75	9.7
Al^{3+}	NO_3^-	83	0	83	0
Zn^{2+}	NO_3^-	81	2.4	78	6.0
Cu^{2+}	NO_3^-	80.5	3.0	77	7.2
Cd^{2+}	NO_3^-	79	4.7	74.5	10.2
Fe^{3+}	NO_3^-	79.5	4.2	74	10.9
Mn^{2+}	NO_3^-	78	6.0	71	14.5
Cr^{3+}	NO_3^-	78	6.0	70.5	15.1
Co^{2+}	NO_3^-	77	7.2	70.5	15.1
Ni^{2+}	NO_3^-	76.5	7.7	69.5	16.3
Pb^{2+}	NO_3^-	70.5	15.1	54.4	34.4
Tl^+	CH_3COO^-	69.5	16.3	52	37.3
Hg^{2+}	CH_3COO^-	65.5	21.1	50	39.8

These data indicate that the highly polarizable Hg^{2+} ion which is responsible for the strong decrease of H is made less effective in the presence of KCl. The chemistry of these compounds suggests the formation of $(HgCl_4)^{2-}$ ions or of a similar complex anion which is less polarizable than the cation Hg^{2+}.

For experiments of this type, it is important to control the temperature fairly accurately because an equilibrium such as

$$HgCl_2+2KCl \rightleftharpoons K_2(HgCl_4)$$

is temperature sensitive. In general it was found that the temperature is not a major factor. For our experiments, no special precautions had to be taken to control the temperature accurately because even a 10°C deviation from room temperature would have caused H to vary less than one percent. For pure water, H was found to increase 2.4 percent if the temperature was lowered from 32° to 3°C.

VII. CONCLUSIONS

All surface phenomena such as adhesion, wetting of solids by liquids, and heterogeneous catalysis are governed by the polarization properties of ions. Perfect crystals, liquids, or gases provide a symmetrical environment for ions and molecules at least as far as their bulk is concerned. Interfaces, such as solid-gas or liquid-gas, are the seat of highly asymmetrical forcefields which cause the polarizable ions to undergo a strong change in their electronic orbits. This change will not look very spectacular when described by the elec-

tron density function of the atom because it affects only the tail end of this curve, i.e., the part which represents the outer orbitals. However, these orbitals are the seat of optical and chemical properties and, consequently, they determine light absorption, fluorescence, electrical conductivity, as well as oxidation and reduction phenomena. An ion which is exposed to the one-sided polarizing influence of an interface becomes optically and chemically a different individual. It has different light absorption and different fluorescence. If the polarizability of an ion is sufficiently high it may lose those properties which are the result of its electrical excess charge. A Tl^{+} or Pb^{2+} ion is easily hydrated, because their excess charges orient and attract the dipoles of water. However, the same ions adsorbed at a dry clay or a dry glass surface have an electron density distribution which is different from the ions in their gaseous state or from the ions when symmetrically surrounded by water. The O^{2-} ions of the carrier repel the valency electrons of these cations thus increasing their forcefield toward the solid and decreasing their forces emanating into space. The polarized cations lower the surface free energy of the solid and by becoming neutral towards the exterior—the repelled electrons counteract the effect of the positive excess charge —they have lost the property to attract water molecules. It is this decrease of the Coulomb forces directed toward the exterior which causes the solid to appear water repellent. Strictly, there are no repulsion forces acting in the surface which make the carrier hydrophobic but the attraction forces have become too weak to overcome the cohesion of the liquid.

Solids containing large and, therefore, polarizable ions, e.g., I^{-}, S^{2-}, etc., especially when crystallizing in layer lattices (PbI_2, CdI_2, MoS_2), are not easily wet and due to their weak forcefields they assume properties usually associated with lubricants.

In contrast to organic materials with long hydrocarbon chains, the inertness of polarized ions is only temporary. Every one who has walked along a dusty road on a dry hot summer day and been caught by a sudden rain may have observed this phenomenon of temporary hydrophobicity. The dry dust is not easily wet by water and the first rain drops may roll around like mercury. However, after it has rained a few minutes the rain soaks into the ground and soon the mud tells us that the dust did not have permanent hydrophobic properties.

Polarizable ions can adjust their own forcefields to that of the environment. Their Coulomb forces are symmetrical when symmetrically surrounded by ions of the opposite charge. In the asymmetrical forcefield of an interface, however, their electron distribution and with it their valency forces assume directional properties. A heavy metal ion adsorbed at a surface which repels its electron cloud, so that the polarized ion has a higher electron density toward the exterior, assumes the properties of a neutral metal atom. As such, it may be used as a bridge between an ionic substance, for example, glass, and the metals silver, gold, or copper. Polarizable ions are used to enhance the adhesion between glass and metal. Before silvering a glass it is treated with tin compounds in order to make the silver film adhere better.

Enright, Marboe, and Weyl[5] used the decomposition of H_2O_2 into H_2O and oxygen for demonstrating the metallic character of adsorbed heavy metal ions. Hydrogen peroxide is readily decomposed when brought in contact with a noble metal, Au or Pt. Dissolved ions, such as Hg^{2+} or Ag^{+}, have no effect on this reaction. However, if these ions are adsorbed at the surface of an ionic carrier (glass or alumina) they become positive catalysts. Ions of this type act as negative catalysts or catalytic poisons when adsorbed at the surface of platinum, because in its forcefield they form metallic bonds with the metal (high electron density between cation and metal surface) and extend a strong positive forcefield toward the solution which is ineffective as a catalyst for this reaction.

The experiments with flowing water prove that the water-gas interface has a similar deforming influence on polarizable ions at the glass or clay surface. Very probably this interface plays an important role in certain gas-liquid reactions which are catalyzed by heavy metal ions. The rate of oxidation of ferrous sulfate by air or oxygen gas is greatly increased if 0.01 molar cupric ions are present. In a similar fashion the hydration of acetylene gas in diluted acid leading to acetaldehyde is catalyzed by Hg^{2+} ions.

Department of Electrical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts
(Received November 4, 1949)

Measurements are reported on the distribution of ionization in depth of aluminum produced by steady beams of two and three million-volt electrons. The variation of cathode-ray current density in a plane transverse to the beam, the effect on this transverse distribution of additional aluminum scattering foils, and a practical method of cathode-ray dosage computation are given.

INTRODUCTION

In the study of the physical and biological effects of high energy cathode rays[1] it is desirable to know the actual distribution of the ionization energy in the absorber material. An earlier paper[2] reported measurements on the distribution of ionization in depth of water, aluminum, copper, and lead produced by monoenergetic electron beams over the energy range from 0.3 to 1.5 million volts. In the present studies, ionization distribution in depth of aluminum and intensity distribution across the beam were measured for steady streams of electrons in the two and three million-volt range. In order to secure greater uniformity across the field, a study was made of the effect of scatter produced by aluminum foils inserted in the beam. A method of dosage computation which facilitates the determination of maximum, average, and minimum cathode-ray dose on a sample of given size is included.

CATHODE-RAY SOURCE

A pressure-insulated Van de Graaff electrostatic accelerator[3] was used as the source of high energy electrons. These were directed toward the absorber in a continuous stream, homogeneous in energy and controllable over the range from 1 to 3.5 million volts. The electrons emerged from the tube through an aluminum window 0.003 inch thick on which they impinged as parallel particles over an area of about 5 mm diameter. Voltage was measured by a generating voltmeter which had been calibrated at 1.63 million volts by making use of the beryllium (γn) reaction and observing the threshold with a BF_3 counter.

MEASUREMENT TECHNIQUE

A thin parallel-plate ionization chamber was used to measure the distribution of ionization in depth caused by the high energy electrons in their passage through aluminum. The chamber consisted essentially of a stretched aluminum diaphragm 0.0006-inch thick, insulated and separated by 1 mm from a thick aluminum plate which formed the other electrode. The area of the air gap was large compared with that of the cathode-ray beam at the region of measurement. As shown in Fig. 1, the chamber was mounted close beneath the cathode-ray window of the accelerator tube. Thin aluminum sheets were inserted between the cathode-ray window and the ionization chamber to give the effect of placing the chamber at progressively greater depths below the surface of the absorbing material.

A constant beam current I_1 of high energy electrons was directed at the absorber system. Two microamperes of beam current produced maximum ionization currents I_2 or I_3 of approximately 40 μa. I_2 represents the negative ionization current plus the portion of the beam current which passed through the aluminum sheets, and I_3 the positive ionization current minus the portion of the beam current which was absorbed in the aluminum sheets.

Linearity of the ionization chamber was checked by using a fixed thickness of aluminum absorber above the chamber and observing the constancy of the ratio I_2/I_1

over a wide range of beam currents I_1. The collecting voltage was maintained constant at 600 volts, this voltage having been found to be well above the amount for saturation. This check indicated linearity of response to within ± 2 percent for the range of currents used in the experiment.

The distribution of current density in a plane transverse to the beam was measured with the arrangement shown in Fig. 2 by collecting the current passing through spaced holes in an aluminum plate at a distance of 40 cm from the exit window of the accelerator tube. The minimum or inherent scattering of the electron beam was caused by both the 0.003-inch aluminum window and the 40 cm of intervening air. Faraday cages were placed beneath the individual holes spaced radially at $\frac{1}{4}$-inch intervals from the center of the plate. Holes which did not have Faraday cages beneath were plugged to eliminate stray currents. The $\frac{1}{8}$-inch diameter holes in the lower aluminum plate were drilled so

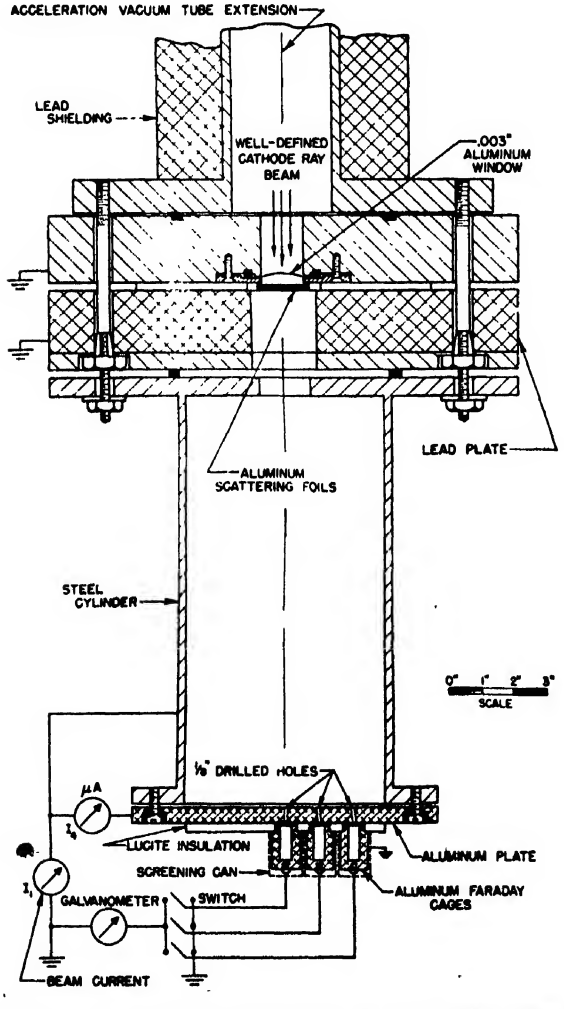

FIG. 2. Apparatus for determining the cathode-ray current density transverse to the beam and the effect of additional aluminum scatterer.

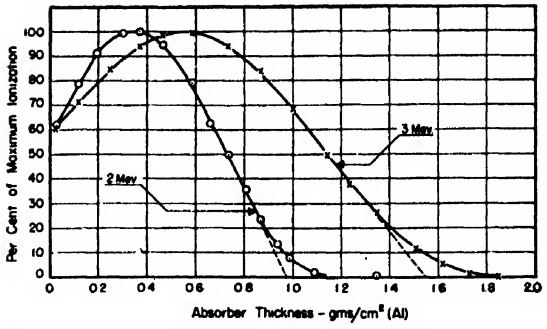

FIG. 3. Distribution of ionization in depth of aluminum produced by cathode rays with energies of two and three million volts.

that their angles with respect to the beam axis were determined by the center of the exit window and the radial distance of the holes from the center of the plate. It was found necessary to shield the individual Faraday cages from ionization in air caused by x-rays. For these measurements the total beam current I_1 was held constant at 50 μa, and the resultant Faraday cage currents of the order of 10^{-8} amp. were read on a galvanometer.

IONIZATION DISTRIBUTION IN DEPTH

Figure 3 shows the ionization distribution in depth of aluminum produced by electron beams of two and of three million volts energy. It is observed that the ionization has a broad maximum at about one-third the greatest range, this previously reported distribution[2] arising from the high scattering tendency of the primary electrons within the absorber. The penetrating power of electrons in aluminum is close to 1 g/sq. cm per two million volts, as determined by the interpolated curve intercept. From other studies[2] at lower electron energies, a corresponding range was found for water, aluminum, copper, and lead, and the general shapes of the ionization distribution curves were closely similar. The range in centimeters can be obtained by dividing the range in g/sq. cm by the density of the absorber material. The tail of the distribution curve is due primarily to those few electrons which have made relatively undeviated paths through the absorber. Ionization due to x-rays produced within the absorber can easily be shown to constitute a negligible addition to the measured ionization currents.

Since the area of the ionization chamber was large in comparison with that of the beam, the curves of Fig. 3 represent approximately the distribution of ionization in depth along the axis of the beam and more accurately the total ionization at each depth. In addition to its primary dependence on electron energy and absorber density, the distribution of ionization energy in an absorber irradiated by essentially parallel and monoenergetic electrons is profoundly affected by electron scattering. Although the ionization density is greatest near the end of the path of a single electron,

the effect of scattering on a beam of such particles is to shift the region of highest ionization and energy absorption to a depth of about one-third the maximum penetration for that energy.

BEAM INTENSITY DISTRIBUTION ACROSS THE FIELD

Figures 4 and 5 show the intensity distribution of two and three million-volt cathode-ray beams in a transverse plane 40 cm from the exit window. The upper curve of each figure shows the distribution resulting from the inherent scatter consisting of the 0.003-inch aluminum window and 40 cm of atmospheric air. The remaining curves show the beam-spreading effects of additional aluminum scatterer placed immediately below the window.

The greater directivity and reduced scatter obtained at the higher beam energies is evident from a comparison of Figs. 4 and 5. In the irradiation of an area four inches in diameter at the 40-cm distance, two million-volt

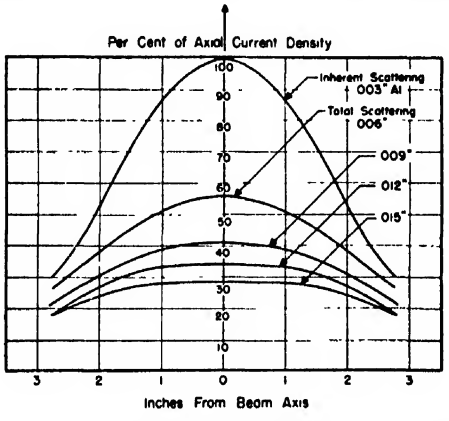

FIG. 4. Distribution of current density for two million-volt cathode rays in a transverse plane 40 cm from the 3-mil aluminum window.

cathode rays with inherent scatter would deliver 52 percent of the axial intensity to the sample edges, while a three million-volt beam would deliver but 30 percent to the edges. Additional scatterer inserted in the beam rapidly increases the uniformity of beam intensity over the selected area, but is attended by loss of charge to outside regions. Modification of the intensity distribution to the transverse plane can readily be accomplished by the addition of solid scatterer or an increase in the air path to the absorber. Because the ratio of scatter to absorption increases with atomic number, it would be preferable to use foils of gold or other high atomic-number metal as the scattering material.

DOSAGE COMPUTATIONS

At the present time there exists a considerable interest in the physical, chemical,[4] and biological[5] effects of high energy cathode rays on living and non-living materials. For such irradiation studies, the cathode-ray equipment may be set up as in Fig. 2 with a solid lower aluminum plate. A current-collecting disk is placed on, and preferably flush with, the top of this plate, but electrically insulated from it. A suitable shutter is used to provide accurate control of the exposure time.

In principle, the cathode-ray dosage rate can be specified with great exactness inasmuch as it is determined by the number of impinging electrons per second and their accelerating voltage. In practice, account must be taken of the distribution of the ionization energy both in depth and across the transverse plane of the absorber. For the case of stationary samples, dosage computations can readily be made with the aid of information contained in Figs. 3–5. The dose delivered to liquids in continuous flow or to solids on a moving belt may often be derived more simply by direct comparison with the known chemical or bactericidal effects of cathode rays as determined on stationary samples.

The total cathode-ray power falling on a disk of diameter D is EI where E is the accelerating potential and I the total beam current to the disk. The average power P absorbed per gram of material distributed uniformly over this disk to a depth R expressed in g/sq. cm is

$$P=[EI/\pi(D/2)^2R]K_1K_2\text{watts/g},$$

where K_1 is the fraction of the total power absorbed in range R and K_2 is a factor close to unity which takes account of the possible change in electron backscatter from the disk area after a sample of the same diameter has been placed upon it. The value of K_1 may be obtained from Fig. 3 by dividing the area under the curve for a sample thickness R by the total area of the curve of energy E. The value of K_2 requires the measurement of electron backscatter for different materials,[6] but can be kept close to unity by making both disk and sample

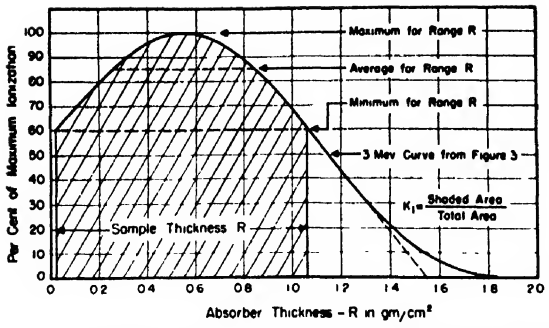

FIG. 6. Ionization-in-depth curve for three million-volt cathode rays applied to a 1.03-g/cm² sample to determine maximum, average, and minimum doses.

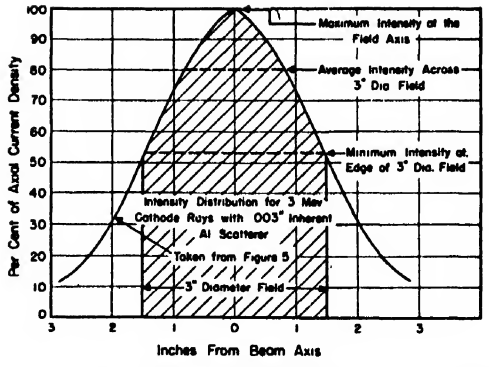

FIG. 7. Transverse beam intensity curve for three million-volt cathode-ray beam applied to a three-inch diameter sample at 40-cm distance to determine maximum, average, and minimum intensities.

cover of the same low atomic number material, such as aluminum.

Cathode-ray dose is best expressed in ergs and joules for physical studies, but may be specified in equivalent roentgens for biological studies. The conversion factors for these units of radiation energy are 1 joule $= 10^7$ ergs; 1 roentgen equivalent physical[7] (rep) $= 83$ ergs per gram of tissue; 10^6 reps $= 8.3$ joules per gram of tissue. The irradiation time is found by dividing the desired dose expressed in joules by the average dosage rate P.

Maximum and minimum doses can be calculated from the average by applying the appropriate dose ratios both for the distribution in depth and the transverse distribution as given in Figs. 3–5. Consider the specific case in which it is desired to irradiate a stationary sample three inches in diameter (7.62 cm) with three million-volt cathode rays. The current to the three-inch collecting disk is taken as 10 μa. For convenience, the sample depth R in g/sq. cm is chosen so that the entrance and exit doses are the same percent of the maximum dose. From the three million-volt curve of Fig. 3 or 6, R is found to be 1.03 g/sq. cm. The ratio of the area included under this curve to depth R to the total area gives coefficient $K_1 = 0.84$. If care has been taken to use low atomic-number materials and to mount the sample for minimum effect on backscatter, then K_2 can be taken as unity. Then

$$P = 3\times10^6 \times \frac{10\times10^{-6}}{\pi(7.62/2)^2} \frac{0.84\times1}{1.03} = 0.54 \frac{\text{watts}}{\text{g}}$$

and the time required to deliver an average dose of 10^6 reps is

$$t = 8.3/0.54 = 15.4 \text{ sec.}$$

From the distribution-in-depth curve of Fig. 6 the average dose is found to be 85 percent of the maximum, and the minimum 60 percent. From the intensity distribution across the beam of Fig. 7, with only inherent scattering, the average intensity is found to be 80 percent of the maximum, and the minimum 52 percent. Therefore the minimum dose is $(0.6\times0.52)/(0.85\times0.8)$, or 46 percent of the average, and the maximum dose is $(1\times1)/(0.85\times0.8)$, or 147 percent of the average. The spread between maximum and minimum doses may be controlled by suitable selection of absorber depth, width, scatterer, and irradiation distance.

ACKNOWLEDGMENTS

We desire to pay tribute to Arthur M. Clarke, our associate on this paper, whose death on January 19, 1949, ended seven years of devoted and effective work in the High Voltage Research Laboratory. The help of Dr. E. W. Webster in making some of the measurements is gratefully acknowledged. This work was assisted by the Joint Program of the ONR and the AEC.

Metal Transfer in the Cutting Process*

MILTON C. SHAW AND CHARLES D. STRANG, JR.
Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts
January 27, 1950

THERE are generally thought to be two distinct types of continuous chip formed in single point metal cutting—that produced in the presence of a so-called built-up edge and that produced when no built-up edge is present. The built-up edge is a metal appendage which accumulates at the cutting point of the tool when the metal is cut under conditions conducive to high friction and welding. The built-up edge can be found adhering to either the tool face or the workpiece and is frequently macroscopically visible. Figure 1 is a photo-micrograph of a polished

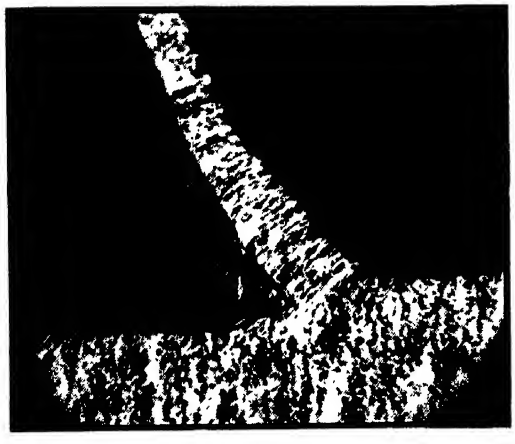

FIG. 1. Photo-micrograph showing built-up edge, magnification, 60 times.

and etched specimen obtained by cutting a sample of annealed SAE 4027 steel in air with the end milling cutter shown in Fig. 2. The large built-up edge can be seen at the junction of the chip and the freshly cut surface.

The chip shown in the photo-micrograph of Fig. 3 was produced under conditions least favorable to the formation of a built-up edge. The workpiece and the tool were submerged in carbon tetrachloride, one of the most effective cutting fluids known, and the cutting velocity was adjusted to be in the range where the carbon tetrachloride has sufficient time to react (below approximately 40 ft. per min.) with the metal being cut to form a low shear strength solid lubricant. This compound is thought to prevent or decrease metal-to-metal contact between chip and tool face and so prevent formation of a built-up edge. No built-up edge is evident in Fig. 3 nor was any transferred metal visible on the cutting tool when it was examined under the microscope. In spite of this, the autoradiograph of Fig. 4 shows that considerable material from the workpiece has been welded to the face of the tool.

This autoradiograph was produced by machining a specimen of SAE 4027 steel which had previously been made radioactive by neutron irradiation in the pile at Oak Ridge. A new tool, identical to the first, was used for this experiment and was carefully cleaned and washed in water to remove any loose chips or residual radioactive iron chloride produced as the metal was machined under carbon tetrachloride. The cutting end of the tool was placed in contact with a sheet of x-ray film and exposed for a period of two

FIG. 2. End milling cutter.

weeks. Figure 4 is a positive print and the white areas indicate the presence of the radioactive built-up edge. It will be seen that the built-up edges does not extend across the full width of the tool face inasmuch as the workpiece was annular in cross section.

This simple experiment establishes the fact that even under the most ideal conditions of cutting fluid action, some welding occurs between the chip and tool face with attendant transfer of metal and further that the presence or absence of a built-up edge is merely a matter of degree. While the invisible built-up edge indicated by Figs. 3 and 4 is insignificant from the standpoint of cutting geometry, it is of considerable interest with regard to friction and tool wear. Although carbon tetrachloride does not entirely prevent metal to metal contact and welding at the chip-tool interface, it does act to reduce greatly the amount of welding or transfer and the size of the built-up edge. The iron chloride that is formed when carbon tetrachloride reacts with the metal during cutting probably reduces the real area of metal-to-metal contact and at the same time may produce a transferred layer that is weak in shear, consisting in part of steel and iron chloride.

Under usual cutting conditions, the built-up edge is welded to the tool face whereas it is generally found attached to the chip when the operation is suddenly stopped for the purpose of preparing photo-micrographs as shown in Fig. 1. This paradox may be readily explained on the basis of decreased shear strength with increased temperature. During cutting, the temperature at that surface of the built-up edge furthest from the tool face is higher than that at the tool face and slip consequently takes place in the region of temperature-reduced shear strength. When a photo-micrograph specimen is prepared by suddenly stopping the tool in the act of producing a chip, the metal quickly cools and the shear strength of the highly worked metal at the interface of the built-up edge and the chip exceeds that at the tool face. Therefore, when the tool is withdrawn, the built-up edge is usually found adhering to the chip rather than to the tool. On the other hand, remnants of built-up edge are often found on the face of a tool which has continued cutting to the very end of the workpiece.

The relatively large amount of metal transfer (built-up edge) which occurs when cutting metal in air as compared to that observed in dry friction experiments[1] may also be explained by the

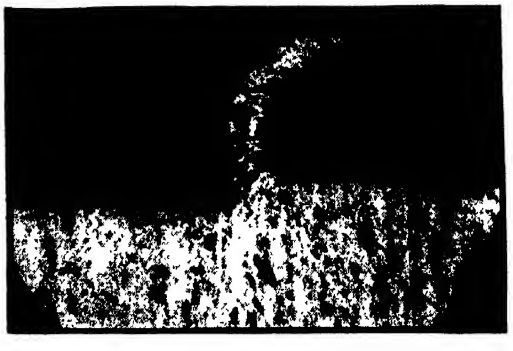

FIG. 3. Photo-micrograph of chip formed beneath the surface of carbon tetrachloride. Magnification, 60 times.

FIG. 4. Autoradiograph of end milling cutter used to machine radioactive steel.

decrease in shear strength with increase in temperature. When cutting metal, considerable energy is expended in plastic deformation along the shear plane. The energy thus dissipated causes an increase in the internal energy along the shear plane, a consequent rise in temperature and hence a decrease in shear strength. The portion of the material in the built-up edge adjacent to the tool face is at a lower temperature and hence has a greater shear strength. The presence of the plastic deformation in the shearing process thus acts to allow the transfer of an unusually large quantity of metal from the chip to the tool face before the built-up edge produced becomes unstable and passes off with the chip.

In the field of metal cutting research, as in many other branches of physics and engineering, the use of radioactive materials provides a means for detecting changes of very small magnitude. This technique should prove particularly valuable in studies of the chemical reactivity of cutting fluids, the general nature of cutting fluid action, and in detecting very small rates of tool wear.

* The radioactive steel used in these experiments was irradiated at Oak Ridge under authorization of the United States AEC and was made available through the generosity of Professor J. T. Burwell, Jr. and the Chrysler Corporation.

The Potential Distribution in Pulsed Oxide-Coated Cathodes and Its Consequences for the Velocity Distribution of the Emitted Electrons

R. LOOSJES, H. J. VINK, AND C. G. J. JANSEN
Philips Research Laboratories, N. V. Philips' Gloeilampenfabrieken, Eindhoven, Netherlands
January 23, 1950

OUR investigations[1] concerning the total potential drop across a pulsed, activated oxide* coating of 25 micron thickness showed that a potential difference of e.g. 200 v at a current density of 10 amp./cm² at 827°C can exist.

Further investigations[2] by means of probe potential-measurements showed that, when using a rather pure nickel core containing a few tenths percent of different impurities, there was no appreciable interface potential difference and only a moderate potential drop of e.g. 6 v at 10 amp./cm² at 900°C across 85 microns of an oxide coating of 270 micron total thickness was set up during a pulse.

From these results it was concluded that, at least under the given circumstances, the potential distribution in a pulsed, activated oxide coating is of the form reproduced in Fig. 1. It was supposed that the rather steep potential drop near the surface could give rise to a spread of the electron velocities over tens or hundreds of volts, (a) because of electrons starting not only from points on the surface like *A*, but also emerging from points more inside the porous coating like *B*, or (b) because of all the electrons starting from points like *A*, while the potential at these points would be rather variable in connection with local variations in the properties of the surface layer of the coating. We therefore worked out a method for investigating the electron velocity distribution by means of electrostatic deflection.[3] Great care was taken not to lose any group of electrons especially those with the smaller velocities.

Preliminary results showed that the spread of the velocities of the electrons emitted from a pulsed, activated oxide-coated cathode is much greater than could be expected if the distribution

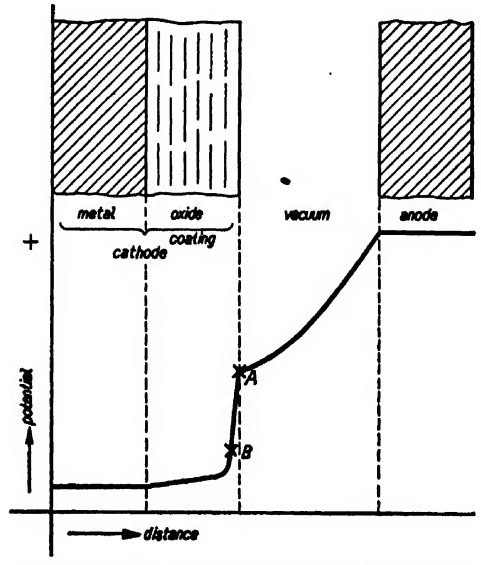

FIG. 1. Potential distribution in an oxide-coated cathode.

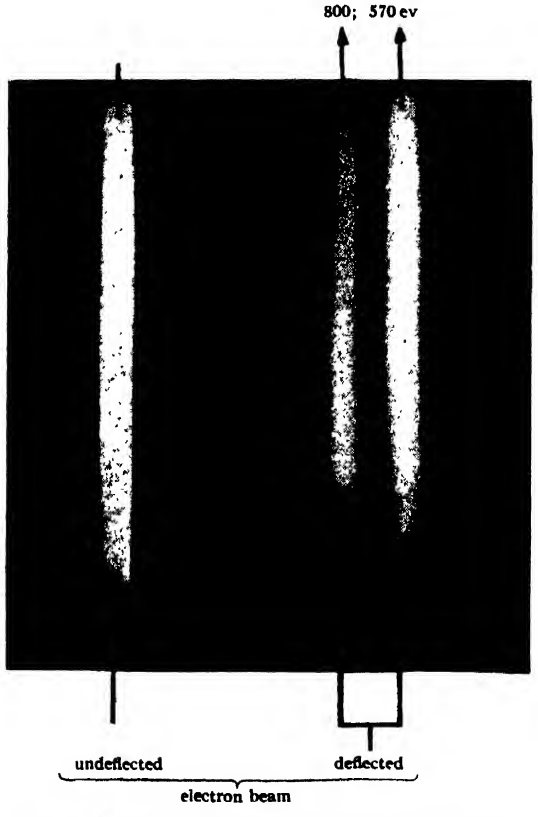

FIG. 2. Electron velocity spectrum of a pulsed oxide cathode. $V_a = 860$ v; $I_a = 14$ amp./cm²; $T = 942$°C.

were Maxwellian. Thus our working hypothesis was confirmed. For example, using square microsecond pulses of 10 amp./cm[2] at 850°C and an oxide coating of 60 micron thickness the energy difference between the fastest and the slowest electrons detectable was 140 ev, the fastest ones still having an energy 60 ev smaller than that which could be computed from the total cathode-anode potential difference.

From all our results it follows that whereas in our cathodes no interface resistance is detectable, a high resistance layer must exist near the surface of the coating. An explanation for this phenomenon might be (a) the fact that the surface is cooler than the bulk of the coating, (b) the fact that the composition of the surface layer is different from that of the bulk,[4] and/or (c) an exhaustion of the electrons in the surface pores by the emission, since according to our theory of the conduction[5] of the oxide coating these same electrons are mainly responsible for the conduction.

We do not think that our results are in contradiction with those of Eisenstein[6] found with a retarding field method.

Another, but unexpected result of our investigations into the electron velocity distribution was the fact that the distribution spectrum was in most cases found to be more or less concentrated in two and even three "lines" instead of being continuous (see Fig. 2). The reason for the occurrence of these "lines" is not yet clear. It might be that electrons are emitted mostly from the surface of the coating and from the "bottom" of the pores in the surface. In view of the high voltages involved even the possibility of emission of secondary electrons from places on the surface, like A, cannot be excluded.

At low temperatures, e.g. 700°C, the spread in the velocities disappears. This can be explained by the fact that with decreasing temperature the thermionic emission falls off more rapidly than the electronic conduction.[5]

* Composition: 52.5 percent by weight BaO, 47.5 percent by weight SrO.

A Sampling of 1949 Books

THE output of new scientific books during 1949 is indeed impressive both in number of books published and in their quality. It seems as though the exposition pent up during the war years is now gradually escaping, and as a result we have an up-to-the-minute survey or treatise in almost every branch of physics. The sampling presented here is a selection from the new books that have come across the Editor's desk during late 1948 and 1949, and is not in any sense a complete list. In each case a few comments are given which may assist the reader in deciding whether or not the book has further interest for him. For easy reference the books are classified as to subject matter.

MATHEMATICS AND MATHEMATICAL PHYSICS

Principles of Mathematical Physics

By WILLIAM V. HOUSTON (new second edition). Pp. 363+xii. McGraw-Hill Book Company, Inc., New York, 1948. Price $5.00.

The purpose of this text is to introduce the student to the more powerful methods of handling physical problems by giving him an opportunity to apply them to simple cases. Designed for intermediate courses, the book is intended to fill the gap between elementary courses in physics and more advanced courses on special subjects. The abundance of problem material forming an integral part of the text is again emphasized, in this second edition, as a principal teaching aid. The student is encouraged to develop the theory for himself by working out these problems, and is urged to depend as far as possible upon his own resourcefulness, insight, and ingenuity.

The chapters on electricity and magnetism have been expanded, and the m. k. s. system of units has been used throughout.

The Mathematical Analysis of Logic

By GEORGE BOOLE (reprinted). Pp. 82. Philosophical Library, New York, 1949. Price $3.75.

This is the first reprinting of a monograph published a century ago and now extremely rare. This short book is believed to have been the first to set on a scientific basis the mathematization of logic and thus prepare the way for the formal study of the foundations of pure mathematics itself.

Elementary Mathematics from an Advanced Standpoint, Vol. II—Geometry

By FELIX KLEIN. Translated from the German by E. R. Hedrick and C. A. Noble. Pp. 214+ix, Figs. 141. Dover Publications, New York, 1949. Price $2.95.

Unlike an ordinary textbook on geometry, this book is intended to give the instructor a comprehensive view of the whole field of geometry, help stimulate his own creative thinking on the subject, and provide him with a broader understanding which he will be able to apply profitably in the classroom, laboratory, or in general reading. The book is divided into three sections: the Simplest Geometric Manifolds, Geometric Transformations, and Systematic Discussion of Geometry and Its Foundations.

Proceedings of Symposia in Applied Mathematics

Pp. 219+vii. American Mathematical Society, New York, 1949. Price $5.25.

This book consists of a series of papers on non-linear problems in the mechanics of continua, including hydrodynamics, elasticity, and plasticity.

Problem Book in the Theory of Functions, Vol. I

By KONRAD KNOPP. Pp. 126. Dover Publications, New York, 1949. Price $1.85.

Used in conjunction with Professor Knopp's previously published *Theory of Functions*, this new English translation of the Problem Book provides the teacher and student with excellent aid in any first course of study covering the theory of functions of a complex variable. This book may also be used to supplement any other textbook in the field.

Introduction to the Theory of Fourier's Series and Integrals

By H. S. CARSLAW (third revised edition). Pp. 368+xiii, Figs. 39. Dover Publications, New York, 1949. Price $3.95.

In preparing this new printing of the third edition, the author has contributed a number of corrections noted since the last printing. This volume contains new tests for uniform convergence of series, a more thorough treatment of term by term integration and the Second Mean Value Theorem, enlarged sets of examples on Infinite Series and Integrals, a new section dealing with the Riemann-Lebesque theorem and its consequences, and a special treatment of the Lebesque definite integral which compares it with the classical Riemann integral.

Modern Operational Calculus

By N. W. MCLACHLAN. Pp. 218+xiv, Figs. 29. The Macmillan Company, New York, 1949. Price $5.00.

Integraltafel. Erster Teil: Unbestimmte Integrale

By WOLFGANG GRÖBNER AND NIKOLAUS HOFREITER. Pp. 166. Springer-Verlag, Vienna, 1949.

Introduction to Applied Mathematics

By FRANCIS D. MURNAGHAN. Pp. 389. John Wiley and Sons, Inc., New York, 1948. Price $5.00.

This is a detailed and self-contained study of the mathematics used in modern physics and engineering. The author gives a relatively full account of vector and matrix calculus, harmonic analysis, spherical harmonics, and Bessel functions. There is a thorough discussion of boundary value problems and integral equations, culminating in Rayleigh's principle; a treatment of mechanical problems by means of the calculation of variations; and a detailed explanation of operational calculus. The book is designed for graduate students and scientific workers with diversified interests.

Numerical Calculus

By WILLIAM EDMUND MILNE. Pp. 393+x. Princeton University Press, Princeton, 1949. Price $3.75.

This book is especially designed for the use of actuarial students, statisticians, applied mathematicians, and others who are forced to seek numerical solutions. It presupposes only a knowledge of the

essentials of algebra, analytical geometry, trigonometry, and elementary calculus. The object is practical, for while numerical calculus is based on the concepts of pure mathematics, it is recognized that the worker must produce a numerical result. This book would be a useful text for undergraduate courses in finite differences and methods of approximation.

Tables of Bessel Functions of Fractional Order, Vols. I and II

By Computation Laboratory of the National Bureau of Standards. Pp. 413 and 365. Columbia University Press, New York, 1948 and 1949. Price $7.50 and $10.00.

These volumes are a continuation of a series published by the Computation Laboratory of the National Bureau of Standards.

Vorträge über Determinanten und Matrizen mit Anwendungen in Physik und Technik

By Werner Schmeidler. Pp. 155. Akademie-Verlag, Berlin, 1949.

Tables of Inverse Hyperbolic Functions

By the Staff of the Computation Laboratory, Harvard University. Pp. 290. Harvard University Press, Cambridge, 1949. Price $10.00.

This is believed to be the first adequate presentation of tables of the inverse hyperbolic functions between the covers of a single volume. The inverse hyperbolic sine, cosine, and tangent are explicitly tabulated to nine decimal places. Differences are available to provide second-order interpolation to this accuracy, and the other inverse hyperbolic functions are readily obtainable. These tables will meet the growing demand in the fields of physics, statistics, engineering, and applied mathematics generally. The book contains the tables, an introduction to the method of calculation, and what is believed to be a complete bibliography of all existing tables of these functions, with critical notes on their range and reliability.

Tables of Generalized Sine- and Cosine-Integral Functions, Parts I and II

By the Staff of the Computation Laboratory, Harvard University. Pp. 462 and 560. Harvard University Press, Cambridge, 1949. Price $10 and $10.

The tables in these two volumes were computed by the automatic sequence controlled calculator, which was presented to Harvard University in 1944 by the International Business Machines Corporation. These tables, which are carried to six decimal places, are invaluable time-savers in the investigation of such questions as self- and mutual impedances, radiation resistance, and distribution of current in antennas and antenna arrays of various types.

Tables of the Bessel Functions of the First Kind of Orders 52 through 63

By the Staff of the Computation Laboratory, Harvard University. Pp. 544. Harvard University Press, Cambridge, 1949. Price $8.00.

Tables of Sines and Cosines to Fifteen Decimal Places at Hundredths of a Degree

By the Staff of the National Bureau of Standards. Pp. 95. Superintendent of Documents, Washington, 1949. Price $0.40.

Tables of Scattering Functions for Spherical Particles

By the Staff of the National Bureau of Standards. Pp. 119. Superintendent of Documents, Washington, 1949. Price $0.45.

The Slide Rule

By Lee H. Johnson. Pp. 242+x, Figs. 138. D. Van Nostrand Company, Inc., New York, 1949. Price $3.00.

This book presents a technique of operation for the Duplex slide rule which makes full use of its versatility and efficiency. A chapter on the Mannheim type is also included.

A Concise History of Mathematics, Vols. I and II

By Dirk J. Struik. Pp. 299+xviii (total), Figs. 49 (total). Dover Publications, New York, 1948. Price $1.50 per volume, $3.00 set.

The author has compressed the history of mathematics into two small volumes. He stresses the continuity and affinity of the Oriental civilizations rather than the mechanical divisions of Egyptian, Babylonian, Chinese, Indian, and Arabian. He is particularly careful to point out the distinctions between established facts, hypotheses, and tradition, especially in Greek mathematics.

Mathematics Dictionary

Glenn James and Robert C. James, editors (revised and enlarged edition). Pp. 432+v. D. Van Nostrand Company, Inc., New York, 1949. Price $7.50.

This dictionary has been designed as a reference work for students and for practicing physicists, chemists, engineers, and statisticians. To the coverage of terms included in the earlier version of the book there have now been added the basic terms in: metric differential geometry, theory of functions of real and complex variables; advanced calculus, differential equations, theory of groups, theory of matrices, theory of summability, point-set topology, analytic mechanics, theory of potential, and statistics. The appendix contains the tables most frequently referred to by mathematicians, physicists, chemists, engineers, and statisticians.

Regular Polytopes

By H. S. M. Coxeter. Pp. 321+xx. Pitman Publishing Corporation, New York, 1949. Price $10.00.

This book attempts to answer questions about the five regular solids. A knowledge of high school mathematics is all that is required for understanding it. There are excursions into such varied subjects as algebra, vector analysis, plane and spherical trigonometry, analytical geometry, integral calculus, crystallography, and topology.

Giant Brains, or Machines That Think

By Edmund C. Berkeley. Pp. 270+xvi. John Wiley and Sons, Inc., New York, 1949. Price $4.00.

Machines that calculate, make decisions, choose between different courses of action, determine most of their own instructions, machines that learn, remember, reason, machines, in other words, that seem almost to think—these machines are the subject of this book. The book describes several existing large-scale mechanical computers, but it is more than a purely descriptive work. Here computing machines are set in perspective; the reader can evaluate their importance to himself and to society. The author compares the machines with human brains and with various types of languages; he indicates their possibilities for the future and the problems of control to direct them toward the greatest good. More than 250 references to the literature are given.

Description of a Relay Calculator

By the Staff of the Computation Laboratory, Harvard University. Pp. 366+xvi. Harvard University Press, Cambridge, 1949. Price $8.00.

This is a description of the relay calculator formerly known as Mark II, that was built by the Computation Laboratory for the

Bureau of Ordnance of the United States Navy. The calculator is now in operation at the Naval Proving Ground, Dahlgren, Virginia. Tape-controlled and completely automatic, the calculator can handle numerical quantities consisting of ten significant digits within the range 10^{-16} to 10^{+16}. It is operated by timed electric impulses provided by a cam unit. All components are duplicated so that the machine may be operated as two independent calculators, solving two problems simultaneously, or as one calculator working on a single problem. The volume includes a complete description of the design and construction of the calculator, a manual of operation, and a discussion of problem preparation and solutions of typical examples. There are 36 plates and many figures illustrating details of construction and wiring.

MECHANICS

Principles of Mechanics

By John L. Synge and B. A. Griffith (second edition). Pp. 530+xvi, Figs. 164. McGraw-Hill Book Company, Inc., New York, 1949. Price $5.00.

This is the second edition of a well-known text in intermediate mechanics. Most readers will be delighted with the philosophical ideas expressed from time to time throughout the book. It concerns the usual chapters in statics, kinematics, dynamics, first considered in a plane and then in a space. Vector methods are used throughout. Three welcome chapters near the end of the book concern Lagrange's equation, special theory of relativity, and theory of dimensions.

Dynamic Principles of Mechanics

By David Rittenhouse Inglis. Pp. 174+x, Figs. 64. The Blakiston Company, Philadelphia, 1949. Price $4.00.

This text is intended for juniors and seniors. Many of the chapters are selected because they illustrate principles fundamental to the understanding of certain important parts of atomic and molecular physics and chemistry. Vector methods are used throughout eight chapters entitled Kinematics of a Particle, Dynamics of a Particle, Coupled Oscillators and Normal Coordinates, Inverse-Square Force and Planetary Motion, A Dynamical System of Several Particles, Statics, Rotation of a Rigid Body, and Impact.

Vectorial Mechanics

By E. A. Milne. Pp. 382+xiii, Figs. 112. Interscience Publishers, Inc., New York, 1948. Price $7.50.

Professor Milne's book is one for advanced students. In his words, he is expounding the view that vectorial mechanics is suitable not only for elegant proofs of general theorems but as a powerful weapon of workaday mathematical investigation, both in research and in solving problems of the type set in English examinations. There are chapters not only on vector analysis but also on tensors. The three main sections of the book deal with vector algebra, systems of line vectors, and dynamics.

Mechanics

By John W. Breneman (new second edition). Pp. 144+xi, Figs. 214. McGraw-Hill Book Company, Inc., New York, 1948. Price $2.50.

The subject covered in this book is usually referred to as engineering mechanics. The text is on a rather elementary level and considers fundamental principles, equilibrium, with examples in bridges and trusses, screws and threads, friction, centroids, curvilinear motion, with a final chapter on work, energy, and power. Helpful tables are provided in appendices concerning trigonometric functions, elements of sections, and so forth.

The Measurement of Stress and Strain in Solids

By the Institute of Physics (London). Pp. 114+x, Figs. 54. Institute of Physics, London, 1948.

This little volume was based on the proceedings of a conference arranged by the Manchester and District Branch of the Institute of Physics in July, 1946. Some of the papers read to the conference were intended to be survey papers, while others were more concerned with the details of the application of the various techniques to specific problems. Twelve papers are included in this book, including three survey papers on electrical resistance strain gauges, recent developments in photoelasticity, and other methods for measurement of strain, such as extensometers and the use of brittle lacquer coatings.

Reissner Anniversary Volume

Polytechnic Institute of Brooklyn, Department of Aeronautical Engineering and Applied Mechanics, editor. Pp. 493+viii. J. W. Edwards, Ann Arbor, Michigan, 1949. Price $6.50.

This volume consists of a collection of contributions to applied mechanics by the friends and former students of Hans J. Reissner on the occasion of his 75th birthday. In addition to the biographical sketch of Dr. Reissner, there are collections of papers in the fields of aerodynamics, dynamics, electricity, elasticity and structures, mathematical methods, plasticity, and propulsion. The reader will find represented in this list many of the great names in mathematical physics.

Elements of Strength of Materials

By S. Timoshenko and Gleason H. MacCullough (third edition). Pp. 426+ix, Figs. 386. D. Van Nostrand Company, Inc., New York, 1949. Price $5.00.

Whereas the original edition of this work presents both the elementary and advanced aspects of the subject, the present work is considerably abridged and is designed primarily for undergraduate courses in elementary strength of materials in engineering colleges.

Applied Mechanics and Statics

By George W. Housner and Donald E. Hudson. Pp. 220+ix. D. Van Nostrand Company, Inc., New York, 1949. Price $3.00.

This book has been prepared as a textbook for the use of sophomore engineering students. The emphasis is on fundamental principles, but the book is not to be considered as a treatise or reference book. The general topics treated are the composition and resolution of force systems, equilibrium, principles of virtual displacement, center of gravity, friction, statically determinant structures, and statically undeterminant structures, with an appendix containing a short bibliography and tables of centroids, moments, and products of inertia.

Mechanics, Statics, and Dynamics

By Merit Scott. Pp. 394+xi. McGraw-Hill Book Company, Inc., New York, 1949. Price $4.50.

The purpose of this text is to serve as a bridge between the first course in college physics and later studies making use of higher mathematics. It is intended also to serve as a reference book, and the initial chapters deal with vector notation and vector analysis. The book is divided into two sections, the first concerning statics and the second, dynamics. Motion is considered, first in one, then in two, and finally in three dimensions.

Elements of Mechanical Vibration

By C. R. Freberg and Emory N. Kemler (second edition). Pp. 227+xiii. John Wiley and Sons, Inc., New York, 1949. Price $3.75.

This is the second edition of the authors' text on mechanical vibration, which concerns primarily the more elementary phases of vibrations and attempts to reduce them to a form in which they can be applied to practical problems. The book is concerned particularly with those problems which can be solved by the use of the simpler forms of differential equations, approximation methods, or the mobility method. Some of the chapter headings are: Vibrations without Damping, Damped Vibrations, Vibration Isolation and Absorption, Equivalent Systems, Beams, Sound, The Mobility Method, and Mechanical and Electrical Models of Vibration Systems.

Mechanical Vibrations

By William Tyrrell Thomson. Pp. 222+viii, Figs. 212. Prentice-Hall, Inc., New York, 1948. Price $5.00.

This text is written primarily for class instruction and follows closely material presented in the course in mechanical vibrations offered to senior and graduate students at the University of Wisconsin. An elementary knowledge of calculus, dynamics, and strength of materials is presupposed, but not familiarity with differential equations. The chapters include: Undamped and Damped Free Vibrations, Forced Vibrations with One, Two, and Many Degrees of Freedom, Vibration of Elastic Bodies, and a chapter on Electromechanical Systems and Analogues.

Design of Machine Elements

By M. F. Spotts. Pp. 402. Prentice-Hall, Inc., New York, 1948. Price $6.65.

This book is intended as a two-semester text for third- and fourth-year engineering students. A brief review of strength of materials is given, in order to emphasize to the student the importance of certain fundamental rules. The chapters include stress concentration and repeated loading, theory of torsion, springs, screws, belts, brakes, clutches, welded and riveted connections, lubrication, ball and roller bearings, spur gears, helical, beveled, and worm gears, and a final very useful chapter on engineering materials.

Analysis and Lubrication of Bearings

By Milton C. Shaw and E. Fred Macks. Pp. 618+xvi. McGraw-Hill Book Company, Inc., New York, 1949. Price $10.00.

The purpose of this book is aptly indicated by a quotation in the preface by A. G. M. Mitchell: "To the machine designer, all bearings are, of course, only necessary evils. . . . Their merit consists in absorbing as little power as possible, wearing out as slowly as possible, occupying as little space as possible, and costing as little as possible." With this philosophy in mind, the general principles of bearing load are developed, and a number of representative examples are discussed. Dimensional analysis is introduced, and there are chapters devoted to hydrodynamic lubrication, rolling contact bearings, boundary lubrication, and a final chapter devoted to a discussion of a representative group of bearing test machines.

Computation Curves for Compressible Fluid Problems

By C. L. Dailey and F. C. Wood. Pp. 33+x, Figs. 33. John Wiley and Sons, Inc., New York, 1949. Price $2.00.

An Introduction to the Mechanics of Viscous Flow

By H. F. P. Purday. Pp. 185+vi, Figs. 79. Dover Publications, Inc., New York, 1949. Price $2.75.

This book is intended as a text to present for the student the application of modern fluid dynamics to problems of lubrication and heat transfer. The author's main object is to show by the simplest means how to calculate velocities, pressures, and boundary resistances arising in laminar fluid motion, and how to adapt the results to serve the theories of bearing lubrication and heat transfer. The book was published in England under the title, *Streamline Flow*.

Deformation and Flow - An Elementary Introduction to Theoretical Rheology

By Markus Reiner. Pp. 346+xix. Interscience Publishers, Inc., New York (U.S. agents), 1949. Price $6.50.

The author explains that this book does not attempt to cover the whole field of rheology. To material mainly of interest to the chemist there has been added other material which should interest the structural or mechanical engineer. The book emphasizes theory, but includes three numerical examples of the application of theory upon one problem each of viscosity, plasticity including strain-hardening, and creep. These were taken from experimental investigations.

The Physics of Rubber Elasticity

By L. R. G. Treloar. Pp. 254. Oxford University Press, New York, 1949. Price $6.00.

This is the fourth volume in a new series entitled "Monographs on the Physics and Chemistry of Materials." The series is intended to summarize the recent results of research in materials and allied subjects, in a form useful to physicists in university and industrial laboratories. The present volume attempts to set down as concisely as possible the essential advances in the study of the elasticity of rubber. The statistical or kinetic theory of elasticity is developed, and is shown to give a satisfactory account of the fundamental mechanical and photoelastic properties of rubber. The book also includes a discussion of the phenomena of crystallization, stress relaxation and flow, the dynamic properties of rubber, and the solution of engineering problems involving large elastic deformations.

Plasticity as a Factor in the Design of Dense Bituminous Road Carpets

By L. W. Nijboer. Pp. 184+xv, Figs. 51. Elsevier Publishing Company, Inc., New York, 1948. Price $5.25.

The importance of a thorough knowledge of the mechanical properties of bituminous road materials is pointed out, and a study is made of the plastic properties of this material. A new test method is developed on the principles of soil mechanics.

HEAT AND THE THEORY OF GASES

Introduction to Statistical Mechanics

By Ronald W. Gurney. Pp. 268+vii, Figs. 59. McGraw-Hill Book Company, Inc., New York, 1949. Price $5.00.

This is an advanced text for graduate students of physics and chemistry. Against a background of atomic physics, the book studies the behavior of large groups of particles, showing how the behavior of matter in bulk follows directly from the properties of the individual atoms. The author has devised methods whereby the student is enabled to grasp the basic principles and the nature of partition functions. A feature of the book is the treatment of metallic alloys, especially the solutions in the alpha- and gamma-phases of iron which form the basis of steel metallurgy. Problems appear at the end of each chapter.

Mathematical Foundations of Statistical Mechanics

By A. I. Khinchin. Translated from the Russian by G. Gamow. Pp. 179+viii. Dover Publications, New York, 1949. Price $2.95.

This book is a mathematical treatment of statistical mechanics on the basis of modern concepts of the theory of probability and a

maximum utilization of its analytical apparatus. The book is written for the mathematician, and its purpose is to introduce him to the problems of statistical mechanics in an atmosphere of logical precision. Among the topics treated in a somewhat novel fashion are the ergodic problems, properties of entropy, and intramolecular correlation.

Scientific Foundations of Vacuum Technique

By Saul Dushman. Pp. 882+xi. John Wiley and Sons, Inc., New York, 1949. Price $15.00.

This book is a broad study of all phases of achieving, maintaining, and measuring very low gas pressures. In the author's words, it presents a survey of "fundamental ideas in physics, chemistry, and (to a smaller extent) metallurgy which will be found useful to both scientists and engineers in dealing with problems in the production and measurement of high vacua."

Vacuum Equipment and Techniques

A. Guthrie and R. K. Wakerling, editors. Pp. 264+xvii. McGraw-Hill Book Company, Inc., New York, 1949. Price $2.50.

This book is concerned with the development and study of high vacuum equipment by the personnel of the University of California Radiation Laboratory for use in electromagnetic separation plants. The problems involved were of a magnitude which made it necessary to do a considerable amount of pioneering work on both equipment and testing. One topic of particular interest is the use of the vacuum analyzer and helium leak detector which were developed for use in the project and proved to be very sensitive instruments.

Glass-to-Metal Seals

By J. H. Partridge. Pp. 238+xii, Figs. 167. The Society of Glass Technology, Sheffield, England, 1949. Price £1 15s. 0d, plus 6d. postage.

This book brings together scattered data about glasses, metals, metal oxides, and the techniques employed in making glass-to-metal seals. It also includes a chapter on the sealing of ceramic materials to metals. The sealing of different glasses to one another and of glasses to ceramic materials are described. The problems of the stresses in the seals and the variation of those stresses when the devices embodying them are in service are also thoroughly examined.

Vacuum Manipulation of Volatile Compounds

By R. T. Sanderson. Pp. 162+viii, Figs. 40. John Wiley and Sons, Inc., New York, 1948. Price $3.00.

This book brings together, in a form designed for easy reference, all the varied essentials which make up the chemical vacuum technique. Through the book this technique becomes readily accessible to the investigator who has no more than the ordinary chemical background. The reader is given a firm foundation for working with high vacuum apparatus and is supplied with all the data necessary for the construction and operation of such apparatus. The book includes vapor pressures, at the same easily producible low temperatures, of almost 400 of the many pure compounds which can conveniently be studied by use of the described manipulative techniques.

A Textbook of Heat

By L. D. Weld. Pp. 436. The Macmillan Company, New York, 1948. Price $5.00.

This is an up-to-date textbook of heat and elementary thermodynamics for upperclassmen. The aim has been to keep the treatment well within the comprehension of students familiar with differential and integral calculus. A carefully selected list of references for supplementary reading is given at the end of each chapter.

Engineering Developments in the Gaseous Diffusion Process

By Manson Benedict and Clarke Williams. Pp. 127+xx. McGraw-Hill Book Company, Inc., New York, 1949. Price $1.25.

This volume describes some of the new engineering procedures and devices developed in connection with the design and construction of gas diffusion plants for separation of uranium isotopes. Topics treated include: special plant instruments and devices including the mass spectrometer for continuous analysis of gas mixtures flowing through a plant, and a recording ionization chamber for detecting traces of radioactive components in a gas mixture; mass spectrometer and engineering methods for testing vacuum-tight systems; engineering processes for handling fluorine and heat transfer ideas applicable to the freezing of liquids.

Heat Transfer

By Max Jakob. Pp. 758+xxix. John Wiley and Sons, Inc. New York, 1949. Price $12.00.

This is a comprehensive work suitable both as a reference work and as a textbook. It shows the development of the ideas which have led to the present knowledge of the subject. The book is international in scope, with particularly thorough coverage of German literature, and should serve the needs of mechanical, chemical, electrical, and civil engineers, and physicists alike.

Third Symposium on Combustion and Flame and Explosion Phenomena

By the Standing Committee on Combustion Symposia. Pp. 748+xiii. The Williams and Wilkins Company, Baltimore, Maryland, 1949. Price $13.50.

This volume contains 100 papers, arranged under eleven categories, which were presented at the Symposium held at the University of Wisconsin in September, 1948. Thirty-eight of the papers were received from European countries.

Steam Power Plants

By Philip J. Potter. Pp. 503+xii. The Ronald Press Company, New York, 1949. Price $6.50.

The aim of this textbook is to present the fundamentals of engineering as applied to the design of steam power plants. No attempt has been made to illustrate all of the various designs of equipment that are available on the market nor to compare similar designs of competitor manufacturers. Descriptions of equipment have been kept to a minimum, and discussions of empirically designed apparatus—such as coal and ash handling systems—have been omitted. Problems and examples have been taken from practical situations to illustrate the principles developed throughout the text.

Thermodynamic Charts for Combustion Processes. Part I Text; Part II Charts

By H. C. Hottel, G. C. Williams, and C. N. Satterfield. Pp. 75, Charts 23. John Wiley and Sons, Inc., New York, 1949. Price $2.60 and $2.40.

ACOUSTICS

Acoustic Measurements

By Leo L. Beranek, Pp. 914+vii. John Wiley and Sons, Inc., New York, 1949. Price $7.00.

In addition to an exposition of acoustic measuring techniques, this book combines data published for the first time with information previously found only in isolated publications. Topics

range from the calibration of microphones and loudspeakers to evaluation of over-all audio systems, and to chapters on the audiometer, speech articulation tests and the sound level meter. The book presents the source of the theory of many electroacoustic phenomena, a description in detail of the basic types of acoustic measuring devices, such as microphones, sources, acoustic impedance bridges and analyzers, and a discussion of the relative advantages and disadvantages of alternate methods for accomplishing electroacoustic measurements.

Sound Absorbing Materials

By C. Zwikker and C. W. Kosten. Pp. 174+ix, Figs. 92. Elsevier Publishing Company, Inc., New York, 1949. Price $3.00.

This book examines the properties that impart sound absorbing qualities to materials or composites, describes their theoretical and experimental study, and shows how these qualities can be conferred upon structures and how they can in many cases be predicted for given surfaces. This latter can be done from mechanical factors such as porosity, compliance, air-resistance, shape, etc. The authors stress the importance of acoustic impedance, which can with advantage be expressed and studied graphically by means of impedance contours. The acoustic behavior of a wide range of materials is discussed and explained.

Theory of Hearing

By Ernest Glen Wever. Pp. 484+xiii, Figs. 136. John Wiley and Sons, Inc., New York, 1949. Price $6.00.

This book is a result of the electrophysiological investigation of the ear's behavior, an investigation begun in 1930 by the author and C. W. Bray and now being carried out actively in many laboratories. The book reviews the development of auditory theory from earliest times and attempts an impartial presentation of all the classical theories of importance. It takes up the principal forms of these theories and brings them face to face with the modern facts about the ear and its actions. It also presents a new point of view in which the two main types of theory—the place and frequency theories—are fused into one and then evaluated with respect to the facts of hearing.

Elements of Sound Recording

By John G. Frayne and Halley Wolfe. Pp. 686+vii, Figs. 480. John Wiley and Sons, Inc., New York, 1949. Price $8.50.

This book covers in detail those subjects which belong peculiarly to the restricted field of sound recording and reproducing and which are not discussed in books devoted to the allied fields of electronics, radio engineering, etc. However, since those interested in studying sound recording have widely different kinds of training and experience, some closely related subjects such as electrochemical analogies, acoustics, vacuum tubes, and audio amplifiers are discussed briefly. For added clarity, numerical examples are used in a number of instances to illustrate the use of design formulas. Complex mathematical analysis is limited to those subjects in which it is desirable for a basic understanding of the point under discussion. The topics covered range from the nature of sound to stereophonic recording.

Installation and Servicing of Low Power Public Address Systems

By John F. Rider. Pp. 208. John F. Rider Publisher, Inc., New York, 1948. Price $1.89.

Inasmuch as the majority of public address installations are those requiring low power equipment—from both an acoustical and economic viewpoint—the apparatus discussed in this book in the main is confined to a rating of 50 watts or lower. Yet a great amount of the subject matter applies equally well to systems of higher power. The book opens with a discussion of the fundamentals of sound and the problems encountered in the public address field; this is followed by an explanation of microphones, phonograph pick-ups, and radio receivers as inputs to an amplifier, then the various types of audio amplifiers, with a chapter devoted to impedance matching.

ELECTROMAGNETIC WAVES AND ELECTRONICS

Principles of Electricity and Electromagnetism

By G. P. Harnwell. Pp. 670+xvi. McGraw-Hill Book Company, Inc., New York, 1949. Price $6.00.

This is a thorough revision of a well-known text for advanced students, and incorporates many important developments in electricity during the past decade. The emphasis is on the phenomena rather than the application of mathematical techniques to particular soluble problems. Increased attention is accorded to the application of the principles of electricity and magnetism to atomic phenomena. Sections have been added on ultra-high frequency techniques, especially those which represent important extensions of the field as covered in the previous edition. No effort has been made to cover the field of radar, but the basic techniques involved are specifically described in this edition. Discussions of wave guides, resonant cavities, and other new topics are included.

Principles of Electricity

By Leigh Page and Norman I. Adams, Jr. (second edition). Pp. 619+xiii, Figs. 323. D. Van Nostrand Company, Inc., New York, 1949. Price $5.50.

This second edition has been brought up to date by the addition of new topics such as the cyclotron, the betatron, and the wave guide, and by the omission of a few topics of diminishing interest. The Gaussian system of units has been employed throughout the book.

Elektrizitätslehre

By R. W. Pohl. Pp. 297. Springer-Verlag, Berlin, 1949.

The Extrapolation, Interpolation, and Smoothing of Stationary Time Series with Engineering Applications

By Norbert Wiener. Pp. 163+ix. John Wiley and Sons, Inc., New York, 1949. Price $4.00.

This book represents an attempt to unite the theory and practice of two important fields of work—time series in statistics, and communication engineering. These fields are widely different in vocabulary and in the training of personnel, and they have drawn their inspiration from two entirely distinct traditions. However, it is believed that they have a unification of theory and method. The author points out that the statistician is completely familiar with methods involving probability theory and correlation, but unable to use the engineer's methods; the communication engineer is just as familiar with the use of the complex plane, but unable to use the statistician's techniques. It is the purpose of this book to introduce methods stemming from both of these existing techniques and to fuse them into a common technique which is more effective than either one alone.

Electric and Magnetic Fields

By Stephen S. Attwood (third edition). Pp. 475+xi. John Wiley and Sons, Inc., New York, 1949. Price $5.50.

This book was written to provide a smooth transition from the study of mathematics, mechanics, and physics to advanced, professional-level electrical engineering. The author has divided this new edition into four parts. The electric field is discussed first. Next the magnetic field is treated and the field formulas are devel-

oped under the assumption of constant permeability. In the third part the ferromagnetic field introduces the modification of the basic magnetic relations necessary to account for the use of magnetic material in which permeability cannot be considered constant. The fourth section treats in an elementary manner the interactions between electric and magnetic fields that simultaneously occupy the same space. The formulas in the book have been recast in the rationalized form of the m.k.s. system.

Basic Electrical Engineering

By George F. Corcoran. Pp. 449+vii. John Wiley and Sons, Inc., New York, 1949. Price $4.50.

This is a textbook of electrical engineering which maintains throughout a level suitable for beginners. Each electrical or magnetic concept is exactly defined at the place of its introduction. Arrangement of subject matter is likewise planned to suit the beginning course. First d.c. theory is considered, with d.c. circuit analysis by the mesh and nodal methods. This is followed by electrical field theory, magnetic field theory, inductance, capacitance, and non-linear circuit elements. There is a wide range of problems with each chapter.

Electronics in Engineering

By W. Ryland Hill. Pp. 274+viii. McGraw-Hill Book Company, Inc., New York, 1949. Price $3.50.

This text is designed for senior and graduate students in engineering and allied sciences who find the need for an understanding of electronics and its applications to measurement and control in their respective fields. The treatment is sufficiently analytical to interest such students, and yet contains enough practical applications to illustrate the uses of electronics to the various engineering fields. The book provides material for a one-quarter or one-semester course covering vacuum and gas-filled tubes, rectification, amplification, feedback, the cathode-ray oscilloscope, and simple control and instrumentation techniques.

Electrical Engineers' Handbook; Electric Power. Vol. I

Harold Pender and William A. Del Mar, editors (fourth edition). Pp. 1700+xii. John Wiley and Sons, Inc., New York, 1949. Price $8.50.

The editors point out that the growth of knowledge and the greater degree of specialization in the various phases of electrical engineering have necessitated a considerable enlargement of this well-known handbook. An effort has been made to keep the book compact and readable.

Learning Electricity and Electronics Experimentally

By Leonard R. Crow. Pp. 525+xi. Universal Scientific Company, Vincennes, Indiana, 1949.

The author of this book aims to use the experimental or project approach to the subject of electricity, employing the simplest possible language. Some of the specific points treated in the book are energy and electrical effects, magnetism and electromagnetism, electromagnetic induction, magnetic flux control, rotating magnetic fields, current control by magnetic saturation.

Theory of Oscillations

By A. A. Andronow and C. E. Chaikin. Pp. 358+ix, Figs. 313. Princeton University Press, Princeton, 1949. Price $6.00.

This is a condensed and edited translation of the first comprehensive treatment of non-linear oscillations ever to be published. The original work, by two leading members of the Soviet Institute of Oscillations, was published in Russian in 1937. Since the field of non-linear oscillations is not as well known as it deserves to be, numerous examples are given, and a special index of physical examples is included. Practical applications are emphasized, and the examples given in the original Russian edition are preserved. The book begins with a treatment of linear systems, giving the newcomer to the field familiar ground from which to work, but it rapidly progresses to various types of non-linear systems, using both mechanical and electrical examples. The book will be useful to electrical, aeronautical, and mechanical engineers, to mathematicians and physicists, and to any scientists working with oscillatory phenomena.

Micro-Waves and Wave Guides

By H. M. Barlow. Pp. 122+x, Figs. 70. Dover Publications, New York, 1949. Price $1.95.

The first part of this volume presents a physical picture of wave-guide modes, synthesized from constituent plane waves in association with ordinary transmission line elements. The coaxial cable, representing the common meeting ground of wave-guide modes and the simple transverse electromagnetic wave, is discussed. The final section deals with the measurements and applications of microwaves, giving the reader an appreciation and knowledge of the methods adopted in actual practice.

Radar Systems and Components

By the Technical Staff of Bell Telephone Laboratories. Pp. 1042+xiv. D. Van Nostrand Company, Inc., New York, 1949. Price $7.50.

About one-half of Bell Telephone Laboratories' total research effort during the war was devoted to radar. The Laboratories shared with the Radiation Laboratory at Massachusetts Institute of Technology the responsibility for the bulk of research and development in this field in the United States. In order that the scientific advances achieved might be recorded in detail (so far as security considerations would permit), the papers appearing in this volume were prepared and were originally published in the *Bell System Technical Journal*. While the work described was directed toward radar development as its immediate objective, it has a broad application to the new field of microwave transmission.

Aerials for Metre and Decimetre Wavelengths

By R. A. Smith. Pp. 218+xii, Figs. 125. Cambridge University Press, New York, 1949. Price $3.75.

The author of this book points out that the extension of radio technique to extremely short wave-lengths greatly increased the scope of aerial design. Half-wave and full-wave dipoles have manageable dimensions when the wave-length is less than 12 meters, and arrays for many special purposes may be designed. In this book the upper limit has been set at 12 meters, the longest wavelength used for radar. The lower limit has been fixed at 10 cm. A limited number of applications have been selected to illustrate general principles.

Electrical Transmission of Power and Signals

By Edward W. Kimbark. Pp. 461+xi. John Wiley and Sons, Inc., New York, 1949. Price $6.00.

This is the first textbook to apply transmission-line theory to all three fields of power, telephone, and ultra-high frequency transmission. It contains transmission-line (hyperbolic function) charts, tables and graphs of the characteristics of power-line conductors, power transmission and distribution lines, telephone lines and cables, submarine telegraph cables, and radiofrequency lines. This volume is a useful reference book for professional engineers and will be found of value in electrical transmission courses.

Elements of Electromagnetic Waves

By Lawrence A. Ware. Pp. 203+x. Pitman Publishing Corporation, New York, 1949. Price $3.50.

This text was prepared to meet the need for an elementary introduction to the basic ideas of electromagnetic theory, employ-

ing the rationalized m.k.s. units. It is intended as first-course material for either juniors or seniors, and the only prerequisites are calculus and the fundamentals of alternating-current theory. The text is prepared to serve as an introduction to the more advanced treatments of the subject.

Radio-Frequency Heating Equipment

By L. L. Langton. Pp. 196+ix, Figs. 95. Pitman Publishing Corporation, New York, 1949. Price $3.75.

This book deals with the design of equipment for radiofrequency heating, and also with some applications of the technique. The reasons underlying the advantages gained by using the technique in these applications are fully discussed; this serves as a guide to the advantages to be expected when the technique is applied elsewhere.

Terrestrial Radio Waves; Theory of Propagation

By H. Bremmer. Pp. 343+x, Figs. 91. Elsevier Publishing Company, Inc., New York, 1949. Price $6.75.

This book describes the mathematical methods by which the electromagnetic field of a radio transmitter can be computed, taking into account the curvature of the earth's surface. Special attention is paid to the physical interpretation of the mathematical deductions. The complicated formulas which are basic for numerical computations of the "ground-wave" have been collected in a practical form in a separate chapter.

Earth Conduction Effects in Transmission Systems

By Erling D. Sunde. Pp. 373+xiii. D. Van Nostrand Company, Inc., New York, 1949. Price $6.00.

This presentation is primarily concerned with fundamental methods in the analysis of earth conduction effects and basic principles underlying protective measures against resultant circuit disturbances. For conciseness and better exposition of basic formulas and considerations, much of the mathematical detail has been omitted in most derivations or covered by reference to other literature.

The Mathematics of Circuit Analysis

By Ernest A. Guillemin. Pp. 590+xiv. John Wiley and Sons, Inc., New York, 1949. Price $7.50.

This volume contains a collection of a variety of principles and methods essential to a thorough understanding of electrical network theory. It is designed specifically as a source book to supplement the usual undergraduate engineering mathematics curriculum. It is appropriate also for use as a textbook in a course in higher mathematics for engineers.

Communication Circuits

By Lawrence A. Ware and Henry R. Reed (third edition). Pp. 403+x. John Wiley and Sons, Inc., New York, 1949. Price $5.00.

In this third edition the authors cover the essentials of the transmission and lead logically to such subjects as filters, impedance matching, and wave guides. Features of this edition include the use of rationalized m.k.s. system of units; a radical revision of the chapter on transmission-line parameters; a treatment of attenuation in wave guides based on Poynting's theorem; the addition of many new problems. Although a knowledge of calculus and the elements of a.c. theory has been assumed, the more advanced mathematics that is needed for certain portions has been included in the appendices.

Pulses and Transients in Communication Circuits

By Colin Cherry. Pp. 317+xvi, Figs. 129. Chapman and Hall, Ltd., London, 1949. Price 32s. net.

This book is meant as an introduction to circuit transient analysis for communications engineers, which will bridge the gap between simple conventional alternating current theory and operational methods of analysis. It is intended to give students of steady-state circuit theory the essential groundwork, using, wherever possible, rigorous physical arguments and only elementary mathematics. Mathematical language and notation are avoided as much as possible. Electrical wave forms are dealt with, rather than analytical functions, thus giving the book a geometrical flavor.

Networks, Lines and Fields

By John D. Ryder. Pp. 462+x, Figs. 195. Prentice-Hall, Inc., New York, 1949. Price $5.50.

In this text the author has attempted to expand upon the subjects of networks, resonance, and wave filters in such a way as to develop in the undergraduate student a definite familiarity with "network theory," or the description of network performance by certain measured or defined parameters. The rationalized m.k.s. system of units is used throughout.

Radio Engineering

By E. K. Sandeman. Pp. 775+xxiv. John Wiley and Sons, Inc., New York, 1948. Price $6.50.

Originally planned as instructions for maintenance engineers at B.B.C. transmitting stations, this book is designed to give beginners in radio the working principles they need. Experienced engineers and designers of radio equipment and circuits will find it a useful reference volume. Practical ends are stressed, either in the form of technical facts, designs, or methods or else in the form of essential formulas.

Electric Circuits and Machines

By B. L. Robertson and L. J. Black. Pp. 434+vii. D. Van Nostrand Company, Inc., New York, 1949. Price $5.00.

This is a textbook intended primarily for third-year students of mechanical engineering, or for non-electricals in general, to give them a strong minor in electrical engineering.

Radio at Ultra-High Frequencies, Vol. II

By Alfred N. Goldsmith *et al.*, editors. Pp. 485. RCA Review, RCA Laboratories Division, Princeton, New Jersey, 1948. Price $2.50.

This is the eighth volume in the RCA Technical Book Series and the second on the general subject of radio at the higher frequencies. The present volume covers the period 1940–47. Papers are presented in seven sections: antennas and transmission lines; propagation; reception; radio relays; microwaves; measurements and components; navigational aids. The appendices include a bibliography in the field of ultra-high frequency radio, and summaries of all papers appearing in Vol. I, which is now out of print.

Electrical Measurements in Theory and Application

By Arthur Whitmore Smith. Pp. 371, Figs. 250. McGraw-Hill Book Company, Inc., New York, 1948. Price $4.25.

This is a thorough revision and modernization of a well-known standard text, incorporating many changes to clarify the explanations and present improved methods. The meter-kilogram-second (m.k.s.) system has been used for the definitions of the units of the electrical and magnetic quantities, resulting in great simplification of the approach to these definitions. Several new measurement methods have been added, especially for the measurement of capacitance and inductance.

Advances in Electronics, Vol. I

L. MARTON, editor. Pp. 475+xi. Academic Press, Inc., New York, 1949. Price $9.00.

This volume is the first of a series of yearly publications devoted to articles in the general field of electronics. The aim is to publish critical and integrated reviews on physical and engineering electronics. The editors and publishers of the book were obliged to use a somewhat arbitrary definition of the word "electronics," and thus limit the choice of materials to a reasonably restricted field. In this volume the topics covered are: oxide-coated cathodes, secondary electron emission, television pick-up tubes and the problem of vision, the deflection of beams of charged particles, modern mass spectroscopy, particle accelerators, ionospheric research, cosmic radio noise, propagation in the f-m broadcast band, electronic aids to navigation.

Electronics: Experimental Techniques

BY W. C. ELMORE AND MATTHEW L. SANDS. Pp. 417+xviii. McGraw-Hill Book Company, Inc., New York, 1949. Price $3.75.

This volume describes the most useful and the most successful circuits for making nuclear and other physical measurements. In addition to the description of complete circuits—pulse amplifiers, counting circuits, sweep circuits, timing circuits, testing equipment, etc.—the book contains a discussion of the circuit elements that constitute the basis of the complete circuits.

Theory and Design of Electron Beams

BY J. R. PIERCE. Pp. 197+xiii. D. Van Nostrand Company, Inc., New York, 1949. Price $3.50.

This book represents an effort to collect the minimum amount of theoretical material necessary for a good understanding of electron flow and electron focusing in devices other than electron microscopes and image tubes. Much of the elementary material found in books on electron optics is included. There is, however, no extensive treatment of aberrations. Instead, there is considerable emphasis and material on space charge and thermal velocities. Problems are included, partly so that the book can be used as a text, but more so that "the reader will have to do things for himself in order to understand them."

Fundamentals of Radio-Valve Technique

BY J. DEKETH. Pp. 535+xxii, Figs. 384. N. V. Philips' Gloeilampenfabrieken, Eindhoven, The Netherlands, 1949. Price $5.00.

In this book the author aims at giving technicians and research workers an account which will be of value to those who make, use, or maintain apparatus employing electronic valves. The mathematical treatment is restricted, and the subjects treated include resonance, short-wave technique, and low frequency modulation.

Microwaves and Radar Electronics

BY ERNEST C. POLLARD AND JULIAN M. STURTEVANT. Pp. 426+vii. John Wiley and Sons, Inc., New York, 1948. Price $5.00.

No extensive background in communications or electronics is required for use of this book. The usual student background in physics, chemistry, and electrical engineering is sufficient. The essential facts about microwave circuits are developed on the fundamental basis of electricity and magnetism, rather than from an extension of the theory of circuits with lumped parameters. Pulse circuits are considered as a unified subject, since the fundamental problems and basic methods of solving such problems accompany all types of pulse circuits. Much attention has been devoted to the applications of microwave and radar electronic techniques which have been considered in various scientific periodicals since the end of the war.

Industrial Electronics Reference Book

BY ELECTRONICS ENGINEERS OF THE WESTINGHOUSE ELECTRIC CORPORATION. Pp. 680. John Wiley and Sons, Inc., New York, 1948. Price $7.50.

This reference book presents the basic theory and the vital application principles of industrial electronics. It is intended to help the reader to appraise accurately the possibilities as well as the limitations of new electronic devices, and also to help technicians to develop new applications and projects which will have a better chance of giving the desired results. The authors deal mostly with basic electronics application information and treat the specific apparatus less fully because of the many changes still taking place. The generous use of illustrations in the volume helps to elucidate every phase of the text material.

The Characteristics of Electrical Discharges in Magnetic Fields

A. GUTHRIE AND R. K. WAKERLING, editors. Pp. 376+xviii. McGraw-Hill Book Company, Inc., New York, 1949. Price $3.50.

This volume was prepared in an effort to collect the results of studies carried out in the California Radiation Laboratory on the characteristics of electrical discharges in magnetic fields. The primary emphasis is placed on the case of electrical discharges in the vapors of uranium compounds. The book does not cover all of the investigations, although the most significant studies are included. More than half of this book is devoted to work carried out by members of a British scientific mission.

Basic Electronics

BY ROYCE G. KLOEFFLER AND MAURICE W. HORRELL. Pp. 435+xiv. John Wiley and Sons, Inc., New York, 1949. Price $5.00.

The authors cover the fundamental theory of electronics in condensed form, assuming the reader has a knowledge of elementary physics, but no previous training in electronics. The authors' approach covers both the power and communication fields. Included among the subjects discussed are the developments of the transistor and mechano-electronic transducer. As a convenience to the reader, the authors have included curves and data of the basic tubes. This means that most of the problems can be solved without referring to any of the tube handbooks.

Photoelectricity and Its Application

BY V. K. ZWORYKIN AND E. G. RAMBERG. Pp. 494+xii. John Wiley and Sons, Inc., New York, 1949. Price $7.50.

This volume replaces the second edition of *Photocells and Their Application* by V. K. Zworykin and E. D. Wilson. It retains the aim of its predecessor—to present the reader with practical reliable data on the properties, preparation, and applications fo photoelectric devices. Throughout, the emphasis is on practical aspects.

Theory of Dielectrics

BY H. FRÖHLICH. Pp. 180+vi, Figs. 47. Oxford University Press, New York, 1949. Price $4.50.

This book, which is mainly written for applied scientists, is intended to give a systematic account of the theory of dielectric properties, and thus to provide a background against which applications can be made. The reader is assumed to have a certain ele-

mentary knowledge of atomic and molecular physics, statistical mechanics, electrostatics, and little mathematics beyond the calculus.

Atmospheric Electricity

By J. Alan Chalmers. Pp. 175, Figs. 36. Oxford University Press, New York, 1949. Price $3.75.

This book is intended to serve both as an introduction to the study of atmospheric electricity and as a short work of reference. It was written primarily for physicists but should prove useful to meteorologists and others interested in the subject. There are chapters on the ions in the atmosphere, the earth's vertical field, the conductivity of the air, the year-around current, point discharge currents, precipitation currents, the transfer of charge, the thunder cloud, the lightning flash, and the separation of charge.

TV Picture Projection and Enlargement

By Allan Lytel. Pp. 179+xi. John F. Rider Publisher, Inc., New York, 1949. Price $3.30.

This book, with its numerous illustrations, will appeal to those interested in television servicing. The author discusses the fundamentals of light, the Schmidt projection system, and refractive projection systems.

Understanding Television

By Orrin E. Dunlap, Jr. Pp. 128. Greenberg, Publisher, New York, 1948. Price $2.50.

This little book discusses the steps that led to television, the mechanisms which match the human eye, the necessity for high antennas and relay stations, the coaxial cable, and the receiver itself. The author describes how a television program is put together, both in the studio and in the field.

OPTICS AND SPECTROSCOPY

Introduction to Theoretical and Experimental Optics

By Joseph Valasek. Pp. 454+x. John Wiley and Sons, Inc., New York, 1949. Price $6.50.

This is a four-part book, covering geometrical optics, physical optics, radiation and spectra, and experiments relating to each of these fields. In line with the author's special interests, the subjects of x-rays, photographic optics, and ophthalmic lenses are treated in greater detail than is customary in books dealing with optics. This book holds useful information for many engineers and physicists working in industry and in research laboratories. It serves as an introduction to optical engineering, a field which is steadily growing more important. For example, students of photography, mechanical engineers who use optical methods of stress analysis, and optical mineralogists all can use the principles of optics contained in this book. Although the author assumes the reader has a knowledge of calculus and general physics, he keeps the mathematical treatment as elementary as possible.

Optik

By R. W. Pohl. Pp. 356, Figs. 565. Springer-Verlag, Berlin, 1948.

Physical Aspects of Color

By P. J. Bouma. Pp. 312, Figs. 113. Elsevier Publishing Company, Inc., New York, 1947. Price $5.50.

The physiologist, the psychologist, the physicist, the illumination engineer, and the chemist each has studied the problem of color perception from his own point of view and expressed the results in his own particular technical language. The author of this book has aimed to cast the subject matter in such a form that it may well enrich the knowledge of many a scientist and at the same time serve as a guide to the beginner—presumed to possess a secondary school knowledge of mathematics and physics—for the study of problems of chromatics. Starting from the established laws of color mixing, the author gives a complete insight into the origin and perception of colors in a logical and systematic manner.

Elementary Photography

By Guilford G. Quarles (new second edition). Pp. 345+xii, Figs. 86. McGraw-Hill Book Company, Inc., New York, 1949. Price $4.50.

As before, this text provides a treatment of photography between very elementary ones and those of an advanced, technical nature. The book assumes no previous knowledge of the subject, and an effort has been exerted to make the new edition even more easily understandable to the student and more teachable from the point of view of the instructor. A major revision of the order of the chapters has been made in order to bring the student as quickly as possible to active photography—i.e., the making of pictures.

Die Optik in der Feinmehtechnik

By Kurt Räntsch. Pp. 317, Figs. 299. Carl Hanser-Verlag, Munich, 1949.

Photographic Optics

By Arthur Cox. Pp. 412+xi. Pitman Publishing Corporation, New York, 1949. Price $5.75.

The subtitle of this book is "The Technique of Definition." The photographer should be able to discriminate between lenses in the same way he does between films and filters. This practical book, written in simple language and containing many diagrams and tables, deals with the importance of lenses in obtaining the best results with the camera, and shows how the proper type of lens must be used in the right kind of camera for each kind of subject. The photographer is shown why the correct focal length, best aperture, and sufficient covering power are considerations that eventually decide the picture.

Spectroscopic Properties of Uranium Compounds

By G. H. Dieke and A. B. F. Duncan. Pp. 290+xviii. McGraw-Hill Book Company, Inc., New York, 1949. Price $2.75.

This volume represents a comprehensive study of the spectroscopic properties. Correlation of absorption measurements with those obtained from fluorescence spectra have seldom been made for such a large amount of data. This work should be an important source of information and data in the development of future theories of the solid state.

Practical Spectroscopy

By George R. Harrison, Richard C. Lord, and John R. Loofbourow. Pp. 605+xiv. Prentice-Hall, Inc., New York, 1948. Price $6.65.

In this book the authors have avoided the historical method of approach and instead have attempted to give a comprehensive view of the status and possibilities of experimental spectroscopy as it exists today. In Chapter I they "view the field as from a great altitude, to enable the reader who is unacquainted with the methods and accomplishments of spectroscopy to judge for himself which parts, if any, may be of importance to him." In the remainder of the book they reconsider the various topics in considerably greater detail.

Practical Spectroscopy

By C. Candler. Pp. 190+viii. The Jarrell Ash Company, Boston (U.S. agents), 1949. Price $6.10.

This book is intended as a course of instruction in all branches branches of practical spectroscopy. The subject matter has been written primarily around the Hilger Barfit wave-length spectrometer. However, it is believed that this should not detract from its interest to those equipped with other apparatus. Experiments are given at the close of each chapter.

Absorption Spectrophotometry

By G. F. Lothian (third edition). Pp. 196, Figs. 71. Hilger and Watts, Ltd., London, 1949. Price $7.60.

Although this work forms the third edition of an already well-known publication, *The Practice of Absorption Spectrometry*, it has been so completely revised and largely rewritten that it is virtually a new work. It is a valuable handbook for the investigator who is employing spectrophotometry and contains much that will be of interest to those who are contemplating the use of that method. It describes the apparatus to be used and also shows the accuracy to be anticipated and the essential conditions for realizing that accuracy. Examples of work done in selected fields are included.

Infrared Determination of Organic Structures

By H. M. Randall, Nelson Fuson, R. G. Fowler, and J. R. Dangl. Pp. 239+v, Plates 354. D. Van Nostrand Company, Inc., New York, 1949. Price $10.00.

This volume is intended to supply some of the background which is required by investigators, whether they are chemists, biochemists, or physicists, using infra-red spectra to determine molecular structure. Methods of approach have been outlined; the possibilities inherent in the method have been explored; currently established correlations between structure and the absorption spectrum have been itemized; the instruments and techniques have been described.

An Introduction to Molecular Spectra

By R. C. Johnson. Pp. 296+xiii, Figs. 151, Plates 8. Pitman Publishing Corporation, New York, 1949. Price $7.50.

The author has attempted to provide a textbook on molecular spectra for the student who has graduated in physics or chemistry, or who is approaching graduation, and desires an understanding of the subject within the limits of ordinary mathematical equipment at that stage. At one or two points the author has introduced the results of wave mechanics, but has not assumed familiarity in the use of this method.

Contribution to the Study of Molecular Structure

In both French and English. Several contributors, in commemoration of Victor Henri. Pp. 314. Maison Desoer Editions, Liege, Belgium, 1948.

Luminescent Materials

By G. F. J. Garlick. Pp. 254+viii, Figs. 127. Oxford University Press, New York, 1949. Price $5.50.

This book describes recent research on the physical properties of luminescent materials. It is concerned with experimental and theoretical studies of such phenomena as fluorescence, phosphorescence, thermoluminescence, and the effects of infra-red radiation on phosphors. Associated phenomena, such as photoconductivity, dielectric changes, and the action of strong electric fields are also discussed. The preparation, constitution, and classification of materials according to their luminescence characteristics are given an important place in the text.

ATOMIC AND NUCLEAR PHYSICS

Foundations of Nuclear Physics

With bibliography compiled by Robert T. Beyer. Pp. 272. Dover Publications, New York, 1949. Price $2.95.

Here are thirteen important papers on nuclear physics, presented unabridged and in the original language of their authors. Selected from scientific journals published both in this country and throughout the world, these are the essential primary source materials in this field. This volume also contains a comprehensive guide (120 pages in length) to published material on nuclear physics in which entries are classified according to subject matter.

Wave Mechanics and Its Applications

By N. F. Mott and I. N. Sneddon. Pp. 393+xii, Figs. 68. Oxford University Press, New York, 1948. Price $10.00.

The aim of this book is to give a straightforward account of wave mechanics designed for those who want to use it. There are chapters dealing with applications to atomic and molecular structure, radiation, and collision problems, and the properties of solids. Modern relativistic quantum mechanics is also discussed. The book should be useful as a textbook to the theoretical physicist beginning research in the subject, and to his experimental colleagues as a reference book, while several chapters could usefully be studied by an advanced student of physics in his final year.

Theory of Atomic Nucleus and Nuclear Energy-Sources

By G. Gamow and C. L. Critchfield. Pp. 344+vi, Figs. 62. Oxford University Press, New York, 1949. Price $9.00.

This is the third edition of Gamow's *Structure of Atomic Nucleus and Nuclear Transformations*, of which the second edition has been out of print since 1944. The book has been practically rewritten. The authors have attempted to write it in an inductive way, starting from the properties of elementary particles from which the nuclei are made and working up to more and more complex nuclear properties. Considerable space has been devoted to thermonuclear reactions and their application to cosmological problems.

Two Lectures: I. The Present Situation in the Theory of Elementary Particles. II. Electron Theory of Superconductivity

By W. Heisenberg. Pp. 52. Cambridge University Press, New York, 1949. Price $1.00.

The two lectures here printed were delivered at the Cavendish Laboratory as an introduction to discussions on two different topics in atomic theory. The first lecture tries to explain why the well-known divergencies in meson theory and nuclear physics may be considered, not as a difficulty, but rather as a natural and therefore satisfactory feature of the present "correspondence" theory. The second lecture deals with an application of quantum mechanics, the theory of superconductivity. The views presented in it may be considered as an attempt to combine different features of the previous rather discordant theories into a consistent picture of the phenomenon.

The Physical Principles of the Quantum Theory

By Werner Heisenberg. English translation by Carl Eckart and Frank C. Hoyt (reprint of 1930 edition). Pp. 184+viii, Figs. 19. Dover Publications, New York, 1949. Price $2.50.

In this book the author, a Nobel prize winner, gives a physical picture of quantum theory, covering not only his own contribu-

tions but also those of Compton, Simon, Schrödinger, Einstein, Wilson, Rupp, Davisson, Germer, Thomson, Bohr, and others. Although there is a mathematical appendix, only elementary formulas and calculations have been used in the text itself, so far as practical.

Nuclear Radiation Physics

By R. E. Lapp and H. L. Andrews. Pp. 487+xiv. Prentice-Hall, Inc., New York, 1948. Price $6.00.

This volume is the outgrowth of an elementary manual originally written by the present authors and published within the Military Establishment as "Radiological Safety." Basically, the authors have tried to present a logical and simple interpretation of the phenomena of nuclear physics. In each chapter illustrative examples are given in order to serve as an introduction to the calculations of radioactivity and to guide the student in the technique of solving the problems that appear throughout the text. An essentially non-mathematical approach has been employed, in the hope that the subject matter would not be too involved for non-physicists.

The Theory of Groups and Quantum Mechanics

By Hermann Weyl. Pp. 422+xvii. Dover Publications, New York, 1949. Price $4.50.

The author of this book postulates the importance of the theory of groups in discovering the general laws of quantum theory. Showing how concepts arising in the theory of groups find their application in physics, he illustrates his argument with many examples. Included are discussions of Schrödinger's wave equation, de Broglie's waves of a particle, the Jordan-Holder theorum and its analogs, Burnside's theorem, Lie's theory of continuous groups of transformations, the Pauli exclusion principle and the structure of the periodic table, quantization of the Maxwell-Dirac field equations, and Young's symmetry opreators.

The Theory of Atomic Collisions

By N. F. Mott and H. S. W. Massey (second edition). Pp. 388+xv, Figs. 69. Oxford University Press, New York, 1949. Price $8.75.

This new edition contains a systematic treatment of the new "dispersion" method developed for nuclear collisions and of its application to a wide variety of nuclear phenomena—the scattering and radiation capture of neutrons and protons by various nuclei as well as the scattering of alpha-particles. Nuclear fission is also discussed.

Atoms in Action

By George Russell Harrison (third edition). Pp. 406+x. William Morrow and Company, New York, 1949. Price $5.00.

This "layman's guide to modern science," an account of our most important physical discoveries and their contributions to everyday life, has been completely revised and expanded. It includes new material on atomic energy, radar, and electronics. As in previous editions, the author explains difficult technical matters in simple, graphic language.

Elementary Modern Physics

By Gordon Ferrie Hull. Pp. 503+xvi. The Macmillan Company, New York, 1949. Price $5.25.

This book is intended to gather together, for the use of students, the main developments in physics in recent years—to present the experimental facts and the more elementary theories.

Artificial Radioactivity

By P. B. Moon. Pp. 102+x, Figs. 28. Cambridge University Press, New York, 1949. Price $2.50.

This monograph gives an outline of the main phenomena and techniques of radioactivity, as met with in the study of the light-weight and medium-weight radioactive nuclei that can now be made in great variety. It is chiefly intended for readers who wish to be put into touch with the recent literature on the subject. The radioactive properties of a good many individual nuclei are discussed.

The Science and Engineering of Nuclear Power, Vol. II

Clark Goodman, editor. Pp. 317. Addison-Wesley Press, Boston, 1949.

Whereas Vol. I of this work was primarily a general survey of the fundamentals of chain-reacting systems, the present volume considers specific aspects in some detail such as source materials, isotope separation, vacuum techniques, pile kinetics, rockets, health physics, and future developments. The contents should be of value to all scientists and engineers seriously interested in the industrial applications of nuclear energy. The editor states that the contents of these two volumes "alone should be sufficient proof that 'atomic secrets' are largely figments formed in the minds of well-meaning persons who happen to be ignorant of this special field. A workable basis for the free exchange of ideas must be found. Mankind cannot continue to stand in mortal fear of the greatest scientific accomplishment of our time."

Atomic Energy Levels, Vol. I

By Charlotte E. Moore. Pp. 309+xliii. Circular 467 from the National Bureau of Standards, Washington, D. C., 1949. Price $2.75.

This volume is a compilation of all known data on the energy levels of elements of atomic number 1 through 23. It was designed to meet the needs of workers in nuclear and atomic physics, astrophysics, chemistry, and industry. This volume is the first of a series being prepared by the Bureau as part of a general program on atomic energy levels derived from observations of the optical spectra of atoms and ions. Spectra are presented in order of increasing atomic number, and under a given atomic number they are listed in order of increasing stages of ionization. For each spectrum a selected bibliography covering the analysis is given.

Excited States of Nuclei

By S. Devons. Pp. 152+ix, Figs. 27. Cambridge University Press, New York, 1949. Price $2.50.

This monograph was written mainly from the experimental standpoint. It gives a description of experimental methods and examines typical experimental results in detail. An attempt has been made to include examples taken from recent research and particularly to provide a broad picture of the situation which is up to date.

Trilinear Chart of Nuclear Species

By William H. Sullivan. John Wiley and Sons, Inc., New York, 1949. Price $2.50.

This publication was originated in the Chemistry Division of Clinton Laboratories during November 1946 and sponsored initially by it and by the Argonne National Laboratory. Its preparation was also facilitated and supported by the AEC and by the National Research Council.

Ionization Chambers and Counters: Experimental Techniques

By Bruno Rossi and Hans H. Staub. Pp. 243+xviii. McGraw-Hill Book Company, Inc., New York, 1949. Price $2.25.

Part I of this volume discusses the general physical principles underlying the operation of ionization chambers and counters, with special emphasis on subjects that are of importance in modern detection techniques. Original results are included which were obtained at the Los Alamos Laboratory in the course of assembling important nuclear data. Part II presents detailed discussions for a number of detectors developed and used by the authors and others at Los Alamos for the study of different kinds of radiations.

Radioactive Measurements with Nuclear Emulsions

By Herman Yagoda. Pp. 356+ix, Figs. 75. John Wiley and Sons, Inc., New York, 1949. Price $5.00.

This volume is a description of the theory and practice of nuclear emulsion technique—the use of photographic emulsions in studying radioactivity. The author gives a detailed description of many practical methods for the use of such emulsions, and in addition he explains the theory which underlies the operations involved. The book describes carrier precipitation methods, emanations, alpha-star formation, and radiocolloid adsorption phenomena. The bibliography of 700 items is another valuable feature of the book.

Cosmic Ray Physics

By D. J. X. Montgomery. Pp. 370+viii. Princeton University Press, Princeton, 1949. Price $5.00.

This volume presents a survey of the entire field of cosmic-ray studies. Because of the uncertainty of theory in the regions of energy involved and the complexity of the phenomena, the emphasis of the book is experimental with theory subordinated. The various experimental techniques are discussed and explained, and numerous illustrations are used throughout. The book presupposes a knowledge of general physics equivalent to that of an upperclass undergraduate or a beginning graduate student.

On the Theory of Stochastic Processes and Their Application to the Theory of Cosmic Radiation

By Niels Arley. Pp. 240, Figs. 53. John Wiley and Sons, Inc., New York, 1949. Price $5.00.

The purpose of this book is to investigate in further detail the so-called fluctuation problem in the theory of cosmic radiation. Part I deals with the theory of stochastic, or random, processes. It is aimed at giving a further generalization of Feller's and Lundberg's theories for the purpose of application of stochastic processes to the theories of cosmic-ray showers. Part II discusses in detail the fluctuation problem in the theory of the cosmic-ray showers treated in the first part.

Introduction to Radiochemistry

By Gerhart Friedlander and Joseph W. Kennedy. Pp. 412+xiii. John Wiley and Sons, Inc., New York, 1949. Price $5.00.

Included in the early chapters of this book is descriptive information about atomic nuclei, nuclear reactions, and the machines used for the acceleration of nuclear projectiles. Later chapters introduce in logical sequence the quantitative treatment of radioactive decay processes, the various types of radioactive disintegration, the radiations emitted, their interactions with matter, and their detection. The book presupposes no previous knowledge of nuclear physics. At the end of each chapter are lists of references which call attention to standard works and recent literature on specific topics. Exercises are also included at the end of each chapter.

Radioactive Tracer Techniques

By George K. Schweitzer and Ira B. Whitney. Pp. 241+vi, Figs. 13. D. Van Nostrand Company, Inc., New York, 1949. Price $3.25.

This manual is designed to serve as a guide for laboratory work and instruction in the utilization of radioactive tracers. The first four chapters deal with topics pertaining to all radioactive laboratory work. Next basic experiments are presented. The remainder of the book is devoted to material illustrating chemical, physical, and biological tracer methods.

Isotopic Tracers and Nuclear Radiations with Applications to Biology and Medicine

By William E. Siri (with contributions by five others). Pp. 653+xiv, Figs. 136. McGraw-Hill Book Company, Inc., New York, 1949. Price $12.50.

This book has been developed to bridge the gap between those books intended solely for the nuclear physicist and those which merely describe the results of research in which radioactive isotopes and nuclear radiations were used. To this end, the authors have presented the theory, the methods of measurement, and the principles of applications of tracers and radiations without stressing unnecessary and complicated features of nuclear physics or rapidly outdated experiments in biology.

Fear, War, and the Bomb

By P. M. S. Blackett. Pp. 244. Whittlesey House, McGraw-Hill Book Company, Inc., New York, 1949. Price $3.50.

The author, winner of a 1948 Nobel prize, asserts that the world today has an atom neurosis. He believes that we are handcuffed by fear, and that before we can achieve lasting peace, that fear must be replaced by a firm belief in the long life of civilization. The author believes that the atomic bomb cannot bring about a cheap, quick military knockout in a war between Russia and the United States, nor is that war imminent. When this book was first published in Great Britain it aroused an immediate storm of controversy. The author, a former member of Great Britain's advisory committee on atomic energy, holds a position sharply at variance with the official attitudes of the British and American governments.

Constructive Uses of Atomic Energy

S. C. Rothmann, editor. Pp. 258+ix, Figs. 11. Harper and Brothers, New York, 1949. Price $3.00.

This book describes atomic energy applications in such fields as industrial power, chemistry, metallurgy, aviation, ceramics, soil-fertilizer research, and biological, pharmaceutical, and medical research. It is a collection of fourteen articles by scientists in atomic research.

SOLID STATE PHYSICS

Progress in Metal Physics, I

Bruce Chalmers, editor. Pp. 401+viii. Interscience Publishers, Inc., New York, 1949. Price $9.50.

The purpose of this volume, which is to be the first of an annual series, is to present authoritative reviews of the present state of knowledge in specialized aspects of the field that includes both physical metallurgy and metal physics. Nine authors have contributed chapters.

Fourier Technique in X-Ray Organic Structure Analysis

By A. D. Booth. Pp. 106. Cambridge University Press, London; The Macmillan Company, New York, 1948. Price $2.75.

This book gives a comprehensive account of the technique of organic crystal structure determination by Fourier methods, and

indicates the relative scope of the various techniques. The treatment is from fundamentals, but the reader is assumed to have an adequate knowledge of geometric crystallography and of the theory of space groups.

Crystals and X-Rays

By K. Lonsdale. Pp. 199+viii, Figs. 138. D. Van Nostrand Company, Inc., New York, 1949. Price $3.75.

This book is based on a course of public lectures given at University College, London, in the spring of 1946, and is designed to interest those who do not now use x-ray crystallography but who might well do so; and to instruct those who are making use of x-ray crystallographic methods.

On the Systems Formed by Points Regularly Distributed on a Plane or in Space

By M. A. Bravais. English translation by Amos J. Shaler. Pp. 113+viii, Figs. 42. The Crystallographic Society of America, care of Philips Laboratories, Irvington, New York, 1949. Price $3.40 to members, $3.90 to non-members.

With this volume the Crystallographic Society of America begins publication of its Memoir Series. This work by Bravais, concerned with the development of the fourteen space lattices, marked an important milestone in the science of crystallography.

The Adsorption of Gases on Solids

By A. R. Miller. Pp. 133+ix, Figs. 38. Cambridge University Press, New York, 1949. Price $2,50.

This book has been based upon "Some Problems in Adsorption" by J. K. Roberts, a *Cambridge Physical Tract* published in 1939. Since the original tract was written, certain statistical theories have been developed in connection with this work and other advances have been made. Hence it seemed desirable to rewrite the book. Nearly half of the present work is new material.

Prüfen und Messen der Oberflächengestalt

By Johannes Perthen. Pp. 257, Figs. 115. Carl Hanser-Verlag-München, Munich, 1949.

Metals Reference Book

Colin J. Smithells, editor. Pp. 735+xvi. Interscience Publishers, Inc., New York, 1949. Price $13.50.

The object of this book is to provide a convenient summary of data relating to metallurgy and metal physics. So far as possible the data are presented in the form of tables or diagrams with the minimum of descriptive matter, although short monographs have occasionally been included where information could not otherwise be adequately presented. The values given are those which contributors have selected as the most reliable after a critical review of the published data. A limited bibliography at the end of each section enables the reader to refer to the more important original sources.

Treatise on Powder Metallurgy, Vol. I. Technology of Metal Powders and Their Products

By Claus G. Goetzel. Pp. 778+xxvii, Figs 300. Interscience Publishers, Inc., New York, 1949. Price $15.00.

This is the first of three volumes intended to serve as an introduction into the field for the novice who wants detailed information, as a reference book for the initiated, and for the engineer who has to solve immediate problems.

Hydrogen in Metals

By Donald P. Smith. Pp. 367+xiii. The University of Chicago Press, Chicago, 1948. Price $10.00.

This monograph takes up the absorption and retention of hydrogen by massive metal. Rates of absorption, from gas and at the cathode, are discussed, as well as the factors which influence them. Existing solubility data are presented in numerous tables and graphs, with critical comment.

Metallic Creep and Creep Resistant Alloys

By A. H. Sully. Pp. 278+xii, Figs. 138. Interscience Publishers, Inc., New York, 1949. Price $5.50.

In this book the author has attempted to present the viewpoints of both the industrial worker and the academic researcher in the field of creep resistant alloys. The development of the existing theory of the strength of metals is described with special reference to creep, and an attempt has been made to explain certain metallurgical factors affecting creep on the basis of this theory. A detailed summary of experimental techniques for the study of creep phenomena has also been included as well as a survey of the creep properties of most of the well-known ferrous and non-ferrous alloys. Some speculations on future developments in creep resisting alloys are made.

Technology of Light Metals

By A. von Zeerleder. Pp. 366+xiv, Figs. 396. Elsevier Publishing Company, Inc., New York, 1949. Price $7.50.

This handbook deals with the working up of aluminum and magnesium alloys from the ore to the semimanufactured goods, taking into consideration the possibilities of the latest metallurgical improvements. To prevent this book from becoming too voluminous, some less important portions of the 1936 edition have been eliminated, with more space devoted to the most recent testing and working methods.

Metal Rectifiers

By H. K. Henisch. Pp. 156+xi, Figs. 55. Oxford University Press, New York, 1949. Price $3.75.

This is the second volume of a series intended to summarize the recent results of long-range research in materials and allied subjects, in a form useful to physicists in universities and industrial laboratories. The book deals with the theory and practice of dry rectification, especially those aspects of the subject which are parts of physics rather than of engineering. Attention is paid especially to the theories of rectification put forward by Schottky, Wilson, and others, and to the experimental work which is relevant to their verification.

Titanium

By Jelks Barksdale. Pp. 591+xii, Figs. 15. The Ronald Press Company, New York, 1949. Price $10.00.

The purpose of this book is to meet the need for a working reference volume on titanium. Abstracts of the literature on titanium were studied by the author, and essential information incorporated into the text. Exact references to all the material consulted are included.

Industrial Rheology and Rheological Structures

By Henry Green. Pp. 311+xii, Figs. 78. John Wiley and Sons, Inc., New York, 1949. Price $5.50.

Believed to be the first of its kind, this book is a manual and practical working guide for making rheological and structural microscopic investigations. It can be used by university or industrial laboratory where researchers deal with such articles as printing inks, paints, oils, varnishes, biochemicals, resins, plastics, food, cement, and asphalt.

Engineering Laminates

ALBERT G. H. DIETZ, editor. Pp. 797. John Wiley and Sons, Inc., New York, 1949. Price $10.00.

This book contains valuable information for everyone concerned with the design, manufacture, and use of structural materials. The book completely explains the mechanics of laminate materials from basic properties, through physical and chemical properties, to industrial uses. Discussions of wood, metallic, and rubber-based laminates are included. Throughout the book the authors have emphasized engineering properties, design, manufacture, and use. The book has a contributing staff of 24 engineers, architects, builders, metallurgists, designers, and professors.

High-Polymer Physics—a Symposium

HOWARD A. ROBINSON, editor. Pp. 572+xiii. Remsen Press Division, Chemical Publishing Company, Inc., Brooklyn, New York, 1948. Price $12.00.

Thirty-nine physicists and chemists, all rather prominent experts in their special fields, contributed to this symposim on hte relatively new subject of high-polymer physics. The results discussed come largely from industrial research laboratories rather than from college research groups. The physicist had to help the chemist, and vice versa, to explain the phenomena encountered in high polymers. This volume is the product of their cooperation.

APPLIED PHYSICS NOT INCLUDED ELSEWHERE

Mathematical Biophysics

BY NICOLAS RASHEVSKY (revised edition). Pp. 669+xxiii. University of Chicago Press, Chicago, 1948. Price $7.50.

This study is intended to lay the foundation for a mathematical biology, analogous in its methods to mathematical physics and based on the physical interpretations of biological phenomena. In this new edition the author has included recent developments in the field of mathematical biophysics and has incorporated most of the material formerly published in his *Advances and Applications of Mathematical Biology*. This edition contains 200 pages of new material, including the theory of embryonic development, the theory of cancer, and an elaboration on the theory of cell division. Also included are a number of new chapters on learning, abstractions, logical thinking, and perception of visual patterns.

Biological Reactions Caused by Electric Currents and by X-Rays

BY J. TH. VAN DER WERFF. Pp. 203, Figs. 38. Elsevier Publishing Company, Inc., New York, 1948. Price $5.00.

This book is a theoretical study of the phenomena of excitation in the nerve by different electric currents and of the biological reactions caused by x-rays, both based upon a common principle.

The Atmospheres of the Earth and Planets

GERARD P. KUIPER, editor. Pp. 366+vii, Figs. 91. The University of Chicago Press, Chicago, 1949. Price $7.50.

Physical Principles of Oil Production

BY MORRIS MUSKAT. Pp. 922+xv. McGraw-Hill Book Company, Inc., New York, 1949. Price $15.00.

The purpose of this book is to formulate and correlate present information concerning the physical principles and facts underlying the mechanics of oil production. A further purpose has been to stimulate and encourage additional research and study of the subject to fill in the many gaps in our present knowledge, clarify the many aspects which are still subject to speculation and conjecture, generalize the simplified and idealized treatments of special problems, and to improve the correlation between laboratory theories and field observations. The approach of the book consists in the detailed analysis of the physical concepts and principles which are developed as foundations for the interpretation and study of actual oil field performance. Many examples from actual oil field operation demonstrate the basic characteristics of the various types of producing mechanism and operation.

Seismicity of the Earth and Associated Phenomena

BY B. GUTENBERG AND C. F. RICHTER. Pp. 273+vii, Figs. 34. Princeton University Press, Princeton, 1949. Price $10.00.

This is an account of the relative seismicity of various parts of the earth during the limited period (since about 1904) for which sufficiently accurate data are available. Geographical and geological relations of the principal earthquake zones and areas are discussed, including correlation with mountain structures, oceanic deeps, gravity anomalies, and active volcanoes. A new checklist of active volcanoes is included. The origin of earthquakes is discussed, particularly with reference to folding and thrusting in the structural arcs of Pacific type.

Oscillations of the Earth's Atmosphere

BY M. V. WILKES. Pp. 76+ix, Figs. 23. Cambridge University Press, New York, 1949. Price $2.50.

This monograph discusses all that is known to date of the oscillations of the atmosphere. It treats of the lunar and solar air tides, their measurement, manifestations, and causes; the theory of oscillations in a rotating atmosphere; the numerical evaluation of air tides; the outward flux of energy; the height of the earth's atmosphere; the temperature variation, etc. Observational and mathematical methods of arriving at a knowledge of the properties of the atmosphere are referred to as they arise, and the book concludes with a general discussion of results.

Some Recent Researches in Solar Physics

BY F. HOYLE. Pp. 134+xii, Figs. 8. Cambridge University Press, New York, 1949. Price $3.00.

The aim of this monograph is to provide an account of the present state of solar physics. The first two chapters are largely devoted to an account of the observational material concerning sunspots, the solar cycle, the chromosphere, and the corona. In the third and fourth chapters a new theory of the origin and structure of the chromosphere and corona is presented, while in the remainder of the book such diverse topics as electromagnetism in the solar atmosphere, solar and terrestrial relationships, the emission of radio waves by the sun, and the origin of the general solar magnetic field are discussed.

The Solar System Analysed

BY F. C. ATTWOOD. Pp. 88. The Dawson Printing Company, Ltd., Auckland, New Zealand, 1947.

This brief book is subtitled "Old Laws from a New Angle." Chapters deal with the beginning of the solar system, the solar nebula, the origin of the earth's rotation, and so on through a concluding chapter named "Speculation."

Our Sun

BY DONALD H. MENZEL. Pp. 326, Figs. 178. The Blakiston Company, Philadelphia, 1949. Price $4.50.

In language that is easily understood, this volume explains the basic methods for finding out about the sun. It vividly pictures solar activity and the vast explosions occurring in the sun's atmosphere. Included are the many new advances in solar research heretofore restricted from publication because of military classification. The author discusses the relationship between the sun and our natural resources; its probability as a source of heat and fuel; the sun and atomic power; and its effect on radio transmission and weather forecasting.

The Face of the Moon

By Ralph B. Baldwin. Pp. 239+xiv, Figs. 26, Plates XVII. The University of Chicago Press, Chicago, 1949. Price $5.00.

"How and when did the moon arrive at its present state of dilapidated grandeur?" In this interesting volume the author examines and rejects all but one of the processes previously suggested to account for the lunar craters, rays, mountain ranges, and lava flows. He selects as the most probable cause the impacts of giant meteorites on the rocky lunar face and their resultant explosions. Chapters are devoted to a description of the strange and beautiful formations found on the moon, to a discussion of modern and ancient meteoritic craters known to exist on earth, to an analysis of the impact theory in the light of knowledge of man-made explosion pits, to an investigation of the possible effects of a lunar atmosphere, to the dating of the major changes on the face of the moon, and to a consideration of the possibility of meteoritic infalls on other planets.

Hydrology

By C. O. Wisler and E. F. Brater. Pp. 419+xi, Figs. 132. John Wiley and Sons, Inc., New York, 1949. Price $6.00.

This textbook presents the fundamental principles of hydrology as they have been developed up to the time of writing. The distribution graph, the unit hydrograph, the theory of infiltration capacity, and many other recent developments are presented. The many applications cited throughout the book make it useful to the general practicing engineer, forester, and agriculturist, as well as to the student who is looking for the basic principles of hydrology. The book provides information which can be used in the determination of the maximum flood flow that may be expected every few years, as in airport drainage and storm sewer design. For the design of a spillway for an important dam, or any flood control work, the authors present methods for determining the maximum flow that will occur with rare frequency, such as once in a thousand years.

Surface Tension and the Spreading of Liquids

By R. S. Burdon. Pp. 92+xi, Figs. 22. Cambridge University Press, New York, 1949. Price $2.50.

The first edition of this book was published in 1940. In this new edition the author has added accounts of all important work published recently. Chapter subjects include the nature of surface forces; measurement of surface tension; the surface of liquid metals; spreading; general conditions; spreading on the surface of mercury; spreading on water; liquids on the surface of solids.

Experimental Immunochemistry

By Elvin A. Kabat and Manfred M. Mayer. Pp. 567+xv, Figs. 88. Charles C. Thomas, Publisher, Springfield, Illinois, 1948.

The authors of this book have undertaken the task of assembling for the first time in one place the scattered techniques which have been developed to fill the needs of immunochemical problems. Main emphasis is placed on quantitative analytical methods. To meet the needs of students as well as of chemists who may not be thoroughly familiar with immunology, and of bacteriologists and immunologists who may not be well acquainted with microchemical methods, introductory and background material in both fields has been included.

Bibliography of Research on Heavy Hydrogen Compounds

Harold C. Urey and Isidor Kirshenbaum, editors; compiled by Alice H. Kimball. Pp. 350+xvi. McGraw-Hill Book Company, Inc., New York, 1949. Price $3.25.

This volume is a collection of about 2000 references to published literature on the subject of the heavy hydrogen isotope. The material is classified according to subject in such a manner that previous work in the field may be readily found. The volume should prove useful to anyone concerned with research on isotopes and their application to specific problems.

Physical Methods of Organic Chemistry, Parts I and II

Arnold Weissberger, editor (second edition). Pp. 1072+xii and 1024+xi. Interscience Publishers, Inc., New York, 1949. Price $12.50 each.

This familiar work has been completely revised and augmented, and as before, appears in two volumes. The new edition has new chapters on temperature measurement, temperature control, vapor pressure, the ultra-centrifuge, electrophoresis, and turbidimetry. The chapters on viscosity, osmotic pressure, diffusivity, dipole moments, radioactivity, and mass spectrometry have been entirely rewritten. All other chapters have been thoroughly revised.

Outlines of Physical Chemistry

By Farrington Daniels. Pp. 713+viii, Figs. 164. John Wiley and Sons, Inc., New York, 1948. Price $5.00.

This is the seventh revision of what was originally the well-known "Getman and Daniels" text on physical chemistry. The illustrations in this edition have been revised in keeping with the author's emphasis on practicality. Hypothetical diagrams illustrating physical chemical phenomena have been replaced with data from laboratory measurements. One-fourth of the numreous problems have been replaced or revised.

Sources of Engineering Information

By Blanche H. Dalton. Pp. 109. University of California Press, Berkeley, 1948. Price $4.00.

This is a guide to engineering literature and data designed as a concise reference for engineering students, practicing engineers, research workers, and librarians. Its arrangement is based on studies of the use of an actual library collection. The book includes information on every type of engineering.

Rocket Propulsion Elements

By George P. Sutton. Pp. 294+ix. John Wiley and Sons, Inc., New York, 1949. Price $4.50.

Airplane Performance, Stability, and Control

By Courtland D. Perkins and Robert E. Hage. Pp. 493+vii. John Wiley and Sons, Inc., New York, 1949. Price $7.00.

This book is divided into two major parts, the first dealing with the problems of airplane design for performance, and the second involving the design of the airplane for adequate stability and control characteristics. In the first part, basic aerodynamics is summarized so that an estimation of airplane drag can be made for subsonic, transonic, and supersonic speeds; propulsion characteristics of the reciprocating engine, turbine propeller, turbojet, ramjet, and rocket are presented; performance methods are analyzed for the basic forces acting on an airplane utilizing any of the above power plants. In the second part of the book, the comparatively new art of designing the airplane for adequate flying qualities has been dealt with, with only subsonic flight being discussed. A modern analysis of the dynamics of the airplane is included.

GENERAL AND HISTORICAL

Reports on Progress in Physics, Vol. XII

Pp. 382. The Physical Society, London, 1949. Price to non-Fellows £2 2s. (postage 1s.).

This volume, containing papers by 19 authors, includes the following subjects: mass spectrometry, nuclear paramagnetism,

phosphors and phosphorescence, spontaneous fluctuations, recent nuclear experiments with high voltage x-rays, linear accelerators, viscosity and related properties in glass, theory of the oxidation of metals, fracture and strength of solids, multipole radiation in atomic spectra, collisions between atoms and molecules at ordinary temperatures, low temperature physics, slow neutron absorption cross sections of the elements, and molecular distribution and equation of state of gases.

Fundamentals of Physical Science

By Konrad Bates Krauskopf (second edition). Pp. 676+xii, Figs. 330. McGraw-Hill Book Company, Inc., New York, 1948. Price $4.50.

The preparation of this second edition was prompted chiefly "by a desire to bring the book up to date in several rapidly advancing fields of physical science." Notable changes are a complete rewriting of the chapter on the atomic nucleus, addition of a section on the uncertainty principle, introduction of Brönsted's theory in the discussion of acids and bases, and increased emphasis on air-mass analysis in weather forecasting.

Physics in the Modern World

By Henry Semat. Pp. 434. Rinehart and Company, New York, 1949. Price $5.00.

This book is addressed specifically to students of the arts and social sciences who are interested in learning and understanding the methods of the physical sciences. This volume is the outgrowth of three years of experience in teaching "Physics in the Modern World" to non-science students at the College of the City of New York. (Similar courses of the same length are given in chemistry, biology, and geology-astronomy.)

The Nature of Physical Theory

By P. W. Bridgman (reprint of 1936 edition). Pp.138+vi. Dover Publications, New York, 1949. $2.25.

This book is a study of modern scientific theory which views the problem of correlating reality with the various theoretical structures set up in the past fifty years. It analyzes the inadequacies of physical theories in supplying the answers to all questions, but points out the real service these concepts render within limited frames of reference. The author investigates and weighs the contributions of Newton, Bohr, Einstein, Heisenberg, and others. He discusses such basic concepts as the wave and corpuscular theories, the "clocks" of relativity, the "laws" of probability, and the mathematical system itself.

Science at War

By J. G. Crowther and R. Whiddington. Pp. 185, Figs. 51, Plates 51. Philosophical Library, Inc., New York, 1948. Price $6.00.

This is a detailed account of science's contribution to the war effort, based on the official archives and documents assembled by the scientific advisory committee to the British Cabinet. This volume should be of fundamental interest to the American scientist as well as to the intelligent layman interested in science. Among the basic topics dealt with in the book are radar, the atomic bomb, operational research, science, and the sea.

The Principles of Scientific Research

By Paul Freedman. Pp. 222, Figs. 11. Macdonald and Company, Ltd., New York, 1949. Price $3.05.

This book is addressed chiefly to young men and women embarking on or concerned with scientific research, but it is also intended for business executives in whose power, to a considerable extent, the successful conduct of scientific research lies.

The Universe and Dr. Einstein

By Lincoln Barnett. Pp. 127. William Sloane Associates, New York, 1948. Price $2.50.

This book is a report on what the men at the forefront of science know about the nature of the universe. The story of the search for essential truth about the universe is here told simply, in the vocabulary of the intelligent layman. This book can be understood by the high school student of physics and chemistry and still could be read with profit by outstanding scientists of today.

Man and This Mysterious Universe

By Brynjolf Bjorset. Pp. 174+vii. Philosophical Library, New York, 1949. Price $3.75.

This small book is intended as a synthesis of the many aspects of modern civilization, bringing within its scope the contribution of the East as well as of the West, showing how it has grown from the civilization of the past and how it will probably develop in the future. The author has traveled for thirty years and lived in more than fifty countries.

After Dinner Science

By Kenneth M. Swezey. Pp. 182. Whittlesey House, McGraw-Hill Book Company, Inc., New York, 1948. Price $3.00.

For everyone interested in popular science, here is a book full of pictures and fascinating scientific experiments that can be performed with ordinary household materials and without any previous scientific knowledge. The author takes the mystery out of science. With photographs and easy-to-understand explanations he shows the reader how he himself can demonstrate the basic laws of scientific phenomena. This is a volume that the whole family can enjoy.

Mendeleyev—the Story of a Great Scientist

By Daniel Q. Posin. Pp. 345+xii. McGraw-Hill Book Company, Inc., New York, 1948. Price $4.50.

This is the first biography in English of this famous Russian chemist and physicist. It reveals an almost unbelievable story of triumph in a man with a burning desire to be a scientist. It was Mendeleyev who first unlocked the doors of Russia's great natural resources. As a young man he had begun his studies handicapped by illness and poverty. Studying and teaching in the daytime, he spent most of the night in his laboratory. He discovered a plan of unity among the chemical elements which led him to fromulate the Periodic Table. When he died at 73, he had been acclaimed by every country in the world.

Albert Einstein, Philosopher-Scientist

Paul Arthur Schilpp, editor. Pp. 781+xvi. The Library of Living Philosophers, Northwestern University, Evanston, Illinois, 1949. Price $8.50.

This volume contains Albert Einstein's autobiography. In addition, contributions from 25 scholars and scientists in eleven countries (among them six Nobel Prize winners) discuss various aspects of Einstein's scientific work and achievements. In Part III of the volume Einstein replies to the comments, analyses, and criticisms of his contemporaries. An exhaustive bibliography of Einstein's writings is included.

Scientific Autobiography and Other Papers

By Max Planck. Pp. 192. Philosophical Library, New York, 1949. Price $3.75.

This is a collection of the last writings of one of the greatest physicists of our time. The essays that make up this small volume deal with problems such as: true and fictitious issues in science; meaning and limit of exact science; physics and causality; natural sciences and the religious world. The autobiographical notes tell the story of Max Planck's own personal and scientific development.

On the Shielding Qualities of Different Concrete Mixtures*

P. C. Gugelot and M. G. White
Palmer Physical Laboratory, Princeton University, Princeton, New Jersey
(Received April 4, 1949)

Absorption curves for neutrons and γ-radiation produced by 16-Mev protons on beryllium are measured in absorber blocks of various concrete mixtures to obtain information on their shielding properties. It is shown that a mixture of cement, scrap iron, and limonite ore is as efficient as water in slowing down and capturing neutrons and, in addition, has sufficient density ($\rho=3.5$ g/cm^3) to be an effective absorber for γ-radiation. Compared to ordinary concrete, a three-foot wall of iron and limonite concrete is superior by a factor of 280 for neutrons and by a factor of 20 for γ-radiation. Boron is shown to be of little value in this type of shielding. Mechanical properties of the scrap iron-limonite concrete are satisfactory for structural purposes. From the practical cost standpoint, a concrete made entirely of limonite ore is shown to be a reasonable compromise.

I. INTRODUCTION

With the construction of larger accelerators and nuclear reactors, the problem of shielding against radiation becomes more and more important. It is not only necessary to protect against health hazards, but also to reduce the background for experiments.

Water shields commonly used around cyclotrons are effective in slowing down and capturing neutrons of a few Mev. However, for very high neutron energies the slowing down qualities of this medium decreases, owing to the small scattering cross section of fast neutrons in hydrogen. In addition, the absorption of γ-radiation in water is negligible. It is, therefore, necessary to find a shielding material which is effective in slowing down neutrons, and with sufficient density to be an efficient γ-ray absorber.

The theory of slowing down of neutrons has been worked out in a hydrogenous medium by Fermi.[1] His theory describes the mean square distance $(r^2)_{Av}$ which a neutron with the initial energy E_0 travels in being slowed down to an energy E_1. The "Age-theory," developed by Bethe, Korf, and Placzek,[2,3] calculates the spatial distribution of neutrons in a medium. By using the age of a neutron:

$$\tau=1/6(r^2)_{Av}=\frac{1}{3[1-(2/3A)]\xi}\int_{E_1}^{E_0}\lambda^2\frac{dE}{E}$$

$$\xi=1-\frac{A}{2}[1-(1/A)]^2\log(A+1)/(A-1),$$

where A = atomic weight of element of which the absorber is composed, and λ = mean free path of the neutrons of energy E, the slowing down equation can be written in a simple form:

$$\Delta q=\partial q/\partial\tau.$$

q = number of neutrons per cm^3 slowed down to energy E_1, the solutions of which are Gaussian functions. Placzek[4] and Marshak[5] extended the theory to absorbers composed of heavy nuclei, and to mixtures of different nuclei. Higher approximations were developed showing that the Gaussian distribution of neutrons of final energy E_1, obtained by the age-theory, is valid only to distances equal to τ/λ and then only when many collisions are necessary to slow the neutrons down ($A\gg1$). At larger absorber thickness the neutron density decreases exponentially. These calculations are all based on slowing down of neutrons by elastic collisions;

therefore, they are only valid for initial neutron energies lower than the first excited states in nuclei. The poor knowledge about nuclear excitation levels makes calculations above these energies uncertain and experiments are needed.

Measurements were carried out by Munn and Pontecorvo[6] with heterogeneous mixtures of water with iron or bismuth. They obtained the mean square distance $(r^2)_{Av}$ required to slow Ra+Be neutrons down to 1.44 ev (In detectors) and to thermal energy (Dy detectors). Values observed by these authors are:

for water: $(r^2)_{Av\text{-}In}=278$ cm^2, $(r^2)_{Av\text{-}th}=330$ cm^2,
for water+Bi (density 5.3 g/cm^3): $(r^2)_{Av\text{-}th}=562$ cm^2,
for water+Fe (density 3.9 g/cm^3): $(r^2)_{Av\text{-}In}=319$ cm^2,

showing that it is possible to use mixtures of water and iron in which $(r^2)_{Av}$ is nearly the same as in pure water, but with the greatly improved γ-ray absorption of the iron.

Tittle and Goodman,[7] in order to carry out absorption experiments in which the components of the mixture are easily interchangeable, studied the difference in neutron distribution between homogeneous and heterogeneous mixtures of C, O, and H. Neutrons from a Ra+Be source were used and In-resonance neutrons detected. The intensity distribution was found to be the same for the different mixtures with equal C, O, and H concentrations at distances >20 cm from the source.

Hildebrand and Moyer[8] obtained absorption coefficients for 80-Mev neutrons detected by an ionization chamber. The half-value thickness for water is 55.9 cm and for concrete (ordinary and barite) 24.1 cm.

Concrete with 5–10 percent water was also investigated by Jensen and Ritter[9] with neutrons from a Ra+Be source. Spherical and plane geometry were used. In the first case, a distribution for In-resonance neutrons was obtained of the form $r^2I=$ const. $\exp(-r/L')$ ($r>40$ cm), $L'=21.8$ cm. For the plane geometry the intensity decreased exponentially: $I=$ const. $\exp(-r/L)$ ($r>40$ cm), $L=15.3$ cm. The authors show that, at absorber thickness where the fast neutron flux is in equilibrium with the slow neutron flux for spherical geometry, $Ir=$ const. $\exp(-r/L_s)$, in which $L_s=L$, and $1/L'=1/L-1/r$. A water wall of 65-cm thickness reduces the neutron flux in this case as much as 160 cm concrete ($I/I_0=10^{-3}$).

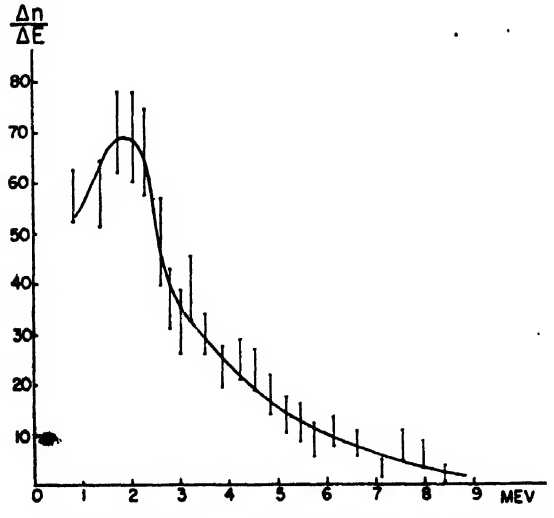

FIG. 1. Neutron spectrum from 16-Mev protons on a thick Be target.

II. EXPERIMENTAL ARRANGEMENT

Before the radiation shield around the Princeton frequency modulated cyclotron[10] was constructed, we made absorption measurements with different concrete mixtures in order to design a wall which would reduce background sufficiently to make possible careful experiments with the deflected proton beam. Cubic blocks of 46-cm edge were cast, having a steel tube of 7.5-cm diameter through the center of the block. Slabs of 5.3-cm thickness, prepared from the same mixture, fitted smoothly into the tube. In this way slow neutron detectors or a Geiger-Müller counter could easily be placed between the slabs and an almost homogeneous absorber was obtained. The absorber blocks were placed in a reproducible position in the forward direction of neutrons generated by 16-Mev protons on a thick Be target. To obtain information on the energy of the neutrons and to be able to compare our results with the experiments which were carried out with a Ra+Be neutron source, we studied the neutron spectrum by measuring proton-recoil tracks in 100μ Ilford C2 photographic emulsions (Fig. 1). Tracks in the forward direction, originating and ending in the emulsion, were measured and corrected for scattering cross section[11] and for loss of tracks in a layer of finite thickness. The plate was bombarded outside the acceleration chamber 52 cm from the internal Be target. An appreciable number of the low energy tracks is due probably to neutrons which suffered collisions in the iron of the magnet. This spectrum differs from a Ra+Be neutron spectrum[12] in the low energy range; however, the high energy tail is in both cases somewhat similar. In a total of 900 tracks, five were found with energy >9 Mev.

To be effective, a shield must strongly absorb fast neutrons, slow neutrons and gamma-rays since all these particles are radiated by nuclear machines and also result from the stopping of fast neutrons. A complete

study of shielding materials should include attenuation measurements on all these types of incident radiation using detectors which are specific for the radiation in question. However, for neutron studies, we have confined ourselves to the use of thermal or silver resonance neutron detectors and for gamma-rays a copper walled Geiger-Müller counter was used. The attenuation of fast neutrons we infer from the slopes of the slow neutron intensity curves at large absorber thickness since all *incident* slow neutrons are removed by the early part of the absorber and only fast neutrons are left to produce the detected slow neutrons. Considerable care must be exercised in using data obtained near the back of a block because room-scattered low energy neutrons can falsify the curves.

The slow neutron intensity in the absorber blocks due to the total incident cyclotron flux was obtained by activating silver foils of 2.5-cm diameter and 0.7-mm thickness between the slabs and the intensity of the 2.37^m Ag^{108}-period was measured with a thin wall G-M tube. The counting rate was corrected for decay and background and then compared with the activity of a monitor foil. To obtain the activation by resonance neutrons, the Ag foils were placed in an envelope of 0.45 g/cm^2 Cd (Ag^{108} has resonance levels at 50 and 15 ev). Silver was chosen because of its convenient half-life. The size of the punched foils was identical. In general, only the front side of the foils was measured. All these data are given in the "*B*" curves of Figs. 3–10. Runs in which the activity on both sides was investigated showed that the error introduced by measuring only one side was less than 4 percent. An uncertainty in foil position of 1–2 mm resulted from the rather rough faces of the slabs.

The diffusion of *thermal* neutrons incident on the test blocks was studied by interposing water cans between the cyclotron and test blocks and then taking attenuation curves with and without cadmium absorber placed *between* the water cans and the test block. These data are the "*A*" curves in Figs. 3–10. According to the diffusion theory, for plane geometry the intensity of thermal neutrons decreases exponentially. The $1/e$-value thickness is the "diffusion-length" l; it is connected with the transport mean free path λ and capture mean free path Λ by $l=(\frac{1}{3}\lambda\Lambda)^{\frac{1}{2}}$.

The influence of the finite size of the test blocks on the absorption curves was estimated in the following way: The neutron attenuation curve obtained in the cement +iron+limonite ore test block was compared with the attenuation curve obtained by placing water cans in front of the test block leaving an opening of 15×15 cm in the center. This in effect decreases the size of the absorbing block. That this is the actual case is shown by the slow neutron intensity distribution perpendicular to the fast neutron beam (Fig. 2). The neutron density obtained with the water can "diaphragm" (curve 2) has a pronounced maximum in the center, and the slope of the attenuation curve was unchanged from that

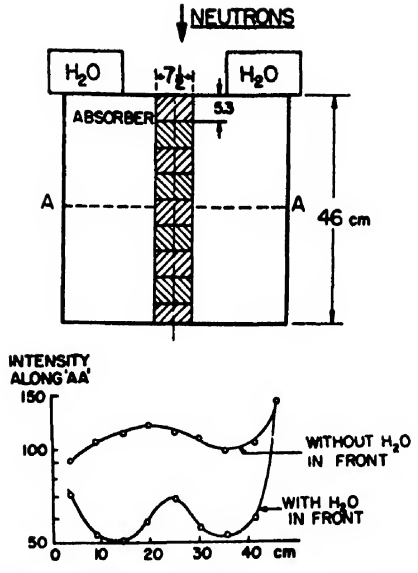

FIG. 2. Absorber block and thermal neutron distribution inside the absorber perpendicular to the fast neutron flux, showing the effect of neutron collimation by water tanks in front of the absorber.

obtained when the entire block was irradiated. The slow neutron intensity at large thickness of absorber is mainly caused by neutrons slowed down by a large number of small angle deflections, and the subsequent diffusion of slow neutrons contributes very little to the observed half-value thickness of the attenuation curve.

Gamma-ray attenuation, when measured by exposing test blocks to the entire cyclotron radiation and studying the counting rate of a copper walled Geiger-Müller counter cannot be expected to yield precise results since a few counts will be due to fast neutrons causing knock-on ions in the counter. More important, the fast neutrons will create gamma-rays in the test block. Nevertheless, as a practical matter, the attenuation of a shield as measured by a Geiger-Müller counter is of considerable interest. Figure 11 collects all the Geiger-Müller counter data for the various absorbers.

III. RESULTS FROM NEUTRON ABSORPTION EXPERIMENTS

a. Water

For this experiment a tank was used of larger dimensions than the concrete absorbers. The neutron detectors were placed in a hard rubber holder. Figure 3 shows the absorption curves so obtained. Figure 3A gives the attenuation of *thermal* neutrons which strike the water tank after being generated in a preceding layer of water. Curve 1 corresponds to the intensity distribution resulting from *all* incoming neutrons, curve 2 to the intensity distribution resulting from the faster than thermal neutrons which succeed in passing a cadmium sheet placed between the test water tank and the slow neutron generating water cans. The difference of these two curves shows the exponential decrease in

the intensity of incoming thermal neutrons. The diffusion-length is $l=2.7$ cm; it compares within the error to the value 2.88 cm obtained for water by Allison *et al.*[13] with In detectors. The deviation is caused by the uncertainty in position of the Ag-foils and by the Cd shield which eliminates neutrons reflected by the water cans back into the tank. Curve 3, of Fig. 3B, shows the total Ag activity caused by exposing the test tank to the direct cyclotron radiation, curve 4 the intensity produced by resonance neutrons only and the difference of 3 and 4 corresponds to the thermal neutron intensity. This curve yields a half-value thickness of 5.5 cm for absorber thickness larger than $r=20$ cm. From 3B it is possible to calculate $(r^2)_{Av}$ for thermal and resonance neutrons:

$$(r^2)_{Av}=\frac{\int_0^\infty I(r)r^2dr}{\int_0^\infty I(r)dr}$$

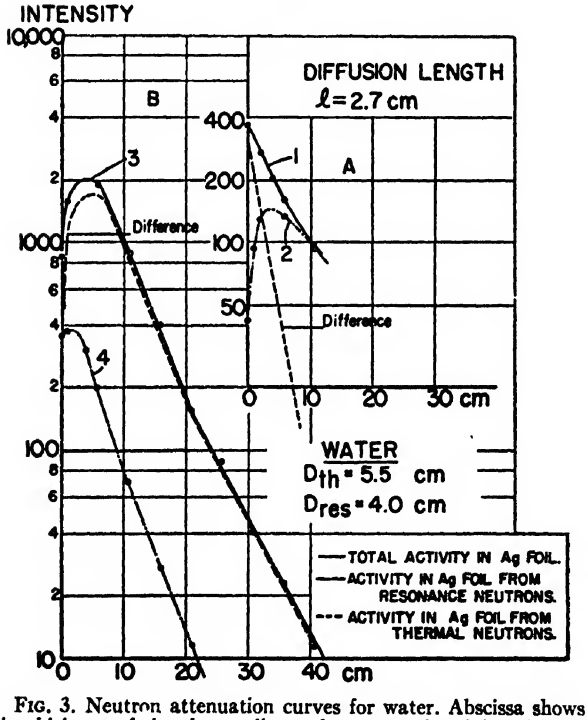

FIG. 3. Neutron attenuation curves for water. Abscissa shows the thickness of absorber, ordinate the corrected activity of silver detectors. A. Attenuation curves for incoming thermal neutrons, a layer of 15-cm water is placed between absorber and cyclotron. Curve 1. No Cd between absorber and waterlayer. All neutrons after passing through the 15-cm thick waterlayer can enter the absorber. Curve 2. Cd between absorber and waterlayer. Only faster than thermal neutrons enter the absorber tank. The difference of 1 and 2 shows the attenuation of incoming thermal neutrons from which the diffusion length of thermal neutrons is calculated. B. Attenuation curve of incoming fast neutrons. The absorber is only shielded by Cd. Curve 3. Ag detectors sensitive to all neutron energies. Curve 4. Ag detectors wrapped in Cd and thus are only sensitive to faster then thermal neutrons. The difference between 3 and 4 shows the Ag activity from thermal neutrons. From this curve the half-value thickness D_{th} is obtained.

[13] See J. H. Rush, Phys. Rev. 73, 271 (1948).

$I(r)$: The activity of the detectors, which is proportional to the slow neutron-intensity at position r.

For thermal neutrons: $(r^2)_{Av\text{-}th}=119.2$ cm².

For resonance neutrons: $(r^2)_{Av\text{-}res}=62.3$ cm².

For the Ag detector no precise neutron energy is connected with $(r^2)_{Av\text{-}res}$. The corresponding migration area is for thermal neutrons:

$$M_{th}^2=1/6(r^2)_{Av\text{-}th}=19.9 \text{ cm}^2.$$

The age for resonance neutrons is:

$$\tau_{res}=1/6(r^2)_{Av\text{-}res}=10.4 \text{ cm}^2.$$

According to the diffusion theory we have: $M_{th}^2=\tau_{th}+l^2$. The value for l is 2.88 cm. Hence the age of thermal neutrons is $\tau_{th}=11.8$ cm². The difference in age between thermal and resonance neutrons is: $\tau_{th}-\tau_{res}=1.3$ cm². This value is of the expected order and would correspond to an average resonance energy of about 30 ev. Comparing the age of our thermal neutrons with τ_{th} for thermal neutrons from a Ra+Be source slowed down in water, for which Anderson *et al.*[14] obtained 46.4 cm², shows that we have to deal with a neutron spectrum which extends to very low energies. It was indeed necessary to shield the front of the absorber with Cd to obtain useful values for $(r^2)_{Av\text{-}th}$.

b. Water+Boron

It has frequently been suggested that water shields could be improved by adding boron in the form of borax. Two beneficial effects are to be expected. First,

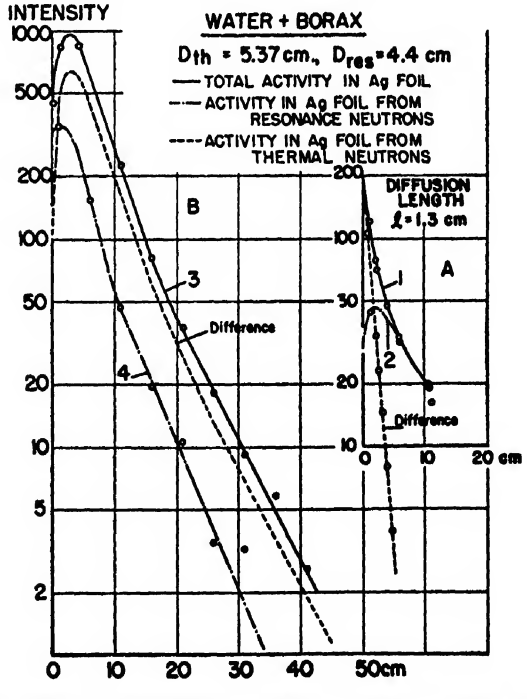

FIG. 4. Neutron attenuation curves for water+3 percent borax.

[14] See J. H. Rush, Phys. Rev. 73, 271 (1948).

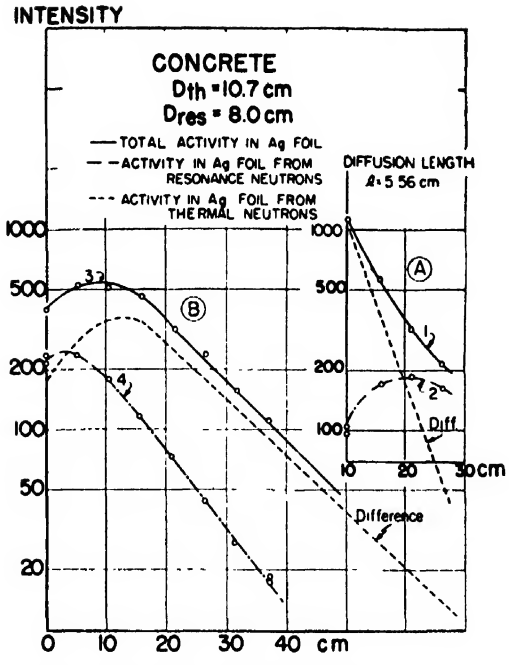

FIG. 5. Neutron attenuation curves for concrete.

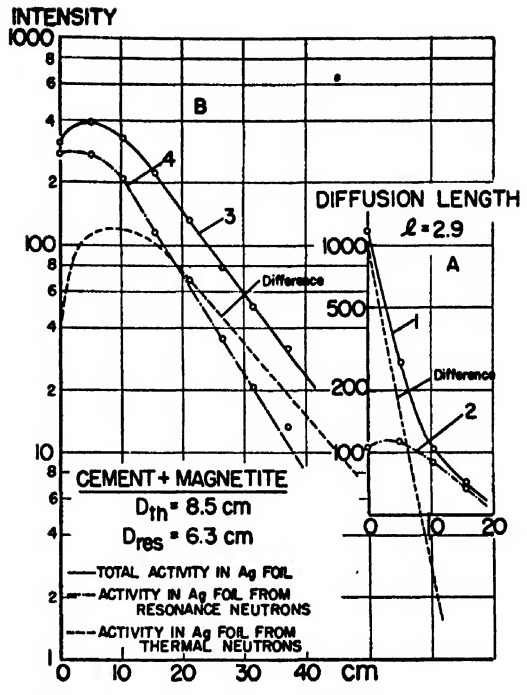

FIG. 6. Neutron attenuation curves for concrete+Pyrex.

the boron capture of neutrons tends to suppress the neutron-proton capture gamma-rays and second, the large boron cross section should reduce the diffusion of slow neutrons. To test the latter point a 3 percent solution of borax in water was substituted for the previously studied pure water. The capture mean free path Λ can be calculated assuming $\sigma_{H_a}=0.4\times10^{-24}$ cm^2 [15,16] and $\sigma_{B_a}=700\times10^{-24}$ cm^2. We obtain

$$\frac{\Lambda \text{ solution}}{\Lambda \text{ water}}=\frac{1}{6.2}.$$

From this it follows that

$$\frac{l \text{ solution}}{l \text{ water}}=\left(\frac{\Lambda \text{ solution}}{\Lambda \text{ water}}\right)^{\frac{1}{2}}=\frac{1}{2.5}.$$

By experiment (Fig. 4A) we observe l solution $=1.3$ and for pure water l water $=2.85$ (Fig. 3A) yielding the ratio

$$\left(\frac{l \text{ solution}}{l \text{ water}}\right)_{\text{exp}}=\frac{1}{2.2}.$$

The agreement between the predicted and observed ratio is reasonably good. However, the half-value thickness obtained from Fig. 4B, which includes *all* neutrons both fast and slow incident upon the borax solution absorber is the same as found for pure water showing that the slope of the attenuation curves is mainly determined by the larger mean free path of the fast neutrons present in the cyclotron radiation.

[15] Manley, Haworth, and Luebke, Phys. Rev. 61, 152 (1942).
[16] E. J. Harringh and J. L. Stewart, Can. J. Research 19, 33 (1941).

It is of interest to compare the effects of boron absorption on the flux of thermal neutrons and silver resonance neutrons. The area under an absorption curve, such as curve 3 Fig. 3B, is *proportional* to the integral

$$F_E=\int_0^\infty I_E(r)dr$$

where $I_E(r)$ is the number of neutrons at thickness r which have been slowed down to the energy E at which the detector is efficient. Thus if there is strong absorption at an energy *higher* than E the integral will be small. By extrapolating the curves of Figs. 3B and 4B we obtain for resonance energy neutrons the following data: In water $F_{res}=2.7\times10^3$; in water plus borax $F_{res}=2.3\times10^3$ showing that in spite of the boron the density of Ag *resonance* neutrons remain unchanged. However, for *thermal* neutrons $F_{th}=2.1\times10^4$ in water, and $F_{th}=5.6\times10^3$ in borax solution indicating that the boron has decreased the number of neutrons in the thermal energy range.

c. Concrete and Concrete+Pyrex

A sample of ordinary concrete was tested in the manner described above. The results are given in Fig. 5. The diffusion length for thermal neutrons is $l=5.6$ cm. The half-value thickness for the neutrons slowed down to thermal velocity is $D_{th}=10.7$ cm. This mixture contains 0.21 g water/cm^3, a number obtained from the amount of water used to make the mixture and from the moisture in the gravel and sand. (A small amount of

water will have evaporated during the setting of the concrete.) Composition: 46.3 percent gravel by weight, 27.6 percent sand, 17.7 percent cement and 8.4 percent water; density $\rho=2.35$ g/cm³. The large half-value thickness is due to the large number of collisions with relatively heavy nuclei which neutrons have to suffer in being slowed down; inelastic scattering will be negligible for Si and O.

Another sample was made containing 1.25 percent Pyrex glass by weight, 46.55 percent gravel, 27.78 percent sand, 18.37 percent cement and 6.05 percent water. The boron had an observable effect on the diffusion length (Fig. 6): $l=3.3$ cm (Pyrex contains 3 percent boron). The ratio of hydrogen atoms to boron atoms is in this case 2.7×10^{2}. If boron and hydrogen were solely responsible for capturing thermal neutrons the ratio of the diffusion lengths would be, taking into account the different hydrogen contents in both mixtures,

$$\frac{l\ \text{concrete+Pyrex}}{l\ \text{concrete}}=\frac{1}{2.7};$$

observed is

$$\left(\frac{l\ \text{concrete+Pyrex}}{l\ \text{concrete}}\right)_{\text{exp}}=\frac{1}{1.7}.$$

This deviation is to be expected because the thermal neutron capture cross sections of Si ($\sigma_a=0.25\times10^{-24}$ cm²) and of other elements of which the absorber is composed were not taken into account. The half-value thickness of the fast neutron attenuation curve decreased to $D_{th}=7.4$ cm. It is not clear whether the Pyrex had any function in decreasing the absorption coefficient D_{th}. This mixture contains only 0.14 g water/cm³. (Density $\rho=2.39$ g/cm³.)

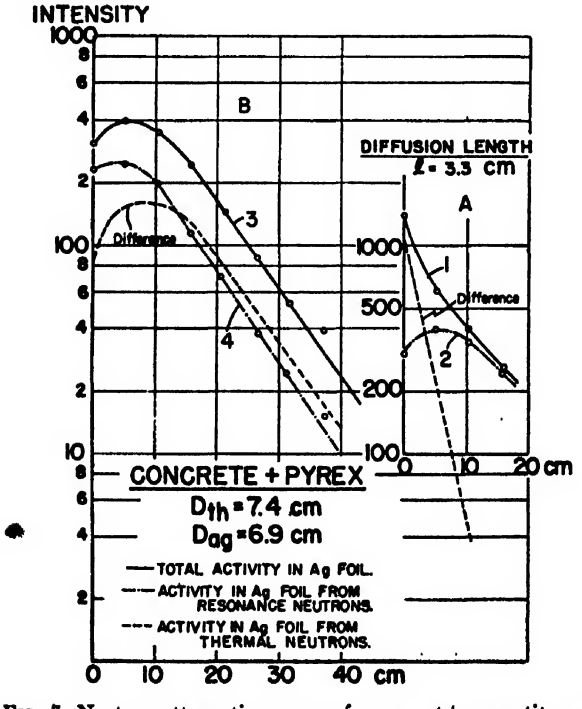

FIG. 7. Neutron attenuation curves for cement+magnetite ore.

d. Cement+Magnetite

No improvement was obtained by replacing the sand and gravel by magnetite ore (Fe_3O_4). This mixture contains 83.5 percent magnetite ore, 11 percent cement, and 5.5 percent water by weight. This amounts to 0.21 g water/cm³ and 1.93 g Fe/cm³; the density is 3.78 g/cm³. The half-value thickness is 8.5 cm (Fig. 7), slightly better than for standard concrete. Because of the iron used in this mixture the diffusion length for thermal neutrons became 2.9 cm. Fe has a relatively large capture cross section for thermal neutrons, $\sigma_{Fe_a}=2.05\times10^{-24}$ cm².[17]

e. Cement+Limonite, Cement+Limonite+Iron, Cement+Limonite+Iron+Pyrex

It was possible to increase the amount of hydrogen in these mixtures by using limonite ore ($2Fe_2O_3\cdot3H_2O$).*

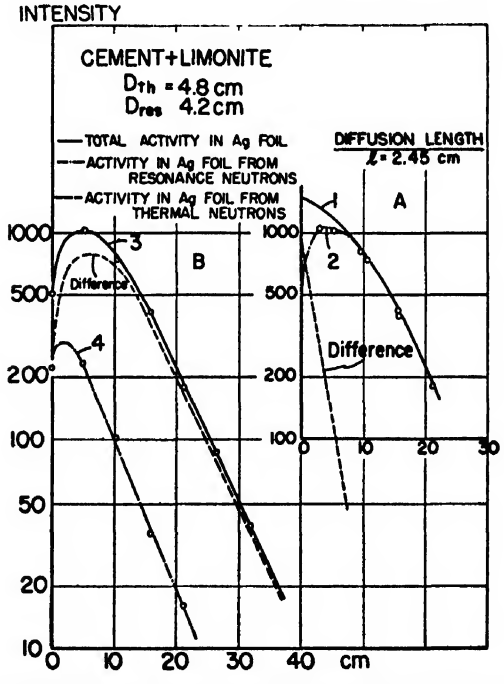

FIG. 8. Neutron attenuation curves for cement and limonite ore

The first absorber contains 68.5 percent limonite, 21 percent cement and 10.5 percent water. Taking the amount of moisture and water of crystallization into account 0.49 g water/cm³ is obtained and 0.93 g Fe/cm³. The density is $\rho=2.63$ g/cm³. The smallest half-value thickness D_{th} was obtained with this absorber: $D_{th}=4.8$

[17] J. W. Coltman and M. Goldhaber, Phys. Rev. 69, 411 (1946).

* Obtained from the Shook-Fletcher Company, Birmingham, Alabama.

cm (Fig. 8). However, the density was not sufficient for satisfactory γ-ray absorption (Section IV). Scrap iron in the form of punchings (about 2 cm diameter and about 1 cm thick) was mixed into the following block (Fig. 9): scrap iron 59.4 percent, limonite 26.35 percent, cement 9.54 percent and water 4.71 percent. A density of 4.41 g/cm^3 was obtained at the expense of lower hydrogen content: 0.35 g water/cm^3 and 3.23 g Fe/cm^3. The half-value thickness D_{th} increased to $D_{th}=5.4$ cm.

For the last block a mixture was obtained with less iron and more hydrogen than in the former absorber. The capture probability for thermal neutrons was again increased by the use of Pyrex: scrap iron 41.4 percent,

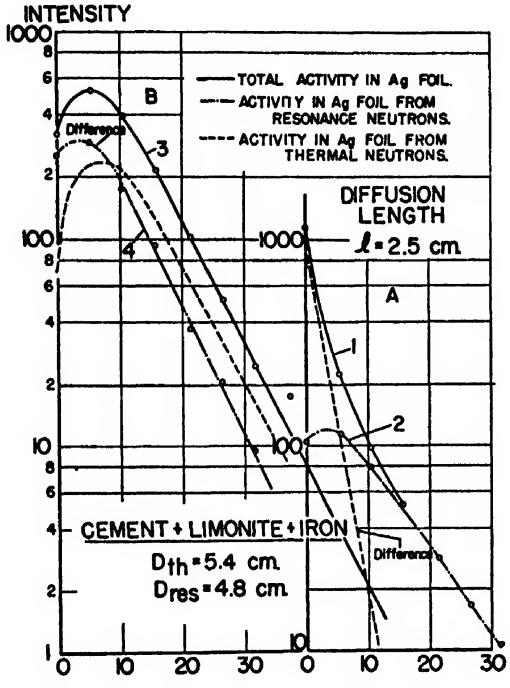

FIG. 9. Neutron attenuation curves for cement +limonite+scrap iron.

limonite 32.8 percent, cement 12.3 percent, Pyrex 0.7 percent, and water 12.8 percent. The density is 3.6 g/cm^3. This amounts to: 0.45 g water/cm^3 and 2.26 g Fe/cm^3. The half-value thickness obtained for thermal neutrons is $D_{th}=5.0$ cm. This smaller D_{th} is probably caused by the larger amount of water per cm^3. Because of the Pyrex used in this absorber, the diffusion length for thermal neutrons became $l=2.3$ cm, instead of 2.5 cm for the former two blocks (Fig. 10). In the cement +iron+limonite+Pyrex block the capture mean free path is, for hydrogen, 83 cm; for iron, 20 cm; for boron, 35 cm.

IV. γ-RADIATION

A Geiger Müller counter was placed between plugs in the test block to obtain information on the background which is to be expected outside the radiation shield when working with counters. A mica window "Victoreen" counter was used with the window closed by a brass cover. The counting rate is also connected with the neutron flux in the absorber because of (n, γ) and $(n, n\gamma)$ processes near the counter and (n, p) and (n, α) reactions in the counter wall. Therefore, with a bad neutron absorber, no steep absorption curves for the counter can be obtained. Figure 11 shows the results for all investigations. No simple exponential relation exists between intensity and absorber thickness. The largest half-value thickness, D_C, was observed for water. D_C remained unchanged in the boron solution, because only multiplication of the intensity by a constant factor <1 is to be expected for the neutron-capture γ-radiation. (All curves are normalized at $r=0$.) 1.25 cm of lead around the counter decreased the counting rate in water to 1/3.4 of its value at $r=0$ and to 1/4.1 at $r=30$ cm. More information is needed about the γ-ray spectrum and the fraction of counts caused by γ-radiation if one is to make detailed calculations.

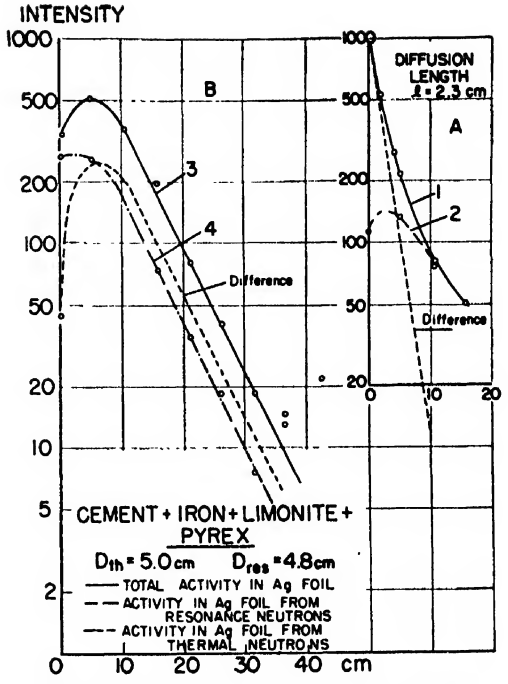

FIG. 10. Neutron attenuation curves for cement +limonite+scrap iron+Pyrex.

For both cement+limonite and cement+magnetite mixtures the same curves were observed. In the more dense magnetite the γ-ray absorption is probably higher than in the former, but this effect is obliterated by low neutron absorption in the magnetite block.

Almost exponential decays with half-value thickness of 7.9 cm are obtained in the limonite+iron absorbers.

V. DISCUSSION

By placing a water shield between an absorber block and the cyclotron, we noticed that the half-value thick-

ness D_{th} increased. Water becomes increasingly transparent for the higher energy neutrons; so the addition of a water layer gives essentially the absorption coefficient for the high energy neutrons in the spectrum. For the cement+limonite+iron absorber (Fig. 9B) a value of $D_{th}=5.4$ cm was obtained without the water shield, but with 15 cm of water in *front* of the block $D_{th}=7$ cm at $r=20$ cm (Fig. 9A). This effect and the observed variations in the half-value thickness of the attenuation curve *in water* (at $r=10$ cm, $D_{th}=4.0$ cm and at $r=30$ cm, $D_{th}=5.5$ cm) showed that considerable care must be exercised in the interpretation of our data. It became necessary to investigate whether or not the half-value thickness of 5.4 cm in the limonite+iron mixture corresponded to the absorption of neutrons from the same part of the energy-spectrum as that which gave rise to a $D_{th}=5.5$ cm in water. The slope of the absorption curve in the limonite+iron block was investigated up to larger thickness of absorber by placing the cement+magnetite block in front of it. $D_{th}=5.4$ cm was obtained for the first 20 cm in the second absorber. At larger distances the intensity started to increase again; the neutron flux being so small that diffusion of almost thermal neutrons through the sides of the absorber became observable.

Thus, it cannot be excluded that the attenuation curve will become less steep with increasing absorber thickness, because of the slowing down process of a small fraction of very high energy neutrons. Insufficient knowledge about the various possible ways in which fast neutrons can be slowed down, e.g., inelastic scattering $(n, 2n)$ reactions, makes a detailed discussion about the form of an absorption curve impossible. However, the comparison of our different absorption curves is justified as long as can be shown that in each absorption experiment the same number of neutrons is slowed down to resonance energy. Thus, the number of neutrons slowed down to resonance energy gives evidence whether in some cases an appreciable number of fast neutrons is not sufficiently slowed down to E_{res} and thus fail to be detected. In Section III we found that

$$F_E=\int_0^\infty I_E(r)dr$$

is proportional to the total number of neutrons slowed down to the energy E. For all absorbers studied F_{res} amounts to *ca.* 3.10^3 (water: $F_{res}=2.73\times10^3$, for cement +iron+limonite+Pyrex; $F_{res}=3.51\times10^3$). This proves that in all cases about the same number of neutrons is slowed down to the silver *resonance* energy. The essentially constant value for F_{res} shows that capture of neutrons faster than E_{res} is in general negligible. The value F_{th} for thermal neutrons differs in some cases by a factor 3, because slow neutrons are absorbed before being detected.

A comparison with other experiments shows that absorption coefficients obtained with Ra+Be sources and those obtained with neutrons from Be+16-Mev protons are almost the same. By plotting $I\cdot r$ from the

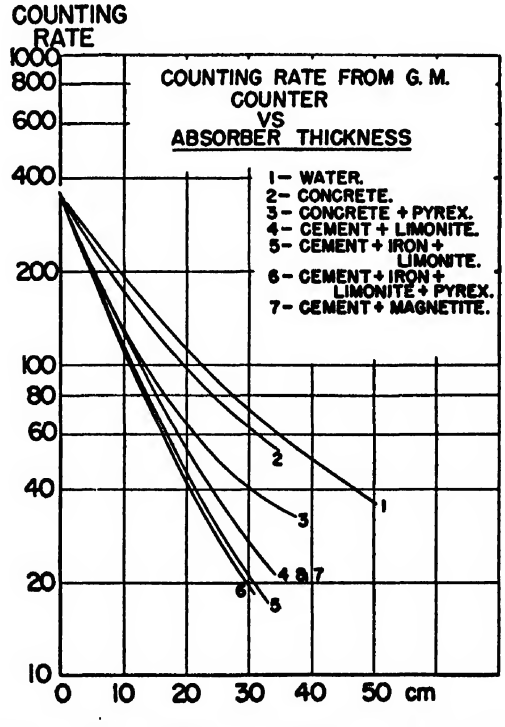

FIG. 11. γ-ray attenuation curves. Abscissa shows the thickness of absorber, ordinate the normalized counting rate of a G-M counter.

[a] A is attenuation factor. [b] n is number of half-intensity values. [c] Columns give thickness in cm to reduce initial intensity by the facto

absorption curve, Rush[18] observed in water with Ra+Be neutrons a half-value thickness of 5 cm is obtained. For plane geometry, Riezler (see Jensen and Ritter[9]) obtained a half-value thickness of 4.9 cm. (For our Be+p neutrons: $D_{th}=5.5$ cm) Jensen and Ritter[9] found a half-value thickness for Ra+Be neutrons slowed down to the In resonance in standard concrete: $D_{In}=10.6$ cm. (For Be+16-Mev p neutrons: $D_{th}=10.7$ cm.) This is in agreement with the high energy part of the spectra obtained for the neutrons from Ra+Be[12] and for the neutrons from the Be^9+p reaction.

It is apparently difficult to increase the density of an absorber without at the same time decreasing the amount of hydrogen available for slowing down neutrons. Since elastic scattering by a heavy nucleus, such as iron, is very inefficient for slowing neutrons it is of interest to investigate the cross section for inelastic scattering and to compare the resulting mean free path for energy loss with that in water. Barshall, *et al.*[19] found about 10^{-24} cm^2 for the inelastic scattering cross section of iron at 3 Mev, and presumably at higher energies the cross section becomes still larger. At 3 Mev the scattering cross section for hydrogen is $2.3\cdot10^{-24}$ cm^2 and decreases as $1/E$ at higher energies. From these cross sections and the composition of a concrete block containing scrap iron and limonite we find that the mean free path for scattering by hydrogen is 18.5 cm, while the comparable number for inelastic scattering by iron is 28 cm. Pure water has a mean free path of about 6 cm for 3-Mev neutrons but for higher energy neutrons the effectiveness of water falls off; so that above about 5 or 6 Mev the iron in our special concrete should be more effective than pure water. To be most effective against high energy neutrons a shield should therefore include heavy nuclei, but in order to slow down neutrons in the range of about a volt up to 3-Mev hydrogen material must be relied upon. These qualitative conclusions are fully borne out by our experiments.

Table I summarizes the data obtained from our experiments. Column 2 gives the amount of water in g/cm^3 calculated (1), from the water added to the mixture, (2) the moisture content of the components and (3), the water of crystallization of the limonite. Column 3 shows the weight of scrap iron+iron in the limonite per cm^3 of material, column 5 the half-value thickness for the neutron attenuation curves obtained with the Ag thermal neutron detectors. The age of thermal neutrons is calculated in column 6. For all concretes, values for the age are appreciably larger than for water. This is probably due to neutrons of about 1 Mev, at which energy the mean free path for a hydrogen collision is still relatively large and inelastic scattering by the iron improbable. This is especially the case in the cement+magnetite test block.

In Table I columns 9 and 10 give the transmission of a 3-ft. wall calculated for two conditions:

1. For neutrons by the expression:

$$T=\frac{\int_{90}^{\infty} I_{th}(r)dr}{\int_{0}^{\infty} I_{th}(r)dr}$$

(For large thickness of absorber r, and exponential attenuation with half-value thickness D, this may be approximated by $T=2^{r/D}$.)

2. For the G-M counter: The absorption curves for the counter are extrapolated with the absorption coefficient obtained from the slope of the curve at $r=30$ cm.

Column 9 shows that for our neutron spectrum the limonite mixtures are as effective as water in stopping neutrons and that compared to ordinary concrete a 3-foot wall of limonite+scrap iron mixture is 280 times more effective against neutrons. Column 10 shows that against γ-rays the limonite plus scrap iron wall is superior to ordinary concrete by a factor of 20, and in comparison with water there is a 60-fold advantage. It is probable that the superiority of iron+limonite would be even more marked at higher neutron energies.

Although boron is frequently suggested for use in shields on account of strong non-radiative capture of neutrons it is apparent from our results that little is to be gained in this direction with respect to either thermal neutron attenuation or suppression of γ-rays.

The concrete+Pyrex absorber has been tested at 90° to the proton beam. A half-value thickness of 5.9 cm

[a] As in the block tests it was necessary to protect the zero absorber silver disk against thermal neutrons coming from the cyclotron by interposing a cadmium filter. The activity of the unshielded detector was 1.77 times larger.

was obtained instead of 7.4 cm in the forward direction, showing that the lower average neutron energy at 90° does indeed lead to larger absorption.

VI. PRACTICAL CONSIDERATIONS

To shield a large installation is always expensive; so practical considerations such as cost, mechanical properties, availability of raw materials and ease with which the shield material can be applied to the actual problem may take precedence over shielding efficacy.

From the mechanical strength standpoint, all the various concrete mixtures showed about the same ultimate compression strength. For example, our tests gave a 28-day strength for ordinary 1-2-3 concrete of 3675 pounds per square inch, while limonite concrete ran 3600 and limonite plus scrap iron about 3000. The early setting properties were normal. Concrete made from scrap iron and limonite is heavy and more difficult to handle in mixing trucks and more difficult to place without voids, but the special problems raised by it are easily solved. The high density of this form of concrete requires sturdy pouring forms and vigorous rodding.

Strength tests showed that the limonite mixtures are adequate for the construction of a radiation shield. An ultimate compression test of cement+iron+limonite cylinders 14 days after casting gave a value of 2193 lb./in.^{2}. For the standard concrete mixture a value of 2210 lb./in.^{2} was observed 7 days after casting.

Limonite ore is widely available, but care must be exercised in specifying high density since some limonite is soft and crumbly. Ore used in our experiments was composed largely of hard, dense lumps ranging from $\frac{1}{8}$ in. to 4 in. to 5 in. A laboratory type crusher reduced the ore to a range of sizes comparable with customary concrete practice. When making up the limonite for incorporation with scrap iron, the ore was crushed somewhat finer than for a pure limonite concrete. A point to notice in specifying limonite is that the amount of absorbed moisture varies considerably with mining conditions and in consequence the amount of water which must be added to make satisfactory concrete will vary somewhat from ordinary concrete practice.

Scrap iron, in the form of small punchings, should be not over $\frac{3}{4}$ in. in size with $\frac{1}{2}$ in. pieces being considerably easier to work. The iron must be grease free and preferably mildly weathered.

Of interest is the comparative cost of the various concretes. Ordinary concrete runs about \$10–\$15 per cubic yard, or about \$10.00 per ton delivered. Limonite ore can be had for \$5.00 per ton at the mine with freight charges increasing the cost to about \$17.00 per ton of ore. Crushing costs are fairly nominal and depend largely on the availability and cooperativeness of local gravel companies. Mixing and delivering of the special concretes, when handled by a commercial concrete firm, may cost as much as the raw materials. Because of the above uncertain factors, it is difficult to quote a reasonable price for limonite concrete, but probably \$40.00 per cubic yard is on the high side. Still more difficult to estimate is the price of scrap iron plus limonite concrete because scrap iron in the most desirable shape is hard to find. The nominal price of scrap iron is presently* \$30–\$40 per ton. Mixing charges are higher for the more dense concretes because of the smaller volume which the mixing trucks can carry. A fair price estimate would be perhaps \$90.00 per cubic yard.

Table II presents the data of Table I in a way which permits cost comparison of different materials for a given attenuation factor. The wall thickness to produce a given attenuation was calculated from the measured half-value thickness on the assumption that there is no change in penetrating power of the radiation for a thickness large compared with 50 cm. Also, for small attenuation the numbers quoted are not accurate because the absorption law is not a simple exponential, e.g., there are *more* thermal neutrons behind 10 cm of concrete than with no concrete at all. With these reservations in mind, one may conclude that to reduce the thermal neutron flux by a factor of one million either water or limonite concrete of one-meter thickness

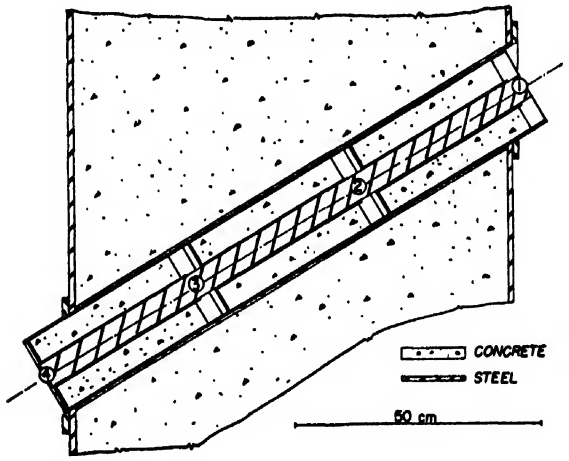

FIG. 12. Cross section through actual cement+limonite+scrap iron shield, showing the port hole, which is directed towards the Be target. The numbers 1 to 4 refer to the positions where the silver detectors and G-M counters were placed to test the actual performance of the shield.

* 1948.

will suffice. Ordinary concrete would have to be about twice as thick. On a cost basis, water is by far the cheapest with straight concrete next and the special concretes much more expensive. On the other hand, a meter of water gives only 10^{-2} attenuation for radiation detectable by a G-M counter while a meter of limonite concrete gives a factor of 10^{-3}, or better, and the scrap iron concrete gives a factor of 10^{-4}. In many installations it is very inconvenient to have a 6-foot wall of water or concrete around the equipment, and in such cases the item of cost is overbalanced by the need for compactness.

Where space and convenience are not at a premium, ordinary concrete is probably the best shielding material. In those regions where limonite, or even magnetite, are readily available and where the transportation, crushing and mixing costs can be kept down it is worth while to use these more costly concretes. On the other hand, the scrap iron concrete is so costly that its use is indicated only where the greater compactness is worth the added price.

VII. PERFORMANCE OF THE COMPLETED SHIELD

Measurements on the finished cement, limonite, and scrap iron shield which has a thickness of 3 feet proved that the neutron and γ-ray attenuation agreed with the extrapolation of the results obtained with the absorber blocks. Figure 12 shows a cross section through that part of the wall in which a port hole has been inserted. The channel is parallel to the neutron flux and in the forward direction of the proton beam incident on the Be target. Three concrete slabs fill the channel. For experimental purposes a 2-in. hole is left in the slabs, which can be closed by a steel rod. For the attenuation measurements, silver disks or a Geiger counter can be placed between the slabs in the usual way.

In Table III the results obtained with the shield are compared with the attenuation expected from the previous experiments. The activity of the Ag detector at position 3 of Fig. 12 was just above the background with the cyclotron off. Only a lower limit for fthe attenuation about 5×10^{-3} could be established at that position; this compares with the value of 2.4×10^{-3} expected from the absorption experiments.

The absorption of the γ-rays appears to have been a little higher than expected, 3.2×10^{-3} against 5.5×10^{-3} at 60 cm. Going from 60 to 90 cm at the outside of the shield the counting rate is only decreased by a factor $\frac{1}{3}$. This is caused by γ-rays transmitted through the doors in the shield which at the time of these measurements are filled with water.

The counting rate for a Victoreen Mica window type counter placed at position 4 of Fig. 12 is 150 counts a minute when a target of Be is bombarded with about 1 μa of 16-Mev protons.

The agreement between observed and empirically predicted attenuation shows that results obtained by our small block tests are sufficiently reliable to permit the design of large shields.

We are indebted to several members of the Princeton faculty for advice on concrete and iron ore problems. In particular, we wish to thank Professor H. F. Winterkorn for his help on concrete problems and Professors A. F. Buddington and E. Sampson for advice on limonite ores. The details of concrete mixing and structural testing were carried out by Professor J. G. Hendrickson of the Engineering School and Mr. B. Setzer of the cyclotron group.

A Bending Method for Measurement of the Tensile Strength and Young's Modulus of Glass Fibers

DAVID SINCLAIR
Johns-Manville Research Center, Manville, New Jersey
(Received August 26, 1949)

The tensile strength and Young's modulus of Johns-Manville experimental drawn glass fibers were measured by a bending method which consists of twisting a loop in a fiber and pulling the ends until the loop breaks. The tensile strength observed by this method was two to three times higher than observed by the conventional straight fiber method, while Young's modulus was practically unchanged. These results may be accounted for by the presence of flaws, since the probability is small that the weakest flaw will occur in the loop, while the straight fiber will always break at the weakest flaw. The apparatus used, a modified Chainomatic balance, is described and the equation of the looped fiber is derived. The method is used to measure the maximum tensile stress and strain attained at the point of minimum radius of curvature of the loop as well as the breaking tensile stress and strain at the actual break point of the fiber. The stress at the break point was found to be as small as one-half the maximum attained in the loop, showing that the strength of the fiber was not uniform.

INTRODUCTION

THE tensile strength of glass fibers is known to vary from a few thousand to two or three million lb./sq. in.[1] depending upon the diameter and length of the fiber, the method of manufacture and amount of handling before test, the age of the fiber and the elapsed time during the test. This wide variation in tensile strength has been supposed to be caused by flaws[1,2] which weaken the fiber at numerous points. The idea is supported by the fact that the tensile strength of fibers increases with decreasing length,[3] since the number of flaws decreases with decreasing length. A very short fiber might therefore be free of any weak flaws and consequently show an unusually high tensile strength.

This paper describes a bending method which provides a measurement of both the breaking stress and strain over a very short length of fiber. The tests were run on Johns-Manville continuous glass fibers made from a plate glass type composition. The method consists of twisting a small loop in a fiber 1 or 2 in. long and pulling the ends until the loop breaks. The tension required to break the loop and the size of the loop at the instant of break are used to calculate the tensile strength at the break point of the loop and the tensile stress attained at the point of minimum radius of curvature of the loop. In addition the extension at these points may be calculated, yielding Young's modulus.

The looped fiber is equivalent to a very short straight fiber since the looped fiber is strained to its breaking point over a length of 1 mm or less. The method is particularly suited to materials such as glass which break under small deformation. In the straight fiber method the extension is too small to be observed conveniently, and short fibers tend to break at the supports. In the looped fiber method the large reduction in the size of the loop during a run magnifies the strain so that it can be readily measured.

Murgatroyd[4] used a somewhat similar method to obtain the breaking strain but not the stress of bent fibers. The fiber was bent in the form of a hairpin between the jaws of a miniature vise which was closed until fracture occurred. A maximum extension of about three percent was observed in 25-micron diameter fibers.

METHOD

The apparatus consists of a Chainomatic balance to which is attached a recording pen, and a 22 speed motor-driven Mono-Drum and loading device. Figure 1 shows the recording pen, P, attached to the chain weight drive, W, which is operated by hand in the usual manner. The drum, D, 10 in. long and 6.25 in. in diameter (50 cm circumference), is motor driven at a constant speed of 1 r.p.m., always in the same direction (from right to left under the pen). The looped fiber is hung from the left pan hook of the balance, and its lower end drawn vertically downward at a constant speed of 0.5 in. per min. by the loading rod, R, which is geared to the drum. A gear shift, G, is used to reverse the direct of motion of the loading rod in preparation for a new test. The magnetic damper, M, provides aperiodic damping of the balance.

In order to mount a fiber for test, one end of a straight fiber 1 or 2 in. long is cemented to a small wire hook which is then hung on the left pan hook. A suitable cement is Picein or low melting point De Khotinsky which is melted by means of an electrically heated wire placed against the wire hook. The lower end of the fiber is then cemented to a piece of straight wire held in a pin vise, V, mounted in the loading rod. The pin vise is free to be rotated or raised in the loading rod in order to facilitate formation of the loop. The cemented ends of the fiber are then straightened by applying a slight tension of about 10 mg with the chain weight, and heating each cemented end enough to soften the cement.

With the slight tension still applied to the straight

fiber the loading rod is driven up or down (and simultaneously the drum is rotated) until the balance needle is at the zero mark. This point is then located on the drum chart (Fig. 2) by a short vertical line near the top of the chart, drawn by returning the chain weight (with attached pen) to zero. This vertical line locates on the chart the abscissa corresponding to the position of the lower end of the straight fiber. The loading rod is then driven up 0.5 in. corresponding to one revolution of the drum and an abscissa of 50 cm on the chart. A loop is now formed in the fiber by turning the pin vise $1\frac{1}{2}$ to 2 revolutions, raising it until the loop snaps into place and then lowering it to its original position (determined by a shoulder on the pin vise).

The vertical line on the chart now corresponds to the position of the lower end of the looped fiber, which is 0.5 in. above the original position of the lower end of the straight fiber. The equations show (see below) that the elevation, L, of the lower end of the looped fiber above the lower end of the straight fiber is proportional to the minimum radius of curvature, R_m, of the loop, i.e.,

$$L=8R_m. \tag{1}$$

The horizontal line on the chart, drawn during the one revolution of the drum, gives the position of zero force on the fiber. The initially large loop exerts a small downward force, T_0, on the left arm of the balance, which should be compensated by lowering the chain weight until the balance needle is again at the zero mark. The looped fiber is now ready for test.

The test is run by driving the loading rod downward while continuously adding chain weight to keep the balance needle at zero. When the loop breaks, no further weight is added, and the drum is allowed to run slightly to record the breaking tension. The wire carrying the lower portion of the fiber is then removed from the pin vise and saved for measurement of the fiber diameter.*

The tension, T, of the fiber at any point on the curve is proportional to the vertical distance from the point to the horizontal zero line. The constant of proportionality is determined by calibration by weighing. Different ranges were obtained by hanging the chain from different points on the balance arm. The minimum radius of curvature, R_m, is proportional to the horizontal distance, L, from the point to the vertical starting line, measured in the direction of travel of the pen. As described above, one horizontal cm on the chart corresponds to 0.01-in. vertical displacement of the lower end of the fiber.

It is shown below that the maximum tensile stress, σ, in the fiber is:

$$\sigma=\frac{16TR_m}{\pi r^3}=\frac{16TL}{\pi d^3}, \tag{2}$$

and the corresponding extension, e, is:

$$e=r/R_m=4d/L, \tag{3}$$

where r is the radius and d the diameter of the fiber.

Young's modulus of elasticity, E, is:

$$E=\sigma/e=(4TL^2/\pi d^4). \tag{4}$$

The ultimate tensile stress and strain are obtained by measurement from the break point on the chart record.

Some practice is required to keep the balance in equilibrium during a test. The rate of increase of tension is at first very low and then increases until it becomes quite rapid as the break point is approached. The operation is facilitated by observing the balance needle through a magnifying lens (not shown in Fig. 1) of the type manufactured for accurate weighing. The curve obtained is slightly wavy, but the fluctuations are small (usually ± 1 mg), particularly as the loop approaches the break point. Figure 2 shows a representative curve redrawn to reduced scale.

The tension required to break the loop in a 20-micron diameter fiber is of the order of 50 mg. Observations of the looped fiber test performed on a completely automatic, electronically operated Chainomatic balance now available on the market, showed severe hunting of ± 10 mg, resulting in a saw-toothed curve on which the location of a point, in particular the break point, was uncertain. A completely automatic instrument of improved stability has recently been developed in this laboratory and is now being tested.

Equations (2) and (3) give the maximum value of tensile stress and strain, respectively, attained in the loop at the point of minimum radius of curvature, which occurs at the base, O, of the loop (see Fig. 4). Measurements of the break point, as described in the following paragraphs, have shown that the fiber frequently breaks at some other point in the loop where the stress and strain are less than at the base, showing that the

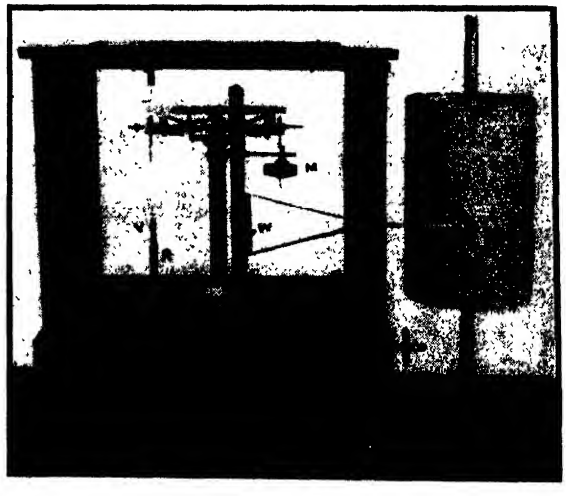

FIG. 1. Semi-automatic fiber balance.

* The diameter was measured with a microscope by placing the broken end of the fiber on a slide in a drop of oil of refractive index 0.05 greater or less than that of the fiber.

strength of the fiber was not uniform. This non-uniformity is not due to variations in the diameter of the fiber. Measurements of the diameter of 20-micron diameter glass fiber samples over a length of several millimeters from the broken end have shown the diameter of any one sample to be constant to two percent. Such a variation in the diameter would cause a variation in the calculated tensile strength of six percent, but the loop has been observed to break at a point where the tensile stress was 50 percent below the maximum attained at the base of the loop.

The measurements of the loop break point were made entirely manually with a preliminary form of apparatus, shown in Fig. 3. The fiber was mounted horizontally with one end fixed in position and tension applied at the other end by a light, circular spring attached to a graduated mechanical slide. The diameter, D, and the position of the loop were observed at the instant of break by means of a low power microscope and micrometer eyepiece. A reading of the mechanical slide was taken corresponding to the straightened fiber with zero tension in the spring, and another at the loop break point. The difference, A, between these two readings is equal to the displacement of the end of the spring attached to the mechanical slide, as shown in Fig. 3.

The displacement, L, is equal to the oppositely directed displacement of the other end of the spring to which the fiber is attached. The equations show that the displacement, L, is proportional to the diameter, D, of the loop (see Fig. 4), i.e.,

$$L=3.75D. \tag{5}$$

Consequently, the total extension of the spring and therefore the tension on the fiber at the instant of break is proportional to $L+A=3.75D+A$. The constant of proportionality was determined by calibration with a Chainomatic balance.

The equations also show that if the fiber breaks at the base of the loop, the remaining portion of the straight fiber (attached to the fixed end) will extend a distance $s=\frac{1}{2}L$ beyond the center of the loop. If the fiber breaks at a point other than the base, the straight fiber will extend a distance $s\pm l$ beyond the center of the loop. Here l is the distance along the fiber from the base of the loop to the break point. Equation (23) shows the tensile stress in the loop as a function of the break point.

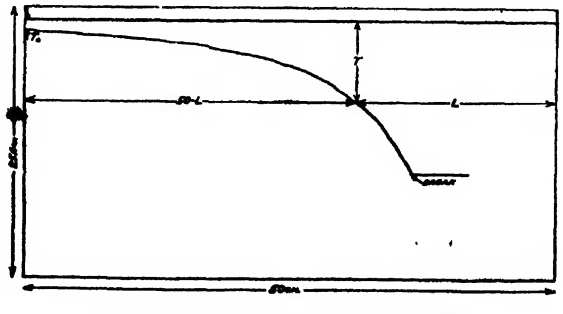

FIG. 2. Chart record of looped fiber test.

After the loop was broken, the fixed portion of the fiber was straightened by wetting the portion attached to the spring and then touching the two portions together along a considerable part of their length. The two portions then clung together so that a slight tension sufficient to straighten them could be applied by the spring. The location of the end of the fixed portion, relative to the recorded position of the loop at the time of break, was read on the micrometer eyepiece. This measurement yields the value of l.

From the above measurements of D and A and the fiber diameter, the tensile stress at the base of the loop can be calculated from Eq. (2). The tensile strength at the actual break point is obtained from Fig. 5, a plot of Eq. (24).

RESULTS

Measurements were made on continuous glass fibers when dry (i.e., not lubricated) and when lubricated with oil applied during the drawing process. Table I gives a summary of the results obtained when using the semi-automatic balance on looped fibers, and a Scott Serigraph on straight fibers. Column 1 shows the type of fiber, column 2 the number of samples tested, column 3 the mean fiber diameter, and column 4 the average deviation from the mean (a.d.). Column 5 shows the arithmetic mean tensile strength, σ_m (at the minimum radius of curvature), column 6 the highest, and column 7 the lowest value of tensile strength and column 8 the average deviation from the mean. Columns 9 to 12 show the corresponding values for the percent extension (also calculated at the minimum radius of curvature), columns 13 to 16 the corresponding values for Young's modulus and column 17 the method.

It is seen that the tensile strength of the dry looped fibers of 20 microns diameter is in average more than twice that of the straight dry fibers. For the lubricated fibers of about 12 microns diameter, the tensile strength of the looped fibers is more than 2½ times that of the straight fibers. No comparison of the extension and Young's modulus could be made between the looped fibers tested on the balance and the straight fibers tested on the Scott Serigraph since the latter apparatus is not sufficiently sensitive to record the small deformation occurring in glass. Previous measurements on straight fibers,† showed the ultimate tensile strain in straight fibers to be one-half to one-third that attained in looped fibers. This ratio is roughly equal to the ratio of tensile strengths obtained by the two methods, so that Young's modulus is about the same for looped and straight fibers.

The straight fibers show an increase in tensile strength with decreasing fiber length. The dry fibers below 1 in. in length are in average 18 percent stronger than those over 1 in. long, and the shorter lubricated fibers are 34

† The straight fiber was broken by applying tension with a calibrated coil spring, and the extension observed with a microscope.

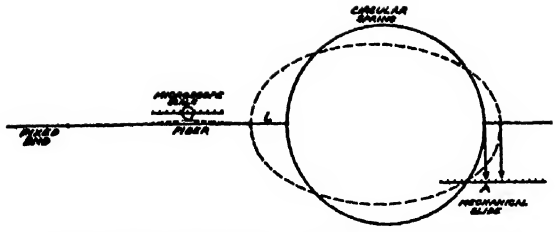

FIG. 3. Schematic diagram of loop break point test.

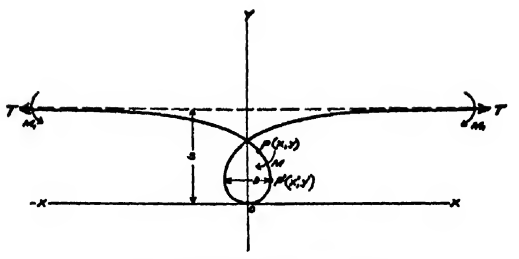

FIG. 4. Diagram of looped fiber.

percent stronger. Straight fibers about 1 mm long would presumably have about the same tensile strength as the looped fibers, provided such short straight fibers could be mounted free of injury or initial strain. This was found to be impossible in practice, the losses of fibers even $\frac{1}{4}$ in. long being excessive. The fiber frequently breaks at one of the cemented ends, or the shock at break causes both portions to fly off since the breaking force of a straight fiber is about 1000 times that of a looped fiber. The losses in the straight fiber test were high even for fibers 1 or 2 in. long. The 39 successful tests of straight fibers over 1 in. long were obtained from a total of 65 tests, while only 38 successful tests of fibers less than 1 in. long could be salvaged from a total of 110. The losses in the looped fiber method were negligible.

No trend in tensile strength with fiber diameter could be observed, because the variation due to flaws was so large. When the tensile strength of the looped dry fibers was plotted against fiber diameter (which ranged from 16 to 32 microns) a typical shot-gun pattern was obtained. The same result was obtained with the lubricated fibers whose diameter ranged from 9 to 16 microns.

Observations of the break point of the loop were made on nine fibers measured with the manually operated spring (Fig. 3). The results, expressed as the ratio of the tensile strength at the break point to the tensile stress at the base, were as follows: 0.999, 0.970, 0.999, 0.890, 0.999, 0.515, 0.997, 0.540, 0.988. These results show that six of the fibers broke very near the base (see Fig. 5), while two of them broke where the tensile strength was little more than one-half the maximum tensile stress attained at the base. In both of the latter tests the diameter of the loop was 0.66 mm, the minimum radius of curvature 0.31 mm and the break occurred within the loop at a distance of about 0.7 mm from its base where the radius of curvature was twice the minimum, or 0.62 mm.

These results show that a region of glass fiber about 1 mm in length can have a tensile strength at least twice as great as that of a nearby region. Additional measurements would probably show a greater variation in the strength of neighboring regions of a fiber. They were not made since this type of measurement is very tedious, and they appear to be unnecessary. The results show nearly a fourfold difference in tensile strength of looped, dry fiber samples. It is to be expected that a sufficiently large number of measurements of the loop break point would eventually show an equally large difference in neighboring regions of some one sample.

DISCUSSION

The results show that the tensile strength of glass fibers increases two to three times when their length is reduced about 75 times. Under the conditions of experiment the variation in the other factors mentioned in the introduction was sufficiently small to have little effect. Although the fibers had a two to one range in diameter the mean diameter was so nearly the same in both types of test that the effect of varying diameter was averaged out. The fibers were taken at random from the same batch and all tests were run at a room temperature of about 75°F and a relative humidity of 45 percent.

Since the fibers were two or three years old and had been roughly handled the observed tensile strength is not representative of the type of glass tested. However, the relative values of tensile strength obtained in the looped and straight fiber tests are in agreement with Anderegg's[2] measurements of the variation of tensile strength with fiber length. Anderegg found that a decrease in length of about 32 times resulted in doubling the tensile strength of 13-micron diameter soda-lime glass fibers. The looped dry fibers (equivalent to a straight fiber about 1 mm long) were $2\frac{1}{4}$ times stronger and the looped lubricated fibers three times stronger than the straight fibers of about 3 in. average length.

The reliability of the 74 tests of looped dry fibers was calculated according to ASTM[5] methods, based on a statistical probability of 0.99. The calculations give tensile strength $\sigma = 2.50 \pm 0.12$ lb./sq. in. (standard

deviation=0.379) and Young's modulus $E=0.825 \pm 0.042$ lb./sq. in. (standard deviation=0.138).

The difference between loading rates in the two tests was relatively small. The loading rate in the straight fiber test was constant at 0.12 lb./min. The rate of stressing, however, varied between 10^5 and 10^6 lb./sq. in./min. depending on the fiber diameter and Young's modulus. The maximum rate of stressing (i.e., in the outermost layer of the fiber) at any time during the looped fiber test can be obtained by differentiating the tensile stress, σ, with respect to the time: [see Eqs. (3) and (4)]

$$\frac{d\sigma}{dt}=E\frac{de}{dt}=-E\frac{e}{L}\frac{dL}{dt}=-\frac{\sigma}{L}\frac{dL}{dt}. \tag{7}$$

dL/dt is negative and constant at 50 chart cm per min. Therefore:

$$d\sigma/dt=50\sigma/L \text{ lb./sq. in./min.} \tag{8}$$

where L is to be measured in cm on the chart as described above. Thus the rate of stressing increases as the test progresses directly with the tensile stress and inversely with the loop diameter.

For example, in Fig. 2 the ultimate tensile stress in this test was 2.70×10^5 lb./sq. in. and the corresponding value of L is seen to be 13.6, from which $d\sigma/dt=10^6$ lb./sq. in./min. At an earlier time during the test when $L=28.7$, $\sigma=1.3\times10^5$ and $d\sigma/dt=2.3\times10^5$. The rate of stressing is of course very small initially but during the latter half of the loop test the order of magnitude of the rate is the same as in the straight fiber test. Anderegg[2] found that a fourfold increase in the rate of stressing of 44-micron diameter soda-lime glass fibers produced no significant increase in the tensile strength. Baker and Preston[6] found that a tenfold increase in the duration of a constant load caused a 15 percent decrease in the bending strength of ¼-in. diameter soda-lime glass rods.

As already described, observation of the actual break point of the loop showed non-uniformity of strength over a very short section of a fiber. In most tests the tensile strength was calculated at the minimum radius of curvature, although the loop may have broken at some other point where the ultimate stress was less. In such cases the calculated value of stress was attained at the minimum radius of curvature without breaking at that point, so that this value represents a minimum stress for this point of the fiber. Also, it may be mentioned that the straight fiber losses occurred equally at both high and low loads so that the values reported are a fair average of the tensile strength obtainable in straight fiber tests.

DERIVATION OF EQUATION OF LOOP

Figure 4 shows a diagram of the looped fiber drawn with the base of the loop, the point of minimum radius of curvature, at the origin, O. The loop is maintained by the equal and opposite bending moments, M_1, and tensions, T, exerted at each cemented end by the supports. T acts along a line parallel to the X axis and at a distance, s, from it. In addition there is an equal and opposite torque at each end, exerted about the line through T, to keep the loop from untwisting. As shown below this torque is so small it may be neglected. The looped fiber is symmetrical about the Y axis.

At any point, $P(x, y)$, of the fiber, let the bending moment be M. The portion of the fiber between P and the left cemented end is maintained in equilibrium by the clockwise moment, M, exerted by the remainder of the fiber, and the counterclockwise moments, M_1, and $T(s-y)$.

Therefore,

$$M=M_1+T(s-y). \tag{9}$$

The bending moment $M=EI/R$, where R is the radius of curvature of the fiber at P, E is Young's modulus of elasticity and I is the moment of inertia of the cross section of the fiber.

When the fiber is long compared to the diameter of the loop the bending moment, M_1, at the end of the fiber is negligibly small (see below). Therefore, writing R in

[6] T. C. Baker and F. W. Preston, J. App. Phys. 17, 170 (1946).

terms of the differential coefficients, Eq. (9) becomes:

$$\frac{1}{R}=\pm\frac{pdp/dy}{(1+p^2)^{\frac{1}{2}}}=b(s-y), \tag{10}$$

where $p=dy/dx$ and

$$b=T/EI. \tag{11}$$

The positive sign on the left side of Eq. (10) applies from 0 to P' (at which point $dy/dx=\infty$), where R is positive; and the negative sign applies from P' to the end of the fiber, where R is negative.

Integrating Eq. (10) gives:

$$\pm 1/(1+p^2)^{\frac{1}{2}}=\tfrac{1}{2}by^2-bsy+c. \tag{12}$$

At the origin $y=0$ and $dy/dx=p=0$. Therefore, using the positive sign, $c=1$.

At the cemented end $y=s$ and $dy/dx=0$. Therefore, using the negative sign:

$$b=4/s^2 \tag{13}$$

so that Eq. (12) becomes:

$$\pm 1/(1+p^2)^{\frac{1}{2}}=(2y^2/s^2)-(4y/s)+1. \tag{14}$$

Integrating Eq. (14) gives:

$$x=\pm s\left(\frac{2y}{s}-\frac{y^2}{s^2}\right)^{\frac{1}{2}}\mp\frac{s}{4}\log\frac{1+(2y/s-y^2/s^2)^{\frac{1}{2}}}{1-(2y/s-y^2/s^2)^{\frac{1}{2}}}. \tag{15}$$

The upper signs apply to the left half of the curve and the lower signs to the right half. Equation (15) has been plotted and its form found to fit closely to the observed form of the loop as shown below.

The measurement of the tensile strength by the method described, requires the length of the fiber, l, which is found to be:

$$l=-\frac{s}{4}\log\frac{1+(2y/s-y^2/s^2)^{\frac{1}{2}}}{1-(2y/s-y^2/s^2)^{\frac{1}{2}}}. \tag{16}$$

Equation (16) gives the length of the fiber, measured from the origin along the fiber to a point having the ordinate y.

Equation (2) gives the tensile strength in terms of L, the total length of the fiber minus the distance between the ends of the looped fiber. The length of the fiber between the points (x, y) and $(-x, y)$ is $2l$, given by Eq. (16). The linear distance between these two points is $2x$, given by Eq. (15). Subtracting Eq. (15) from Eq. (16) and multiplying by 2 gives:

$$2l-2x=2s[(2y/s)-(y^2/s^2)]^{\frac{1}{2}} \tag{17}$$

for negative values of x on the left half of the curve and for positive values of x on the right half of the curve.

The difference, $2l-2x$, is equal to the distance L when $y=s$, the ordinate of the end of the fiber. Although, from Eqs. (15) and (16) the abscissa of the end of the fiber and the length of the fiber are both infinite, their difference is finite as shown by Eq. (17). In any practical case the equations apply when the length of the fiber is more than 10 times the diameter of the loop.

From Eq. (17) when $y=s$,

$$2l-2x=2s=L. \tag{18}$$

Equation (4) for Young's modulus of elasticity can now be obtained from Eqs. (11), (13), and (18), noting that for a fiber of circular cross section of diameter d, the moment of inertia $I=\pi d^4/64$.

In the outermost layer of the fiber at a point where the radius of curvature of the loop is R, the extension $e=r/R$.

The minimum radius of curvature, R_m, which occurs at the base of the loop, is obtained from Eq. (10) when $y=0$, i.e.,

$$R_m=1/bs=s/4=L/8 \tag{19}$$

so that the maximum tensile strain in the fiber is:

$$e=r/R_m=8r/L=4d/L \tag{20}$$

corresponding to Eq. (3).

Equation (2) for the maximum tensile stress attained in the loop is given by the product of Eqs. (3) and (4).

The break point of the loop is obtained with the aid of Eq. (18) which shows that the length of the looped fiber is $2s$ greater than the distance between its ends. This means that if the looped fiber were broken at the base (the origin), each straightened portion would extend a distance, s, beyond the Y axis.

Suppose the fiber broke at a distance, l, from the origin, where l is given by Eq. (16). Solving Eq. (16) for y gives:

$$y=s\pm 2se^{(2l)/s}/(e^{(4l)/s}+1). \tag{21}$$

From Eq. (10) when $y\neq 0$, the strain at any point other than the base is:

$$e=(2d/s^2)(s-y). \tag{22}$$

Therefore from Eq. (4), (21), and (22) the maximum tensile stress, σ_l, at a point in the loop a distance, l, from the origin is:

$$\sigma_l=\frac{32TL}{\pi d^3}\,\frac{e^{(2l)/s}}{e^{(4l)/s}+1}. \tag{23}$$

From Eqs. (2) and (23) the ratio of the tensile strength at the break point to the tensile stress at the base is:

$$\sigma_l/\sigma=\frac{2e^{(2l)/s}}{e^{(4l)/s}+1}. \tag{24}$$

Figure 5 shows a plot of Eq. (24) for values of l/s from 0 to 2.

In making the measurements of the loop break point the diameter, D, of the loop is measured across the loop between the points, $y=y'$, where $dy/dx=\infty$ (see Fig. 4). Therefore from Eq. (14):

$$y'=s(1-1/\sqrt{2}) \tag{25}$$

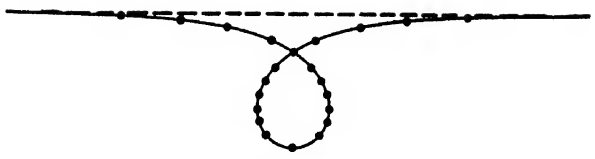

FIG. 6. Photograph of glass fiber loop. Full line—photograph. Circles—calculated points.

so that from Eq. (15), $x'=0.2664s$. Therefore, since $x'=\frac{1}{2}D$

$$D=0.5328s. \tag{26}$$

The assumption that M_1, the moment at the cemented ends, is zero is found to be justified by observation. Since $M=EI/R$, this assumption means that the fiber is straight at the ends. Also from Eq. (15) when $y=s$ this assumption requires a fiber of infinite length. Practically this means that the fiber should be long compared to the size of the loop.

These conditions have been found to be closely maintained in the loops observed. The end portions of the fiber lie along the same straight line to a considerable distance from the cemented ends. (See Fig. 6.) With a fiber 2 cm long the cemented end is located at a distance from the loop of at least 10 times its diameter.

At any point in the fiber, the shearing force, $F=dM/dy=-T$ [from Eq. (9)]. The maximum shear stress occurs at the point P' (Fig. 4) where the shearing force acts perpendicular to the axis of the fiber. At this point the average shear stress, $t=T/\pi r^2$. For a fiber of 10 microns radius and a breaking tension of 50 mg the average shear stress is 225 lb./sq. in. The maximum shear stress, which occurs at the center[7] of the fiber is 310 lb./sq. in. This is negligible compared to the tensile strength of 10^5 lb./sq. in. or more.

The maximum shear in the fiber resulting from the one and one-half to two turns given the fiber to form the loop is produced by one-half to one turn, since one turn is taken out when the loop forms. For a 10-micron radius fiber about 2 cm long the maximum shear strain produced by one turn is 0.3 percent. In most tests one-half residual turn is sufficient to maintain a loop in a fiber 4 or 5 cm long, for which the torsional shear would be less than 0.1 percent.

The one-half turn remaining in a fiber is maintained by equal and opposite couples, C, acting about the cemented ends. The couple, $C=fks$, where f is the normal force between the two halves of the loop at the cross-over point, and ks is the ordinate of the cross-over point. k is a constant $=0.708$. For constant torque in the fiber, C is constant so that the normal force $f=$ const. $\times 1/s$. It was observed that the resulting friction force at the cross-over point was appreciable at the beginning of a test. However, toward the end of the test the friction becomes negligible compared to the tension since the latter increases as $1/s^2$ [Eq. (4)—assuming constant Young's modulus] while the friction force increases as $1/s$. The friction was measured by contracting the loop to near the break and then reversing the direction of the loading rod so as to run the test backward and expand the loop. The friction is added to the tension while the loop is being contracted and subtracted while the loop is being expanded. As a result the return curve tends to lie slightly above the initial curve (of the type shown in Fig. 2), the divergence being significant only at the smaller values of T. In this way the force of friction was found to be about one percent of the tension at or near the break.

[7] S. Timoshenko, *Theory of Elasticity* (McGraw-Hill Book Company, Inc., New York, 1934), p. 290.

EXPERIMENTAL CHECK OF LOOP EQUATION

The ratio, $s/D=1.877$ [Eq. (26)] was measured using glass and Pyrex fibers. The size of the loop was varied by varying the tension over a range of values less than the breaking tension. Using two 20-micron diameter glass fibers, the average of ten measurements gave $s/D=1.887\pm0.005$, 0.5 percent higher than the correct value. Using two 6-micron diameter Pyrex fibers the average of seven measurements gave $s/D=1.870\pm0.015$, 0.4 percent less than the correct value.

A photograph of a 20-micron diameter glass fiber having a loop of 2 mm diameter is shown in Fig. 6. At the edges of the photograph the ends of the fiber are seen to be practically straight and lie on the same straight line (the dashed line drawn to pass through the cemented ends which lie outside the photograph at a distance of one and one-half times the total breadth of the photograph). The ratio $s/D=1.88$ as nearly as can be measured on the photograph. Using the measured value of s, the form of the curve was calculated from Eq. (15). The plotted points lie exactly on the curve as nearly as could be drawn.

ACKNOWLEDGMENT

The writer is greatly indebted to Mr. Paul Greebler of the Physics Section for his assistance in developing the method, and to Mr. H. R. Pittenger of the Physics Section and to Messrs. D. T. Colton, Jr. and Stewart Hayes (formerly of the Physics Section) for running the tests.

Magnetic Field Calculations for Large Cross-Section Cloud-Chamber Coils*

H. W. Koch†
Physics Department, University of Illinois, Urbana, Illinois
(Received September 6, 1949)

A method is described and equations are presented which permit the calculation of the magnetic field characteristics of large cross-section air core coils. The method is applied to the determination of the field non-uniformities on the median plane to be expected with annular cloud-chamber coils of rectangular cross section. The field non-uniformity results are provided in graph form to facilitate the design of cloud-chamber coils.

INTRODUCTION

LARGE, air-core magnetic field coils of the rectangular cross-section type shown in Fig. 1(b) facilitate the study of high energy nuclear particles in the 10 and 100 million electron volt energy ranges. The coils have no windings on the median plane and are used in conjunction with cloud chambers where light and particle beams are admitted on the median plane.

This paper will describe calculations of the magnetic field distributions produced by cloud-chamber coils of large cross-sectional area. Greatest emphasis is placed on the field distribution on the median plane and within the inner radius of the coil. For this region the calculations are presented in a table form. Also, curves are given to allow the determination of the field non-uniformity for almost any rectangular coil configuration with speed and a fair degree of accuracy.

In addition, general equations are derived which permit the evaluation of the absolute magnitude of fields anywhere on the median plane, outside as well as inside the coil bounds. The result is applicable to a wider range of instrument than the cloud chamber: for example, to particle accelerators or to particle analyzers.

To date, the design work on air core coils has been concerned largely with the production of relatively weak, uniform fields for cloud-chamber studies. Since the power requirements were usually small, the field region investigated was chosen close to the axis of the coils. The theoretical methods[1] were based on the assumption that the coil cross section was small compared to the coil radius.

Two general procedures for the small cross-section calculations have been used. In the first method, as employed by Maxwell,[2] the necessary correction due to the cross section was made by the use of Taylor's theorem. The field was expanded to give

$$H=H_0+\frac{1}{24}\left(\xi^2\frac{\partial^2 H_0}{\partial x^2}+\eta^2\frac{\partial^2 H_0}{\partial y^2}\right)+\cdots,$$

where H_0 is the value of the field at the point (x, y) due to a number of coincident circular turns of wire and H is the field at the same point due to the same number of turns of wire spread over a rectangular cross section of axial width ξ and radial depth η.

Gray,[3] Dwight,[4] and Ruark and Peters[5] employ the Maxwell method for calculating fields produced by coils of small cross section. Ference, Shaw, and Stephensen[6] have used Maxwell's method as modified by Lyle.[7]

The second method for handling small cross sections was to integrate the magnetic scalar potential over the area of the coil. Dwight[4] described this method in detail for rectangular cross-section coils. Von Zeipel[8] performed the integration over a cross section which is limited by coaxial cylinders and concentric cones coaxial

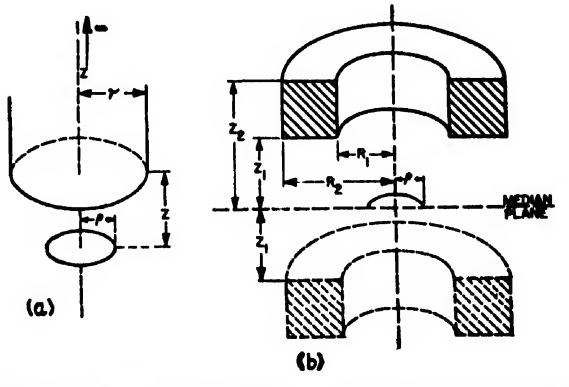

FIG. 1. (a) A semi-infinite solid cylindrical coil of zero core area. (b) The solid rectangular coil above the median plane represents one half of a pair of cloud-chamber coils. It is treated by the addition and substraction of four semi-infinite coils of the type shown in (a).

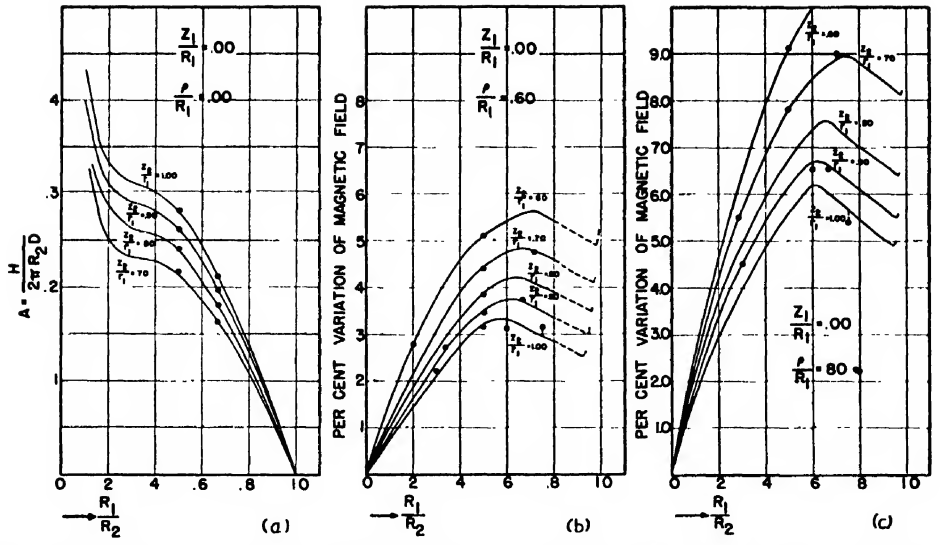

FIG. 2.

FIGS. 2–8. (a) Z component of the magnetic field intensity at $\rho=0$ in gauss-cm per abampere. (b) Z component of the magnetic field variation within a circle of radius ρ for $\rho/R_1=0.6$. The solid points represent calculated points as obtained from Table I. As can be seen, the curve shapes were only partially derived from the points, because of the inaccuracy associated with the points. The specific shapes were obtained from multiple plots and not from individual plots as presented here. The data obtainable from the (b) curves should be accurate to ± 0.1 percent. (c) Z component of the magnetic field variation within a circle of radius ρ for $\rho/R_1=0.8$. The data obtainable from the (c) curves should be accurate to ± 0.2 percent.

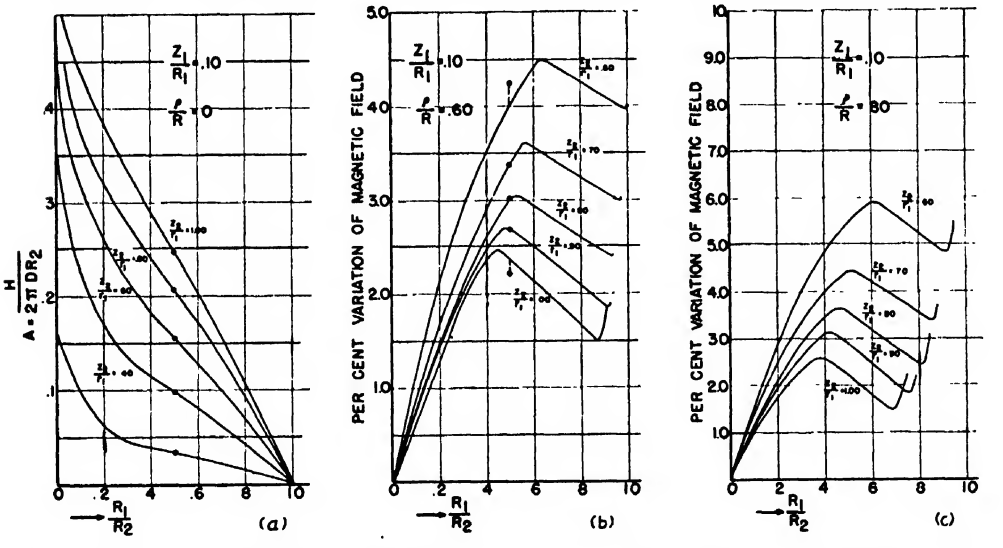

FIG. 3. (See Fig. 2 for caption.)

to the cylinders. Von Zeipel constructed coils to check the calculations.

Foss wrote two papers on the design of air core coils in which the integration procedure is used.[9]

For points close to the air core coils or for points between the coils, the calculations described have limited application because of the slow convergence of the series expressions for the magnetic field or because of the difficulty of integrating exactly over a desired cross section.

Also, calculations are not available on the magnetic field distribution of coils for which the ratio of the inner and outer diameters differ considerably from unity and for which the axial coil height becomes comparable to the radius.

This report will describe a different method for calculating magnetic field distributions, which makes it particularly adaptable to large cross-section coils. The method adopted is to find the field distribution due to a semi-infinite solid cylindrical coil of zero core diameter and unit winding density[10] as shown in Fig. 1(a). By the addition and subtraction of the field of four such semi-infinite coils the field distribution due to the finite hollow coil of Fig. 1(b) can be calculated. The results are still obtained from series expressions. However, the con-

[10] The number of ampere turns per unit area of channel section will be called D.

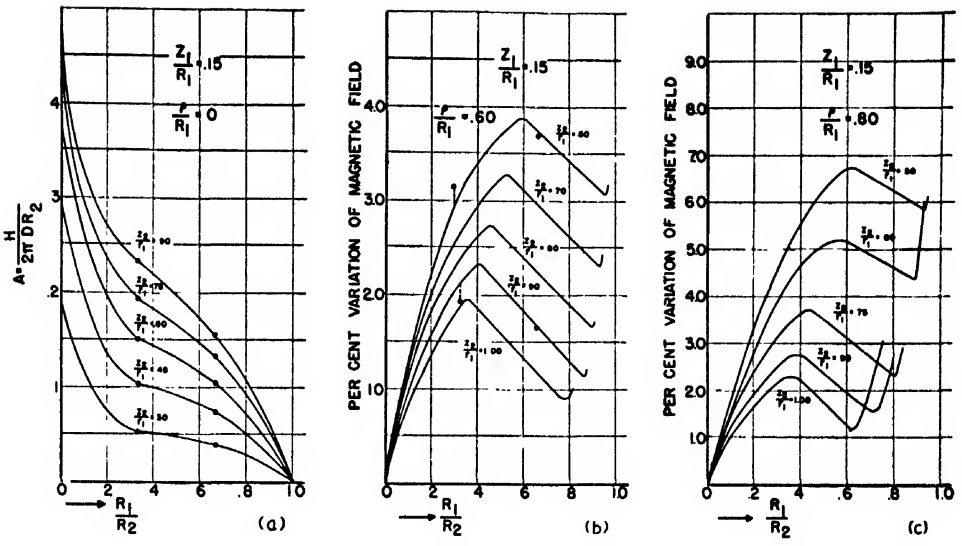

FIG. 4. (See Fig. 2 for caption.)

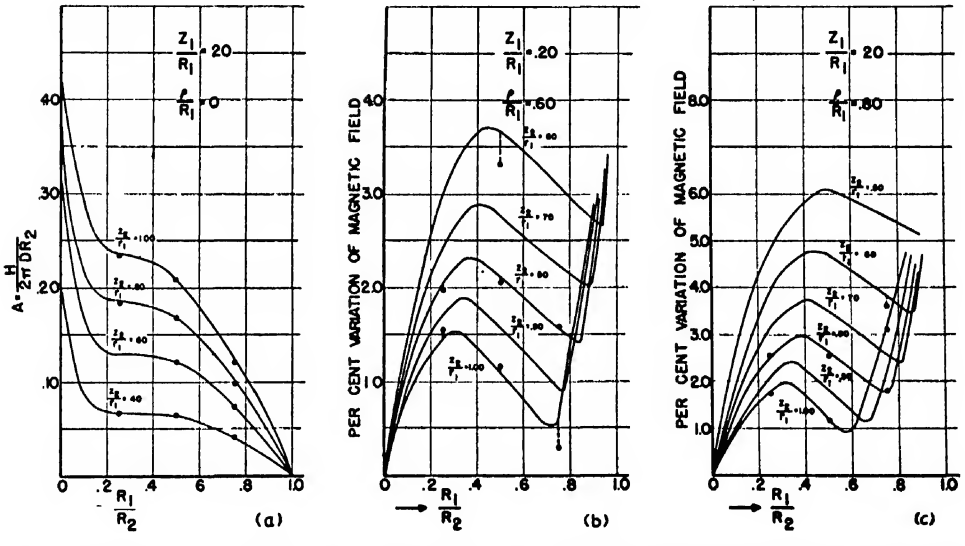

FIG. 5. (See Fig. 2 for caption.)

vergence is reasonable and permits, as an example, the non-uniformity of fields within a measuring circle ρ to be obtained to an accuracy of the order of ± 0.2 percent for ρ's as large as $\rho/R_1 = 0.8$.

The general technique to be described was first used by Butterworth[11] for calculating the mutual inductances for large cross-section coils. The procedure to be followed is very similar to that used by Cockroft[12] in the derivation of his equations. However, the present calculations give magnetic field distributions, while Cockroft used Butterworth's method to determine the mutual inductances and the expected mechanical forces in "Kapitza-type" coils.

THEORY

Consider a one turn coil of radius ρ at a distance of z from the end plane of the semi-infinite, solid coil of radius r, as in Fig. 1(a). The magnetic field in the z direction at any point on the circumference of the one turn coil will be

$$H_z = -\partial\Omega/\partial z, \tag{1}$$

where Ω is the magnetic scalar potential of the solid coil, which must satisfy Laplace's equation at all points external to the solid coil. For this case of circular symmetry about the z axis Laplace's equation can be written as

$$\frac{\partial^2\Omega}{\partial\rho^2} + \frac{1}{\rho}\frac{\partial\Omega}{\partial\rho} + \frac{\partial^2\Omega}{\partial z^2} = 0. \tag{2}$$

A solution of Eq. (2) is

$$\Omega = \int_0^\infty A(\lambda) e^{-\lambda z} J_0(\lambda\rho)\, d\lambda, \tag{3}$$

where $J_0(\lambda\rho)$ is the zero-order Bessel function given by

$$J_0(\lambda\rho) = 1 - \frac{(\lambda\rho)^2}{2^2} + \frac{(\lambda\rho)^4}{2^2 4^2} - \frac{(\lambda\rho)^6}{2^2 4^2 6^2} + \cdots. \tag{4}$$

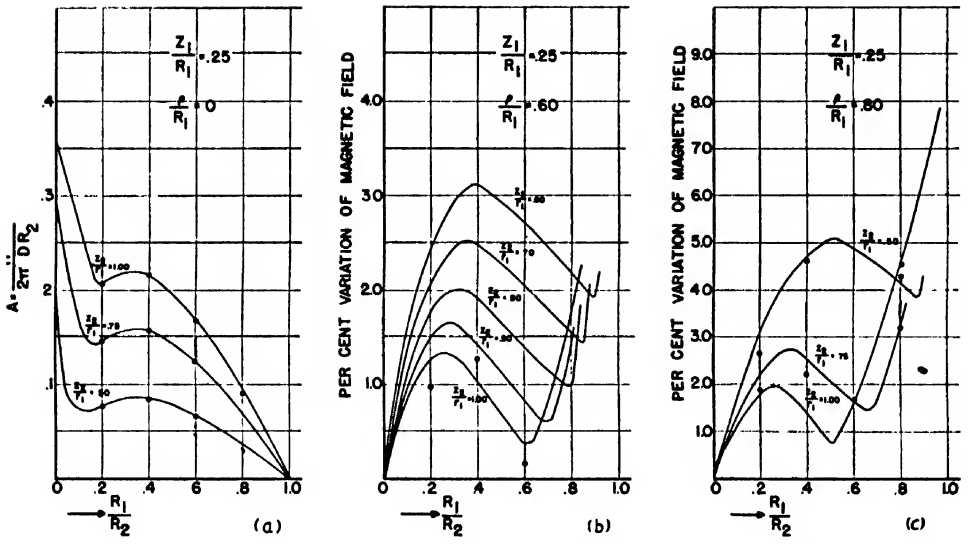

FIG. 6. (See Fig. 2 for caption.)

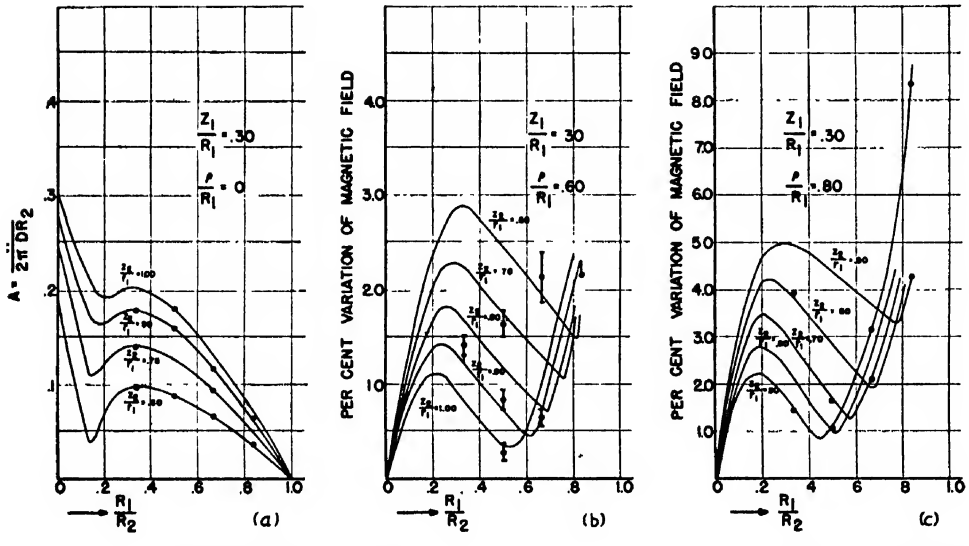

FIG. 7. (See Fig. 2 for caption.)

Case I—For $\rho/r \leq 1$

Since, when $\rho=0$, Eq. (3) reduces to

$$\Omega_0=\int_0^\infty A(\lambda)e^{-\lambda z}d\lambda, \tag{5}$$

Eq. (1) can be written as

$$H_z=\sum_{n=0}^{\infty}(-1)^{n+1}(\rho/2)^{2n}[1/n!]^2\partial^{2n+1}\Omega_0/\partial z^{2n+1}. \tag{6}$$

Ω_0 is the magnetic potential along the axis due to the semi-infinite coil of radius r and D abampere turns per centimeter squared. This is given by

$$\Omega_0=2\pi\int_z^\infty\int_0^r\left[1-\frac{z}{(y^2+z^2)^{\frac{1}{2}}}\right]Ddzdy \tag{7}$$

$$=\pi r^2D\left\{\frac{Z^2}{r^2}\log_e\left(\frac{1+\xi}{z/r}\right)+\xi-\frac{2z}{r}\right\}, \tag{8}$$

where $\xi=[1+(z^2/r^2)]^{\frac{1}{2}}$.

A. For $\rho/r \leq 1$ and $z/r > 1$

The integrand in (7) can be expanded for large z to give:

$$\frac{\Omega_0}{2\pi D}=\sum_{m=0}^{\infty}(-1)^m\frac{(2m+2)!}{[2^{m+1}(m+1)!]^2}\times\frac{1}{(2m+3)(2m+1)}\frac{r^{2m+3}}{z^{2m+1}}. \tag{9}$$

Therefore H_z becomes

$$\frac{H_z}{2\pi D}=\sum_{n=0}^{\infty}(-1)^{n+1}\left(\frac{\rho}{2}\right)^{2n}\left[\frac{1}{n!}\right]^2\times\frac{\partial^{2n+1}}{\partial Z^{2n+1}}\times\left\{\sum_{m=0}^{\infty}(-1)^m\frac{(2m+2)!}{[2^{m+1}(m+1)!]^2}\times\frac{r^{2m+3}/z^{2m+1}}{(2m+3)(2m+1)}\right\}. \tag{10}$$

B. For $\rho/r \leq 1$, $z/r < 1$, and $\rho/z < 1$

H_z from Eq. (6) is

$$H_z = -\frac{\partial \Omega_0}{\partial z} + \frac{\rho^2}{2^2}\frac{\partial^3 \Omega_0}{\partial z^3} - \frac{\rho^4}{2^2 2^4}\frac{\partial^5 \Omega_0}{\partial z^5} + \frac{\rho^6}{2^6 3^2 2^2}\frac{\partial^7 \Omega_0}{\partial z^7} - \frac{\rho^8}{2^8 4^2 3^2 2^2}\frac{\partial^9 \Omega_0}{\partial z^9} + \cdots \quad (11)$$

where the terms $\partial^{2n+1}\Omega_0/\partial z^{2n+1}$ can be determined directly from (8) for small z. It is convenient to separate Ω_0: $\Omega_0 = \Omega_1 + \Omega_2$ where

$$\Omega_1 = \pi D[z^2 \log_e\{r(1+\xi)\} + r^2\xi - 2zr]$$

and

$$\Omega_2 = -\pi D z^2 \log_e z. \quad (12)$$

A substitution of the derivatives of Ω_1 and Ω_2 into (11) results in:

$$\frac{H_z}{2\pi r D} = 1 + \frac{z}{r}\log_e\frac{z}{r} - \frac{z}{r}\log_e(1+\xi) - \left(\frac{\rho}{r}\right)^2 \times \frac{1}{4(z/r)\xi^3} - \left(\frac{\rho}{r}\right)^4 \times 1.5625 \times 10^{-2}\left\{\left(\frac{z}{r}\right)\left(\frac{3}{\xi^5} - \frac{15}{\xi^7} + \frac{1}{\xi^3} - \frac{1}{\xi(1+\xi)^2}\right)\right\} + \left(\frac{\rho}{r}\right)^6 \times 4.3403 \times 10^{-4} \times \left\{\frac{z}{r}\left(\frac{45}{\xi^7} - \frac{735}{\xi^9} + \frac{945}{\xi^{11}} + \frac{9}{\xi^5} + \frac{9}{\xi(1+\xi)^2} - \frac{6}{(1+\xi)^3} - \frac{3}{\xi^3}\right)\right\} - \left(\frac{\rho}{r}\right)^8 \times 2.0345 \times 10^{-5} \times \left\{\frac{z}{r}\left(\frac{525}{\xi^9} - \frac{18585}{\xi^{11}} + \frac{75}{\xi^7} - \frac{45045}{\xi^{15}} + \frac{58905}{\xi^{13}} - \frac{15}{\xi^5} + \frac{15}{\xi^3} - \frac{15}{\xi(1+\xi)^2} - \frac{30}{\xi(1+\xi)^3} - \frac{39}{\xi(1+\xi)^4}\right)\right\} + \left(\frac{\rho}{r}\right)^4 \times 3.1250 \times 10^{-2} \times \frac{1}{(z/r)^3} \times \left\{1 - 3.333 \times 10^{-1}\left(\frac{\rho}{z}\right)^2 + 1.563 \times 10^{-1}\left(\frac{\rho}{z}\right)^4 - 8.75 \times 10^{-2}\left(\frac{\rho}{z}\right)^6 + 5.469 \times 10^{-2}\left(\frac{\rho}{z}\right)^8 - 3.683 \times 10^{-2}\left(\frac{\rho}{z}\right)^{10} + 2.618 \times 10^{-2}\left(\frac{\rho}{z}\right)^{12} - 1.94 \times 10^{-2}\left(\frac{\rho}{z}\right)^{14} \cdots\right\}. \quad (13)$$

C. For $\rho/r \leq 1$, $z/r < 1$, and $\rho/z > 1$

For z less than ρ, the last bracketed term in (13) ceases to converge. This term is derived from the successive derivatives of Ω_2. Thus a distribution of poles must be found which gives the distribution of field

$$H_2 = \sum_{n=0}^{\infty}(-1)^{n+1}\left(\frac{\rho}{2}\right)^{2n}\left[\frac{1}{n!}\right]^2 \times \frac{\partial^{2n+1}}{\partial z^{2n+1}}(-\pi D z^2 \log_e z) \quad (14)$$

in regions for which $z < \rho$. To do this a method similar to that developed by Butterworth is used in which the magnetic field due to an axial distribution of poles extending from $z=0$ to $z=c$ with density $(-\pi z^2 D)$ is found. The field can be shown to be

$$\frac{H_2}{\pi D} = 3z + c - 2(\rho^2+z^2)^{\frac{1}{2}} - 2z\log_e\left[\frac{c+z+(\rho^2+(z+c)^2)^{\frac{1}{2}}}{c+z}\right] + 2z\log_e[z+(\rho^2+z^2)^{\frac{1}{2}}] + \frac{z^2}{(c+z)} - c - \frac{1}{\pi D}F(n, \rho, 1/c). \quad (15)$$

Since H_2 and Ω_2 are independent of the position of c, take $c=\infty$. For $c=\infty$, $F(n, \rho, 1/c)=0$ and

$$\frac{H_2}{\pi D} = 3z - 2(\rho^2+z^2)^{\frac{1}{2}} + 2z\log_e\left[\frac{z+(\rho^2+z^2)^{\frac{1}{2}}}{2}\right]. \quad (16)$$

Equation (16) can now be applied to give H_z for $z < \rho$. Equation (13) for this range of z's is replaced by

$$\frac{H_z}{2\pi r D} = 1 - \frac{z}{r}\log_e(1+\xi) + \frac{z}{r}\log_e\left[\frac{(z/r)+((\rho/r)^2+(z/r)^2)^{\frac{1}{2}}}{2}\right] - \left[\left(\frac{\rho}{r}\right)^2+\left(\frac{z}{r}\right)^2\right]^{\frac{1}{2}} + \left(\frac{\rho}{r}\right)^2 \times 0.25\left\{\frac{z}{r}\left(\frac{1}{\xi(1+\xi)} + \frac{1}{\xi^3}\right)\right\} - \left(\frac{\rho}{r}\right)^4 \times C + \left(\frac{\rho}{r}\right)^6 \times D - \left(\frac{\rho}{r}\right)^8 \times E, \quad (17)$$

where C, D, and E are terms which correspond to the ones in similar positions in Eq. (13).

Case II—For $\rho/r>1$

Again the methods found in Cockroft's paper can be applied. The flux through a coil of radius ρ is

$$\phi_\rho=\int_0^\rho 2\pi\rho H_z d\rho=M_c I_c, \tag{18}$$

where M_c is the mutual inductance of the semi-infinite coil c in which the current I_c flows. Therefore,

$$H_z=(1/2\pi\rho)(\partial M_c/\partial\rho)\times I_c. \tag{19}$$

However,

$$M_c i_\rho=\int_0^r\int_z^\infty \phi_r D dr dz, \tag{20}$$

where

$$\phi_r=-\int_0^r 2\pi y\frac{\partial\Omega}{\partial z}dy=-\pi r^2\sum_{n=0}^{\infty}(-1)^n\left(\frac{r}{2}\right)^{2n}\times\frac{1}{n!(n+1)!}\frac{\partial^{2n+1}\Omega_0}{\partial z^{2n+1}}. \tag{21}$$

A substitution of (21) in (20) results in

$$M_c i_\rho=\pi D r^2\sum_{n=0}^{\infty}\frac{(-1)^n}{2^{2n}}\frac{r^{2n}}{2n+3}\frac{1}{n!(n+1)!}\frac{\partial^{2n}\Omega_0}{\partial z^{2n}}\Big|_z. \tag{22}$$

Therefore, from (19),

$$H_z=\frac{Dr^3}{2\rho}\sum_{n=0}^{\infty}\frac{(-1)^n}{2^{2n}}\frac{r^{2n}}{2n+3}\frac{1}{n!(n+1)!}\frac{\partial^{2n}}{\partial z^{2n}}\left[\frac{\partial\Omega_0}{\partial\rho}\right] \tag{23}$$

where Ω_0 is the magnetic potential of a single turn along the axis and is given by

$$\Omega_0=2\pi\left\{1-\frac{z}{(\rho^2+z^2)^{\frac{1}{2}}}\right\}. \tag{24}$$

Since

$$-\frac{1}{2\pi\rho}\frac{\partial\Omega_0}{\partial\rho}=\frac{z}{(\rho^2+z^2)^{\frac{3}{2}}}, \tag{25}$$

H_z is given by

$$H_z=\pi D r^3\sum_{n=0}^{\infty}\frac{(-1)^n}{2^{2n}}\frac{r^{2n}}{2n+3}\frac{1}{n!(n+1)!}\times\frac{\partial^{2n}}{\partial z^{2n}}\left[\frac{z}{(\rho^2+z^2)^{\frac{3}{2}}}\right]. \tag{26}$$

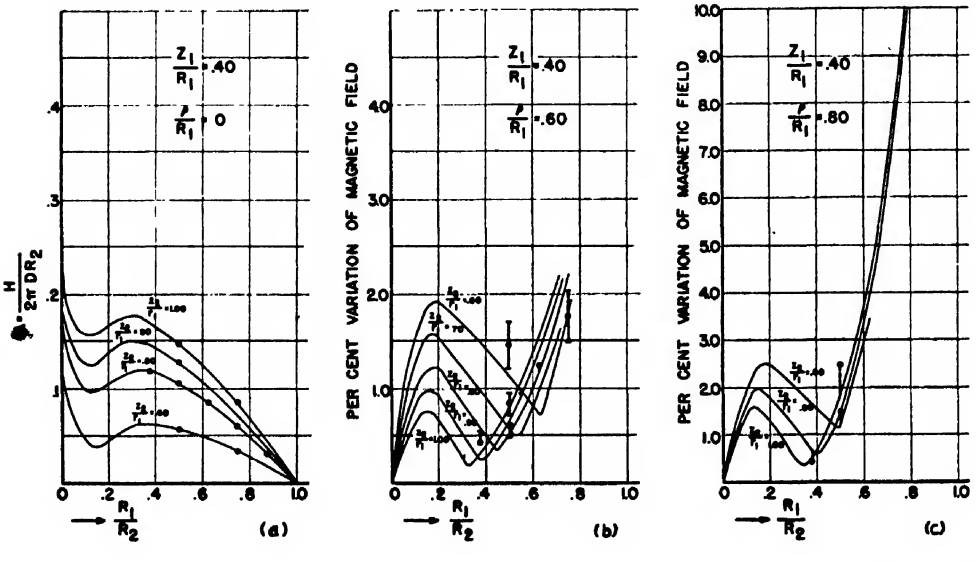

FIG. 8. (See Fig. 2 for caption.)

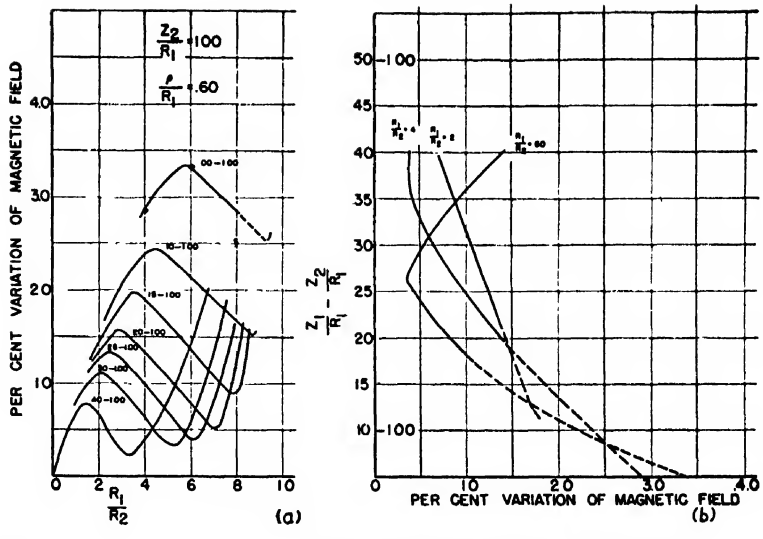

FIG. 9. (a) Percent variation of magnetic field z component variation *versus* R_1/R_2. The constants used for the curves are $\rho/R_1=0.6$ and $Z_2/R_1=1.00$. The variable is Z_1/R_1. The values of Z_1/R_1 and Z_2/R_1 are given above each curve. (b) The data in Fig. 9 (a) have been replotted with the values of Z_1/R_1 and Z_2/R_1 *versus* percent variation of magnetic field.

A. For $\rho/r>1$ and $z/r<1$

Take $\xi=(1+z^2/\rho^2)^{\frac{1}{2}}$. H_z can be evaluated by taking the successive derivatives indicated in (26). The result is

$$\frac{H_z}{\pi Dr^3}=\frac{1}{3}\frac{z}{\rho^3\xi^3}-\frac{3r^2z}{20\rho^6}\left[\frac{2}{\xi^5}-\frac{5}{\xi^7}\right]+\frac{r^4z}{336\rho^7}\left[\frac{120}{\xi^7}-\frac{840}{\xi^9}+\frac{945}{\xi^{11}}\right]-\frac{r^6z}{82{,}944\rho^9}\times\left[\frac{5040}{\xi^9}-\frac{68{,}040}{\xi^{11}}+\frac{187{,}110}{\xi^{13}}-\frac{135{,}135}{\xi^{15}}\right]+\frac{r^8z}{8{,}110{,}080\rho^{11}}\left[\frac{72{,}576}{\xi^{11}}-\frac{1{,}596{,}672}{\xi^{13}}+\frac{7{,}783{,}776}{\xi^{15}}-\frac{12{,}972{,}960}{\xi^{17}}+\frac{6{,}891{,}885}{\xi^{19}}\right]\cdots. \quad (27)$$

B. For $\rho/r>1$, $z/r>1$, and $\rho/z<1$

Ω_0 can be expanded in powers of ρ/z. H_z is then obtained by term by term differentiation of Eq. (26).

$$\frac{H_z}{2\pi rD}=-\frac{1}{6}\left(\frac{r}{z}\right)^2-\frac{1}{4}\left(\frac{r}{z}\right)^4\left(\frac{\rho}{r}\right)^2\left[1+\frac{3}{10}\left(\frac{r}{\rho}\right)^2\right]+\frac{5}{16}\left(\frac{r}{z}\right)^6\left(\frac{\rho}{r}\right)^4\left[1+\frac{6}{5}\left(\frac{r}{\rho}\right)^2+\frac{1}{7}\left(\frac{r}{\rho}\right)^4\right]-\frac{35}{64}\left(\frac{r}{z}\right)^8\left(\frac{\rho}{r}\right)^6\left[1+2.7\left(\frac{r}{\rho}\right)^2+\frac{9}{7}\left(\frac{r}{\rho}\right)^4+\frac{1}{12}\left(\frac{r}{\rho}\right)^6\right]+\frac{105}{256}\left(\frac{r}{z}\right)^{10}\left(\frac{\rho}{r}\right)^8\left[1+\frac{24}{5}\left(\frac{r}{\rho}\right)^2+\frac{36}{7}\left(\frac{r}{\rho}\right)^4+\frac{4}{3}\left(\frac{r}{\rho}\right)^6+\frac{3}{55}\left(\frac{r}{\rho}\right)^8\right]+\cdots. \quad (28)$$

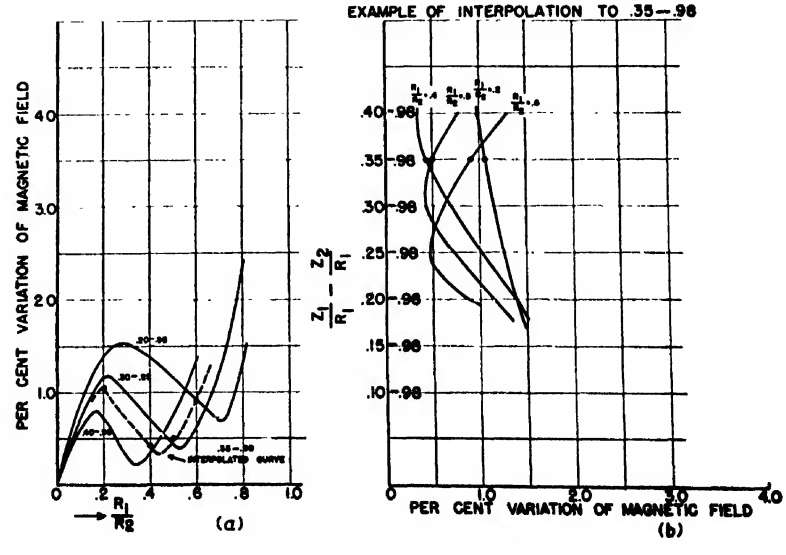

FIG. 10. (a) A plot of percent variation of magnetic field *versus* R_1/R_2 as obtained from the curves in Fig. 10(b). (b) An example of the interpolation to the intermediate values of $Z_1/R_1=0.35$ and $Z_2/R_1=0.98$. The data appearing in this graph were obtained from graphs of Z_1/R_1 and Z_2/R_1 *versus* percent variation of magnetic field [similar to Fig. 10(b)] as obtained from the data in Figs. 2(b), 3(b)···8(b).

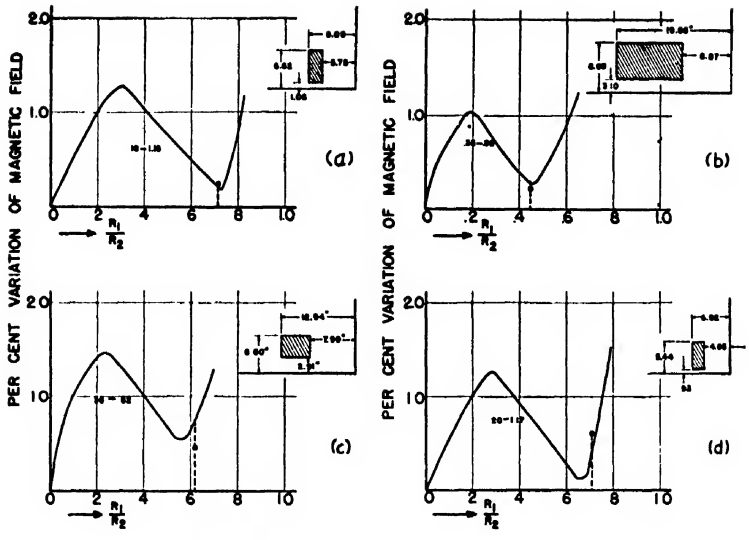

FIG. 11. (a) and (b) The data were obtained from two cloud-chamber coils built at the University of Illinois Betatron Laboratory. (c) The data were obtained from cloud-chamber coils built by Dr. J. R. Richardson in 1939 at the University of Illinois and from the field measurements of Dr. J. A. Phillips, which were privately communicated to the author. (d) The data were obtained from H. R. Crane (see reference 13).

RESULTS

Equations 10, 13, and 17 and Eqs. 27 and 28 permit the calculation of the z component of magnetic field, $H_z(r, z)$, due to a semi-infinite solid coil, whose radius is r and whose distance from the measuring plane is z. Therefore, the field $H_z(R_1, R_2, Z_1, Z_2)$ given by

$$H_z(R_1, R_2, Z_1, Z_2) = H_z(R_2, Z_1) - H_z(R_2, Z_2) - H_z(R_1, Z_1) + H_z(R_1, Z_2)$$

represents the field produced by one finite solid coil of the type shown in Fig. 1(b) and is the result of the addition and subtraction of the fields of four solid semi-infinite coils. The field in the z direction due to two, identical finite coils, one z_1 above the median plane and the other z_1 below the median plane, is twice that due to one coil. There is no radial component of field on the median plane with two coils, because the system is symmetrical.

The five equations enumerated, when the combination principle is used, allow the calculation of the field distributions both inside and outside the bounds of a pair of cloud-chamber coils. Since the present work was primarily concerned with the field distribution close to the axis of cloud-chamber coils and on the median plane, Eqs. 10, 13, and 17 were examined in regions for $\rho/r \leq 0.9$. Table I gives the field values, H_z, divided by $2\pi Dr$ for a semi-infinite solid coil at points for which $0 \leq z/r \leq 1.0$ and $0 \leq \rho/r \leq 0.9$. The values were all calculated using Eq. 13 and they have limited accuracies as indicated by the number of significant figures listed. Each value is in doubt by less than one in the last figure which in most cases has been subtyped.

The $A(=H_z/2\pi Dr)$ values in Table I were used to examine the absolute magnetic fields at $\rho/R_1=0$, 0.6, and 0.8 for a single finite coil whose dimensions are R_1, R_2, Z_1, and Z_2. In order to provide the results in a usable form, curves were drawn which give the fields on the coil axis [Figs. 2(a), 3(a), $\cdots$8(a)], the field variation within the circle of radius, ρ, for $\rho/R_1=0.6$ [Figs. 2(b), 3(b), $\cdots$8(b)], and the field variation for $\rho/R_1=0.8$ [Figs. 2(c), 3(c), $\cdots$8(c)]. The abscissa scale in each set of curves is R_1/R_2. In the case of the field variations within the circle of radius ρ, the percentage variation was obtained by dividing the difference between the maximum and minimum values of field within the circle of radius ρ by twice the mean value of field. All curves of the sets of three graphs (a, b, and c) apply to a constant Z_1/R_1 and a variable Z_2/R_1 as labeled.

The smooth curves, which are based on the calculated plotted points, should be used for predictions of field distributions. The smooth curves are more accurate than the calculated points, which are obtained from the data of Table I, because all the curves in Figs. 2–8 are internally consistent. This was accomplished by replotting the curves of Figs. 2–8 in inverse curves in which Z_2/R_1 was kept constant instead of Z_1/R_1. Any small inaccuracies in the calculated values were immediately apparent. An example of an inverse plot is shown in Fig. 9(a).

The calculated points of Figs. 7(b) and 8(b) were drawn with their estimated accuracies, in order to show the agreements of the points with the smooth curves.

The inverse plots of Figs. 9(a) and (b) are useful also for interpolation to a combination of z_1/R_1 and z_2/R_1, which is an uneven multiple of 0.05 and does not occur specifically in Figs. 2–8. As an example of interpolation, the field variation was desired for a z_1/R_1 equal to 0.35 and a Z_2/R_1 equal to 0.98. The interpolation was accomplished as shown in Figs. 10(a) and (b), which are inverse plots of the data in Figs. 2–8.

DISCUSSION

Little work has been done with Eqs. 27 and 28 because they deal specifically with points outside the coil bounds ($\rho/r > 1$). However, Eqs. 10, 13, and 17, which deal with points where $\rho/r < 1$, have been used extensively and several tests have been made to check their reliability. A crude test of Eq. 6, which forms the basis for Eqs. 10,

13, and 17, was made by differentiating with respect to r and z. The result is the formula for a circular current filament, which can be found in any standard book such as Gray's *Absolute Measurements in Electricity and Magnetism*.

A test was made of the values in Table I by calculating the first and second differences in the ρ/r and z/r directions. This served as a test of the numerical computations.

A test of the theoretically predicted values of field found in Table I and plotted in Figs. 2–9 was made by comparing the field variations predicted with those experimentally determined for four cloud-chamber coils.

The result of the test of the curves is shown in Figs. 11(a), (b), (c), and (d).

Figure 11(b) has drawn on it the cross section of one of the pair of coils to which the curve corresponds. As shown, the z_1/R_1 for the coil is 0.35 and the z_2/R_1 is 0.98. The curve in Fig. 11(b) shows the field non-uniformity for $\rho/R_1=0.6$ as a function of R_1/R_2. The procedure for interpolating to the intermediate values of 0.35 and 0.98 was given in Fig. 10(b). The plotted point for $R_1/R_2=0.45$, in Fig. 11(b) was determined experimentally by measuring the relative field values with two flip coils, each driven by $\frac{1}{4}$ H.P. synchronous motors. The experimental value so obtained is good to an accuracy of ± 0.05 percent. Since the theoretical curve should be accurate to ± 0.1 percent, the agreement of theory with experiment is good.

The only other comments to be made about Figs. 11(a), (c), and (d) are concerned with the comparisons of theory with experiment in the latter two figures. In Fig. 11(c) the experimental value is uncertain because of some uncertainty in the coil dimensions. These were obtained by rough measurements on the completed coil.

In Fig. 11(d) the dimensions were obtained from the drawing in the R.S.I. article by Crane[13] which was assumed drawn to scale.

The following procedure is a summary of the methods exemplified above for calculating the magnetic field characteristics for one annular coil whose dimensions are given by Z_1, Z_2, R_1, and R_2:

1. Calculate the ratios R_1/R_2, Z_1/R_1, and Z_2/R_1.

2. The z component of the magnetic field intensity at $\rho=0$ in gauss-cm per abampere (A) is given on the curves of Figs. 2(a), $\cdots$8(a) as a function of R_1/R_2, Z_1/R_1, and Z_2/R_1. For intermediate values which do not appear on the curves, use the interpolation procedure similar to that used in Fig. 10(a) and (b). D is in abamperes per cm^2 and A is equal to H_s for one coil divided by $2\pi DR_2$. The copper space factor of a non-ideal coil is never 100 percent and the correction factor must be included in the evaluation of the true current density, D.

3. The z component of the magnetic field variation within the circle of radius ρ is given as a function of the coil constants in Figs. 2(b) and (c), 3(b) and (c), $\cdots$8(b) and (c). It is believed that the values obtained from the (b) curves ($\rho/R_1=0.6$) are reliable to ± 0.1 percent and the values obtained from the (c) curves ($\rho/R_1=0.8$) are reliable to ± 0.2 percent. The curves should only be applied to coils, for which the ratio of R_1/R_2 is between 0.1 and 0.9.

The tedious numerical computations involved to obtain Table I and the figures in this paper were capably performed by Mrs. Nelson Grisamore and Mr. Norton Moise. The author acknowledges the helpful criticism of Dr. E. F. Shrader, who carefully reviewed this manuscript.

The Effect of Compressive Stresses on the Linear Thermal Expansion of Magnesium and Steel

JOSEPH L. ROSENHOLTZ AND DUDLEY T. SMITH
Department of Geology and Mineralogy, Rensselaer Polytechnic Institute, Troy, New York
(Received October 19, 1949)

A series of cylinders of annealed, extruded, pure magnesium and medium soft steel were subjected to a sequence of compressive stresses at room temperature and their respective coefficients of linear thermal expansion in the direction of stress application were determined for the range 20° to 100°C. The cylinders were then heat treated to permit either recovery or recrystallization and the changes in length were measured. Characteristic curves are given for each metal in which the coefficient of linear thermal expansion and length changes are plotted as a function of the true compressive stress. It is shown that these properties may be used to determine the stress history of a test specimen for which characteristic curves are available. It is suggested that this stress analysis technique may find application in the study of rock deformation and in the investigation of metals, both before and after failure.

INTRODUCTION

IN a comparative study of a single crystal of the Iceland spar variety of calcite and Yule marble, in which approximately half of the calcite grains have their optic axes in preferred alignment, it was found[1] that the volume thermal expansion of the marble was twice as great as for the calcite. Furthermore, the calcite showed no change in length after cooling to room temperature from 700°C, while the recovery in the marble resulted in an increase in length in excess of 1 percent. Both phenomena are clearly associated with the deformational stresses of unknown magnitude which produced the marble and which were relieved during the heat treatment. This explanation received substantiation when it was found that a second heating-cooling cycle gave coefficients of expansion of the same order of magnitude as for the unstressed single crystal of calcite.

Before beginning a study of the effects of high, confining, compressive stresses on a series of marble specimens, it seemed desirable to investigate metals in order to ascertain what type of expansion changes, if any, might be expected. Toward this end, extruded, pure magnesium was selected for study because several of its physical and mechanical properties are somewhat similar to those of calcite. Among these are anisotropy, large linear coefficient of thermal expansion, α, and deformation by both twinning and slip. The second metal selected was a medium soft steel containing 0.29 percent carbon and 0.43 percent manganese. While this was nominally a hot rolled steel, metallographic examination gave evidence of preferred grain orientation indicating that the rolling was finished somewhat below the critical point. This was desirable from the point of view of this research because it permitted the study of a two-phase system in which sufficient deformation had occurred to produce some grain distortion in the direction of rolling, which was also the direction of compression and testing.

[1] J. L. Rosenholtz and D. T. Smith, Am. Mineral 34, 846 (1949).

PROCEDURE

Test specimens of each metal were cut from single bars and were machined to $\frac{3}{8}$ in. diameter and $\frac{3}{4}$ in. long. The magnesium cylinders were annealed for 1 hour at 300°C; the steel cylinders received no heat treatment because it was desired to retain the original structure. The study of a preliminary series of magnesium specimens showed very significant changes which indicated the particular stress regions where more numerous determinations were required. A complete magnesium series was then subjected to progressively greater compressive stresses to the point of rupture at 19 T.S.I. The maximum stress used for the steel corresponded to the region where failure began by extensive plastic deformation in the vicinity of 40 T.S.I.; no fracture occurred up to 135 T.S.I. As a practical expedient, all specimens were allowed to stand at room temperature for at least two weeks to permit recovery to take place.

A specially designed quartz dilatometer having a sensitivity of 2–3 microinches was used for determining α. The equipment, which has been fully described,[1] consists of a transformer bridge and includes a recorder which gives a complete record of dilatation.

Temperatures were measured with a Type K2 Leeds & Northrup potentiometer using a Pt-Pt 10 percent Rh thermocouple. The furnace was precooled to 10°C before measurements were begun and the heating rate was controlled so that the 20° and 100° points were accurately correlated with expansion. In all cases, the values of α are for the range 20° to 100°C.

As will be shown presently, specimens subjected to widely different compressive stresses may have the same value of α. As a result, a unique solution of stress cannot be obtained from an expansion-stress curve alone. Length changes resulting from recovery or recrystallization appeared to give a second useful relationship. The length recovery of magnesium cylinders after heating to 100°C was too erratic to be helpful. However, annealing at 300°C for one hour gave results consistent with the changes in α. Since the steel cylinders showed no change in length after cooling from 100°C, they were

heated in vacuum for one hour at 650°C for relief of stresses. After cooling to room temperature they were again heated in vacuum to 850°C, the length of the cylinders being measured before and after each heat treatment. A consistent set of values was found as a result of recovery but the results of the full anneal were erratic and could not be used.

STEEL

The results of the investigation of the relationship between α and compressive stress of medium soft steel is shown in Fig. 1. True stresses are used since they reveal the actual compression per unit of area for the respective applied stresses.

Smith and Wood[2] determined the stress-strain curve for the atomic lattice of mild steel (0.1 percent C) in compression, their measurements having been made perpendicular to the direction of stress application. Their curve displays some of the same characteristics as Fig. 1 with the principal exception that it reaches a maximum and then remains constant soon after the yield point has been reached. They divided the behavior of the lattice in terms of three phases. In the first phase, in which the compressive stresses are below the yield point, the crystal lattice obeys Hooke's law and recovers completely when the load is removed. The second phase appears at the yield point where an abrupt, permanent, lattice contraction amounting to 0.03 percent was found. In the third phase, which occurs beyond the yield point, they suggest a "regular increase with stress of the permanent residual lattice strain and the superposition of this residual strain on the reversible elastic expansion induced by the applied stress. The two types of strain are so related that their algebraic sum results in an approximately constant lattice spacing at stresses beyond the yield."

Several important characteristics which did not appear in the strain of the lattice of the mild steel referred to above are found in Fig. 1. In the first place, *AB* corresponds with the first phase of Smith and Wood. However, α does not remain constant as it should have if all stresses were relieved when the compressive loading was removed. While the percentage increase in α is small, it nevertheless increases up to the yield point. It is suggested that this effect is produced by the plastic deformation of some of the steel crystals while most of them are reacting elastically. This seems to correspond to the second stage of deformation of polycrystalline aggregates as described by Boas.[3] The residual stresses surrounding those crystals which experienced plastic deformation may therefore account for the increase in α which becomes progressively larger as the yield point is approached.

The second phase is represented by *BC* which is at the yield point. Here an abrupt drop in α was found in excess of 3 percent. This obviously corresponds to the sudden permanent contraction in the lattice. The third phase, corresponding to *CD*, and amounting to only 6 percent of the total stress range of the curve, gave a phenomenally large increase in α and coincides with Smith and Wood's region above the yield point where the lattice expanded.

The most important departure from agreement with permanent lattice changes is found along *DE*, where Smith and Wood obtain a constant value but where α decreases as much as it previously increased. If we assume, as suggested, that a constant lattice spacing is due to the algebraic sum of the permanent lattice expansion and the reversible lattice expansion, then the marked decrease in α must be some measure of the extensive plastic deformation produced by the relatively high compressive stresses. It appears, therefore, that there is a threshold value, represented by the point *D*, where the spacing decreases while the residual stresses become correspondingly greater. This suggestion is consistent with the explanation of the process of recrystallization given by Seitz[4] who explains that the energy stored during cold-work presumably furnishes the driving force for the recrystallization.

There were no changes in the length of the steel cylinders after cooling from 100°C. However, the changes after heating to 650°C for one hour were quite unexpected since, as shown in Fig. 2, there was either no change or a contraction. At the beginning of this investigation, the dimensional changes were observed as a matter of record. However, when it was found that the steel might possess the same value of α for several widely different compressive stresses, a related property was sought for stress correlation whereby a unique solution would be obtainable. This solution, then, is found for the steel in the length changes induced by a stress relief anneal. The inflection in the length-stress curve coincides with the maximum of the expansion-stress curve.

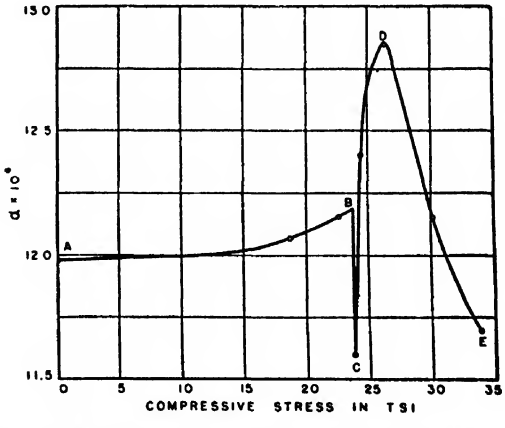

FIG. 1. The relationship between coefficient of linear thermal expansion (20°–100°C) and true compressive stress for medium soft steel.

[4] F. Seitz, *The Physics of Metals* (McGraw-Hill Book Company, Inc., New York, 1943), p. 81.

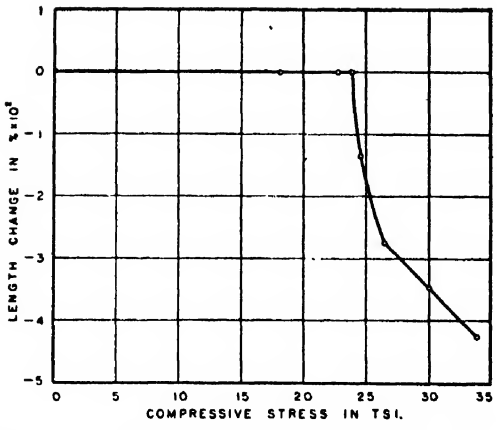

FIG. 2. Percentage change in length of compressed, medium soft steel cylinders after heating for one hour at 650°C.

As for the mechanism of contraction, the abrupt contraction of the lattice spacing at the yield point referred to above coincides with the increase in diameter when plastic deformation begins throughout the steel. As a result, the residual stresses appear to be stored in such a fashion that, when recovery takes place by the heat treatment, expansion of the lattice occurs perpendicular to the direction of compression and thereby causes an actual length decrement.

MAGNESIUM

The effect of compressive stresses on thermal expansion for pure, extruded, annealed magnesium is shown in Fig. 3. The characteristics of the curve are similar to those for steel except for the portion below the yield point. All changes in α at and above the yield point are approximately twice as great as those for steel, but α for magnesium is more than double that of steel. The gradual decrease in α below a true compressive stress of 3 T.S.I. is caused by the fact that measurable permanent deformation occurred, as contrasted with no permanent deformation in steel under a corresponding stress. In other words, appreciable plastic deformation began when the smallest stress was applied and it increased gradually until the abrupt change occurred at the yield point. While it is frequently said that magnesium has no definite yield point, the experimental evidence presented above leads to the opposite conclusion.

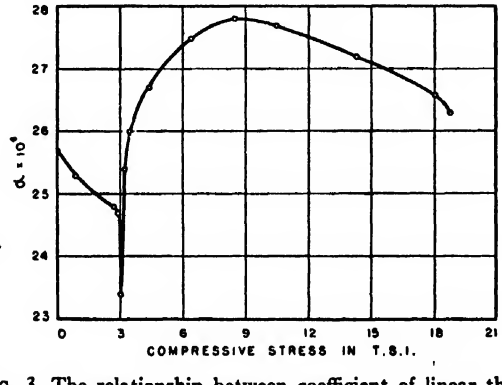

FIG. 3. The relationship between coefficient of linear thermal expansion (20°–100°C) and true compressive stress for pure, extruded, annealed magnesium.

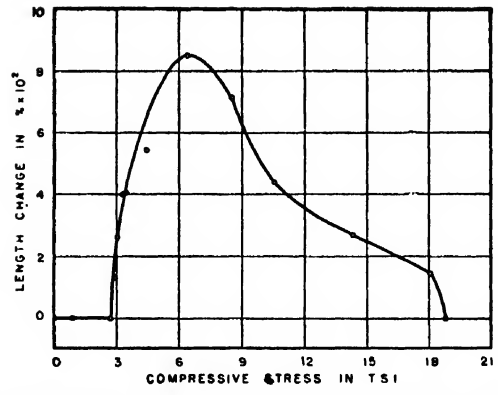

FIG. 4. Percentage change in length of compressed magnesium cylinders after annealing for one hour at 300°C.

As in the case of steel, the same value of α might correspond to two stress values. Measurements after cooling from 100°C could not be used because it was obvious that recovery or recrystallization or both had taken place. Recrystallization may occur in magnesium at 100°C, particularly if it has been stressed. Inasmuch as the different cylinders were stressed to varying degrees, the length changes were too inconsistent to be of use in selecting the correct stress corresponding to a particular value of α.

The results after annealing for one hour at 300°C are shown in Fig. 4. No length changes were measurable up to the yield point, after which the curve is quite similar to Fig. 3. The explanation proposed for the behavior of steel applies equally well to the magnesium. It is possible to arrive at a unique solution of stress from both of these curves except near the peak of the expansion curve where a close approximation would be obtainable.

SUMMARY

It is obvious from the experimental results presented that the coefficient of linear thermal expansion of a material is subject to wide variation and depends upon its previous thermal and deformational history. It is very important to be aware of the fact that if an anisotropic single crystal possesses widely different directional values of α, a polycrystalline specimen of the same material may show an amazingly great variation in α, especially if preferred orientation is pronounced. Disregarding instrumental methods and all attendant factors which pertain to precision of measurement, the published values of α for many materials are so widely divergent as to indicate the importance of knowing their previous history.

The method described above can lead to at least a close approximation of the stresses imposed upon metals

which experience plastic deformation. It is of the utmost importance, however, that the material used in the determination of the characteristic expansion-stress and length-stress curves have the same history as a test specimen for which the unknown superposed stress history is to be determined. This method of stress analysis may be especially useful in the analysis of failure in metals and perhaps in the limit design of structures.

As stated in the introduction, this research was undertaken in an attempt to anticipate how brittle minerals or rocks might react if subjected to compressive stresses under confining pressures. Griggs[5] has already demonstrated that some rocks, such as limestone and marble, behave like metals under high confining pressures. They display an elastic limit and deform by plastic flow when stressed above this point. It is anticipated, therefore, that some minerals and rocks which have been subjected to high, differential pressures will give characteristic curves somewhat similar to those of steel and magnesium. If this proves to be the case, a method will be available for achieving a better understanding of the range of pressures which have been responsible for the great deformational effects produced during metamorphism.

Thermal Noise at High Frequencies

A. VAN DER ZIEL*

Department of Physics, University of British Columbia, Vancouver, Canada

(Received September 6, 1949)

Spenke's discussion of thermal noise from the point of view of the electron theory leads to a result which differs from Nyquist's original formula at frequencies ν such that $h\nu/kT \geqq 1$. This discrepancy is due to the assumptions which Spenke made in his analysis.

1. INTRODUCTION

ABOUT 20 years ago Nyquist[1] published his well-known thermodynamical discussion of thermal noise; since then it has been shown that Nyquist's results could be derived with the help of the electron theory of conduction (Bernamont,[2] Bakker and Heller,[3] and Spenke[4].) Unfortunately Spenke's and Nyquist's results differ at frequencies ν such that $h\nu/kT \geqq 1$. It will be shown that the source of this discrepancy is in Spenke's treatment of the problem.

For our discussion we have to define "available power." A signal generator has an e.m.f. e and an internal impedance $Z=R+jX$; its available power P_a is defined as the maximum power which can be dissipated by an external impedance Z'. This maximum occurs if $Z'=R-jX$, so that:

$$P_a=\tfrac{1}{4}e^2/R. \tag{1}$$

2. THERMODYNAMICAL THEORY OF THERMAL NOISE

Nyquist's[1] analysis consists of three steps:

(a) The available noise power P_a in a small frequency interval $\Delta\nu$ of *any* thermal noise generator is a *universal* function of the frequency ν and the absolute temperature T of the generator. He proved this with the help of the second law of thermodynamics.

(b) The available noise power P_a in a frequency interval $\Delta\nu$ around a central frequency ν is:

$$P_a=\bar{E}\Delta\nu, \tag{2}$$

where $\bar{E}$ is the average energy of a harmonic oscillator of frequency ν and absolute temperature T (a system with two degrees of freedom). Nyquist proved this in a somewhat artificial way but his result cannot be doubted. A more detailed proof of (2) was given by Schremp.[5]

(c) $\bar{E}$ is given by the equipartition law. The average energy of an harmonic oscillator of frequency ν and temperature T is:

$$\bar{E}=kT\cdot f(\nu);\quad f(\nu)=h\nu/kT[\exp(h\nu/kT)-1]^{-1}, \tag{3}$$

and one obtains:

$$P_a=kT\Delta\nu\cdot f(\nu). \tag{4}$$

$f(\nu)=1$ if $h\nu/kT \ll 1$; at those frequencies:

$$P_a=kT\Delta\nu. \tag{5}$$

Equation (5) has been verified experimentally; the deviation between (4) and (5) becomes important in the

infra-red (at least at normal room temperature) and no experimental verification of (4) has been published up to now.*

In order to prove (4) in a less artificial way consider a hollow sphere at a uniform temperature T containing an harmonic oscillator of frequency ν_0 and a circuit consisting of a self-induction L, a capacity C and a resistance R and being tuned at the frequency ν_0. The hollow sphere is filled with black-body radiation of temperature T; the harmonic oscillator and the tuned circuit both interact with this radiation and will assume the temperature T. Their average energy E will be the same and the equipartition law will hold. Half of the average energy of the circuit is stored in the condenser, hence:

$$\tfrac{1}{2}C\langle v^2\rangle=\tfrac{1}{2}\bar{E}, \tag{6}$$

where v is the fluctuating voltage across C. A Fourier analysis shows that P_a is proportional to $\Delta\nu$:

$$P_a=\alpha\Delta\nu. \tag{7}$$

We now have to prove: $\alpha=\bar{E}$. Let the thermal noise of the circuit for the frequency interval $\Delta\nu$ be described by an e.m.f. e in series with R, then after (1):

$$\langle e^2\rangle=4P_aR=4\alpha R\Delta\nu. \tag{7a}$$

The contribution of e to the mean square value of the noise voltage v across C in the frequency interval $\Delta\nu$ is:

$$\langle e^2\rangle\left|1+\left(\frac{1}{j\omega L}+j\omega C\right)R\right|^{-2}=4\alpha R[1+4(\omega-\omega_0)^2C^2R^2]^{-1},$$

if $(\omega-\omega_0)\ll\omega_0$ and $\omega_0^2LC=1$. Integrating over all intervals $\Delta\nu$:

$$\langle v^2\rangle=\alpha/C \quad\text{or}\quad \tfrac{1}{2}C\langle v^2\rangle=\tfrac{1}{2}\alpha \quad\text{or}\quad \alpha=\bar{E}.$$

3. THE CORPUSCULAR THEORY OF THERMAL NOISE

The following model of a conductor is used here: Electrons in the conductor move in all possible directions, they have a Fermi velocity distribution at a temperature T. The electrons which have a velocity close to the top of the Fermi distribution can gain energy when an electric field is applied and thus give rise to conduction. Those electrons can collide with the positive ions of the lattice after having traveled an average "free path length" Ω; as they all have practically the same velocity v, the average time of flight τ_0 along the free path length Ω is Ω/v. It is assumed that the collisions with the positive ions of the lattice occur without an exchange of energy and that the electrons are scattered in random directions after such a collision.

The motion of electons along the free path length Ω gives rise to current pulses of length τ_0 in the conductor (thermal noise). Carrying out a Fourier analysis of the resultant noise current $I(t)$, Bakker and Heller[3] and also Spenke[4] found for its Fourier components i:

$$\langle i^2\rangle=\langle i_0^2\rangle(1+\omega^2\tau_0^2)^{-1}, \tag{10}$$

where $\langle i_0^2\rangle$ is the l.f. value of $\langle i^2\rangle$.

If a d.c. field is applied to the conductor, the electrons gain energy in the field; due to the collisions with the lattice a state of equilibrium is established in which the electrons have an average velocity in the direction of the field. This drift velocity, which depends upon τ_0, constitutes a current and so the collisions with the lattice give rise to a finite d.c. conductivity G_0. If an a.c. field is applied, the conductivity G remains independent of frequency as long as its period is small in comparison to τ_0. If it is comparable to τ_0, the electrons will on the average gain less energy in the field, as its phase changes appreciably during the motion along the free path length; at those frequencies $G<G_0$. Spenke[4] found:

$$G=G_0(1+\omega^2\tau_0^2)^{-1}; \tag{11}$$

this result was first obtained by Kronig.[6] Hence:

$$P_a\equiv\langle i^2\rangle/4G\equiv\langle i_0^2\rangle/4G_0. \tag{12}$$

Evaluation of $\langle i_0^2\rangle$ and G_0 then yields (5). This holds for all frequencies.

Spenke's result is not a very surprising one, for in his model no exchange of energy occurs when the electrons collide with the lattice. The average energy stored in the condenser C of an LCR circuit tuned at the frequency ν_0 will then be in equilibrium with the thermal agitation of the electrons. The average energy for translatory motion as given by the equipartition law does not contain the Planck factor $f(\nu)$ and hence one would expect that, independent of the frequency ν_0:

$$\tfrac{1}{2}C\langle v^2\rangle=\tfrac{1}{2}kT$$

so that (5) should be valid for all frequencies. Nowhere in this model is any room left for an expression containing $h\nu/kT$ and this cannot be improved by using another velocity distribution either.

But in a genuine thermodynamical discussion it is not sufficient to state that the electrons have a velocity distribution corresponding to the temperature T; one has to immerse the conductor in a heat reservoir of large heat capacity and one has to investigate how the spontaneous current fluctuations in the conductor are coupled to this heat reservoir. Undoubtedly this coupling occurs as follows: The heat reservoir is in thermal equilibrium with the lattice vibrations and the electrons couple the current fluctuations to those vibrations. This coupling is due to the fact that in each collision an energy exchange $\pm h\nu$ occurs between the colliding electron and the lattice (ν is one of the frequencies of the lattice vibrations). The average energy stored in the condenser C of an LCR circuit tuned at the frequency ν_0

* It would be worthwhile to test its validity in the centimeter wave-length region at low temperatures. If $T=1.2°K$ then $h\nu/kT=1$ at 1 cm wave-length ($\nu=3\times10^{10}$); the deviation between (4) and (5) is then about 40 percent, which might be detectable with present techniques.

[6] R. de L. Kronig, Proc. Roy. Soc. A124, 409 (1929); 133, 255 (1931).

will therefore be in equilibrium with the average energy $\bar{E}$ of the *lattice vibrations* of frequency ν_0, and $\bar{E}$ is equal to the average energy of an harmonic oscillator given by (3). Hence in the correct theory:

$$\tfrac{1}{2}C\langle v^2\rangle=\tfrac{1}{2}\bar{E}$$

so that we obtain (4) instead of (5).

4. THE SOURCE OF THE ERROR

As it is now clear that Spenke's analysis is wrong, it has to be investigated whether the error is in (10) or in (11). According to the Fourier analysis, fluctuating quantities $X(t)$ have Fourier components x_n of frequency ω_n such that:

$$\langle x_n^2\rangle=4\Delta\nu\int_0^\infty\langle X(t)X(t+w)\rangle\cos\omega_n w dw. \quad (13)$$

The correlation function $\langle X(t)X(t+w)\rangle$ is zero if $|w|\ll\tau$, where τ is the *correlation time* of the fluctuating quantity. If $(\omega_n\tau)\ll 1$:

$$\langle x_n^2\rangle=4\Delta\nu\int_0^\infty\langle X(t)X(t+w)\rangle dw.$$

This integral is independent of the frequency and is completely determined by the equipartition law; any theory using this law will give the right formula at low frequencies even though it gives wrong values for τ and for $\langle X(t)X(t+w)\rangle$. In the latter case the noise spectrum will have the wrong shape at high frequencies.

Lameris[7] found from his reflection measurements in the infra-red that (11) was correct. He deduced from his measurements that at room temperature $\omega\tau_0$ was equal to unity at the frequencies $\nu(=\omega/2\pi)$: 2.36×10^{13} for Ag, 2.39×10^{13} for Au and 5.23×10^{13} for Pt. But after (4) the available noise power shows a marked decrease if $h\nu/kT=1$, this corresponds to $\nu=0.6\times10^{13}$ at room temperature. Hence the correlation time τ of the fluctuations is about 5–10 times as large as the correlation time τ_0 of the resistance. But in Spenke's model $\tau=\tau_0$ so that the error is definitely in (10).

Spenke[4] made the following assumptions:

(a) After collisions the electrons are scattered in random directions. In fact the scattering over small angles is favored.

(b) No energy is exchanged in the collision process. In fact each collision corresponds to an exchange of energy with the lattice. It is therefore likely that an exact calculation of $\langle i^2\rangle$, in which the above facts are taken into account will give (4) instead of (5). The calculation is very difficult, whereas the thermodynamical analysis is very simple.

In order to show that the two above facts work in the right direction, consider a number of electrons dN having a velocity between v and $v+dv$. In calculating the correlation time of the resistance we have the problem: "What is the probability that the electrons will obtain a different velocity v' when traveling along the distance dx?" This will give a correlation time equal to the time τ_0 between two collisions, if on the average the electrons lose the energy gained by traveling in the electric field after each collision (for a more detailed discussion compare Spenke's[4] paper). In calculating the correlation time τ of the current fluctuations the problem is: "How long does it take before there is no longer any correlation between the current due to the motion of these dN electrons and the original current?" If the scattering over small angles is favored, it will take a number of collisions before this is achieved so that τ is much longer than τ_0, just as was required.

5. AVAILABLE NOISE POWER OF AN ANTENNA

Burgess[8] calculated the available noise power P_a in the frequency interval $\Delta\nu$ of an antenna receiving black body radiation of uniform temperature and showed that it was given by (4). That this leads to (4) and not to (5) can be shown by a simple argument.

At low frequencies the energy density of black body radiation is:

$$U_\nu\equiv(8\pi\nu^2/c^3)\cdot kT\Delta\nu \text{ (Rayleigh-Jeans' law).} \quad (14)$$

But at those frequencies $P_a=kT\Delta\nu$, hence:

$$U_\nu=(8\pi\nu^2/c^3)\cdot P_a. \quad (15)$$

Equation (15) describes a property of the antenna which does not depend upon quantum phenomena so that it will hold for all frequencies. But at high frequencies (14) has to be replaced by Planck's law. As this means that (14) has to be multiplied by the Planck factor $f(\nu)$, P_a has to be multiplied by the same factor, so that (4) holds.

The author is indebted to Dr. A. J. Dekker and Dr. F. A. Kaempffer for many discussions on this subject.

Semiconductive Colloidal Suspensions with Non-Linear Properties

HANS E. HOLLMANN
U. S. Naval Air Missile Test Center, Pt. Mugu, California
(Received October 3, 1949)

Semiconductive particles in a colloidal suspension, when subjected to an electric polarizing field, form semiconductive chains. Once the suspension is polarized, its conductivity increases with increasing fields because the forces of electrostatic attraction press the individual particles together, thus strengthening the transition contacts along the chains. Both effects result in an over-all electric non-linearity that is the subject of extensive investigation.

The non-linear characteristics of such colloidal resistors are oscillographed and described in relation to the polarizing field strength by means of simple formulas based on field coefficients of the first and second order.

In addition to a true rectification, resulting from the curved characteristics, a "pseudo-rectification" occurs which corresponds to an average pre-polarization by stronger alternating fields. The alternating forces of electrostatic attraction assure a high frequency response, so that non-linear Lissajous-figures and harmonics, up to radiofrequencies, are produced.

ACCORDING to Debye's theory of polar molecules the behavior of certain substances, especially of polar liquids and polar dielectrics, such as crystals and ceramics with their abnormally high dielectric constant and permittivity, their rotational and frictional dispersion, their Curie temperatures, etc., is caused by the polarization and orientation of their dipole molecules or their molecule-complexes, when subjected to an electric polarizing field.

For the following considerations it is important to recall that the microcrystalline dipoles originally have a random orientation but, when polarized, orient themselves in the direction of the electric lines of force.

In addition to these polar fluids and substances comprised of natural dipole-molecules, it is possible to enter a more macroscopical region in which the molecules or molecule-complexes are replaced by bigger (but nevertheless microscopically small) particles suspended in a liquid—and later embedded in a solid carrier, preferably in colloidal dispersion. In this way, the concept of polar substances is to be transposed to that of polar suspensions. Attention is drawn to these types of polar liquids by the so-called "magnetic fluid"[1] which represents the prototype in the magnetic field just as ferromagnetism relates to ferroelectricity. For the sake of completeness and easier understanding, it may be convenient to recall the characteristics of the magnetic fluid before we turn to the new polar suspensions in the purely electric field.

The sprinkling of iron filings on a surface under the influence of a magnetic field is a well-known method for making magnetic lines of force visible. All the iron particles become magnetized, attract each other, and arrange themselves in the form of chains in accordance with the magnetic lines of force.

This old phenomenon has been put to ingenious use in the magnetic fluid. Instead of sprinkling onto a surface through free air, the iron particles, or more accurately fine iron powder, is mixed with oil, thus forming an iron-oil suspension, wherein the iron particles are much more mobile than on a solid surface. As soon as the magnetic fluid is subjected to a magnetizing field, it thickens, and if magnetized sufficiently becomes of a paste-like consistency. Hence, the magnetic oil is a new type of a thixotropic fluid with the important difference, that its gel-sol-gel transformation can be controlled by means of an external magnetic field instead of by shearing or stirring.

The solidifying effect can be demonstrated by dipping a permanent magnet into the suspension, after which a certain region around the poles becomes so thickened that it can be pulled out in the form of a semisolid bridge.

The magnetic fluid has found an important application in the magnetic fluid clutch. Instead of utilizing the immediate forces of attraction occurring between the two coupling elements of a mechanical or pure magnetic clutch, a small gap between the coupling elements is filled with the magnetic fluid. Under the influence of a magnetic control field, the magnetic fluid becomes a tough semisolid, binds the coupling elements together, and transmits the torque from the driving to the driven element.[2]

The magnetic fluid, furthermore, may be exploited extensively in electromagnetically controlled hydraulic systems where the controllable thixotropic fluid itself replaces the conventional valves.[3] Another application is for the purpose of forming casting molds where the fluid, in which the model has been immersed, solidifys instantaneously and produces a workable mold as long as it is subjected to a strong magnetic field. Finally, the magnetic fluid may be utilized for forming a controllable resistor similar to a relay. However, such an oil-relay

will not de-energize by itself but, in order to restore its initial resistance must be stirred or shaken.

Turning to the field of electrostatics, we obtain the so-called "electric fluid."[4] It can be best understood by recalling the so-called "Lichtenberg figures" which in the field of electrostatics are identical to the aforementioned magnetic figures. A light powder having a high dielectric constant, e.g., lycopodium (club moss), in an electrostatic field, forms chains similar to those of the iron filings in the magnetic field, thereby making visible the electric lines of force. Consequently, intermixing or suspending a fine dielectric powder in an insulating liquid of lower dielectric constant—the simplest being in oil—produces the electric fluid whose viscosity also increases transversely to the applied electric field. Hence, it is possible to apply the aforementioned magnetic experiment to the field of electrostatics. Two suitable electrodes or wires, across which either a high direct or alternating voltage is applied, are dipped into the electric fluid. When the wires are withdrawn, a little bridge or membrane adheres. Naturally, as soon as the polarizing voltage is cut off the dielectric suspension assumes its neutral viscosity and drops off.

It is clear that the electrically controlled thixotropy is much weaker than the magnetic chain effect. This is because the electrostatic forces of attraction are limited basically by the breakdown field strength. This disadvantage, however, is compensated for by a very low consumption of control power. Consequently, an electric clutch, of which the torque moment is transferred via the thickened electric fluid, may be of some practical value in cases where a high frequency response and low control power is required.

Fundamentally, the electric fluid and its thixotropy is not completely new. The oldest example is blood. The analogy was observed years ago, in the field of high frequency diathermy.[5] In that part of the body subjected to the diathermy field the blood particles become polarized and also form dielectric chains. Without going into further detail, it may be mentioned that the increased viscosity hampers the blood circulation in the treated vessels, thus counteracting the increased circulation in the vessels which have been enlarged physiologically under the influence of the diathermic heating; hence, the dielectric chains are in constant conflict with the blood circulation, fortunately without endangering the regulative heat flow.

Another characteristic of the electric fluid is the change of its dielectric constant in relation to the applied electric field. A capacitor containing the electric fluid as dielectricum becomes non-linear, i.e., its capacity is a function of the impressed voltage. In this respect, the electric fluid resembles certain polar substances, i.e., rochelle salt, similar crystals, and ceramics with Seignette-electric properties. Referred to the viscosity effect it is obvious that the electric non-linearity occurs long before any mechanical effect can be observed. It would be beyond the scope of this paper to go into greater detail concerning this electric characteristic.

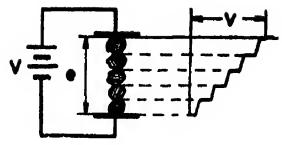

FIG. 1. Qualitative representation of a semiconductive chain and the incremental voltage drop.

After the foregoing introduction, particularly concerning the non-linear capacitor, we proceed to a new concept, namely, an "electric oil" having non-linear or controllable conductivity. For this purpose the dielectric particles must have a certain conductivity which will enable the chain formation to increase the over-all conductivity at the expense of the viscosity effect which now loses its significance. Finally, the electric oil can be mixed or composed in a manner so that its conductivity exceeds its dielectric constant by several orders of magnitude. As a result the wattless component vanishes at the expense of the dissipative component. It is therefore possible to make a non-linear resistor whose value depends on the applied electric field as well as on various external or internal influences. As will be shown in the following pages, the electric oil displays a surprising versatility and creates new fields for numerous applications.

1. THE FORMATION OF SEMICONDUCTIVE CHAINS

In the course of numerous experiments with various mixtures and suspensions, it was found that a suspension of graphite in oil produces very satisfactory results. Besides relatively crude mixtures of coarse graphite powder and lampblack in silicon oil, some colloidal suspensions, such as Oildag, Castordag, and Glydag, operate very stably, particularly so because no sedimentation takes place. Although it is probable that these compositions do not represent an optimum, and taking into consideration that further investigation may disclose better samples, the present investigations are concerned only with graphite-oil suspensions by means of which the unusual behavior and versatility of the electric oil can be proven very satisfactorily.

The process of chain formation can be observed under a microscope. In neutral condition or in the virgin state the particles are distributed irregularly. As soon as the suspension is subjected to a polarizing field, the particles form chains. The picture, however, is not ideal because the primary chains, extending mostly in the direction of the electric field lines, are crisscrossed by secondary

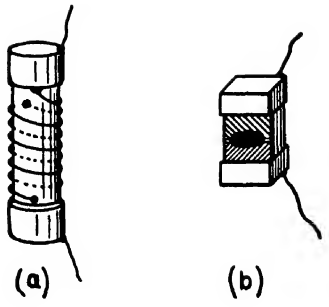

FIG. 2. Two examples of colloidal resistors.

chains extending between points of different potentials along the primary chains, as a result of which a complex network appears instead of individual parallel chains.

The chain formation alone, however, does not suffice to explain the non-linear conductivity. Once the chains are formed at a certain field, a second effect is responsible for the non-linear property, namely, the fluctuating forces of electrostatic attraction along every individual chain, or more accurately, between contacting particles or links. This is explained in greater detail by means of the qualitative representation shown in Fig. 1. The left side illustrates a simple chain between two electrodes with the separation e and the electric field $E=V/e$ where V is the voltage. The right side illustrates roughly the voltage drop along the chain. The semiconductivity of the particles, together with the high transition resistance of the regions where the particles touch each other, effect an incremental voltage drop. Partial fields appear preponderantly at the transition regions, whereas the conductivity prevents higher voltage drops across the particles themselves.

Furthermore, the relatively high fields created in the transition regions produce strong electrostatic forces of attraction between all adjacent particles. As a result, the dielectric chains are reinforced at increasing field strengths so that the increasing over-all conductivity of every individual chain, and therefore of the sum of all chains, may be considered as being caused by the action of innumerable fluctuating contacts between innumerable links. Once the chains are formed, the conductivity continues to increase with increasing field strength, i.e., the over-all conductivity of the electric oil becomes non-linear. A very important result of this contact action is the fact that the non-linearity does not depend on any movement of the particles through the carrier oil but only upon the reinforced pressure along the chains which produces the non-linear conductivity and assures a high frequency response. (A similar effect of strong electrostatic attraction at moderate voltages is known as the Johnson-Rahbek effect[6] occurring in the microscopically small airgap between the surface of a semiconductor, e.g., slate or agate, and an impressed foil electrode.)

[6] K. Rottgardt, "Elektrische Anziehung nach Johnson-Rahbek und ihre Anwendung" (Electrostatic attraction according to Johnson-Rahbek and its application), Zeits. f. Tech. Physik 2, 315 (1921).

The ratio between the dielectric constant of the particles and that of the carrier oil, the conductivity of the particles, and their size, is also of great importance. It can be seen at once that the foregoing theory leads to an important conclusion. If the individual chain contains, for example, N links, the partial voltage drops between subsequent links can be considered as V/N if the potential drop across the particles themselves, in rough approximation, is neglected. Consequently, noticeable forces of attraction occur only under the assumption that V/N exceeds a certain minimum value. This simple relationship determines the applicability of the electric oil, or, more accurately, its non-linearity and voltage sensitivity. The latter quantities can be chosen by matching the electrode separation to the operating voltages, e.g., by selecting the suitable full operating field strength in relation to the size of the particles.

2. COLLOIDAL RESISTORS

For any practical applications or experimental investigations, the space between suitably arranged electrodes must be filled with electric oil so that a non-linear colloidal resistor is obtained. In analogy to a fluid capacitor, a simple form would consist of two flat or cylindrical electrodes with a fixed or variable separation arranged in an insulated container filled with the oil. If an electrical stability as high as possible is desired, care must be taken that there is no surplus amount of oil outside of the electrodes because the electrid field gradually attracts the dielectric particles from the surroundings so that the mixture ratio in the

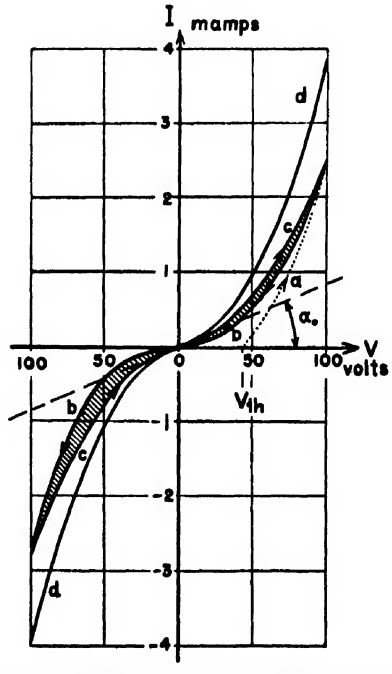

FIG. 3. I–V characteristic of a colloidal resistor at various states of polarization.

inter-electrode space increases at the expense of the surplus oil. Another modification is a glass tube closed at both ends and filled with the oil in which wire electrodes are immersed at each side.

Two more convenient types of oil-resistors are schematically indicated in Fig. 2. Type (a) contains two bare wires which are bifilarly wound around an insulating rod. The non-linearity or voltage sensitivity depends on the separation of the wires, in other words, on the pitch, whereas the resistance range or more accurately, the zero resistance R_0 at very low voltages is related to the surface of the electrodes, i.e., to the length of the bifilar helix.

When a non-linearity as high as possible is required, the second type (b) is very convenient. A minute electrode gap is made by cutting a slit into the silver layer of a little mirror, thus assuring a high polarizing field even at moderate voltages. Naturally, this mirror type may be combined with the former form by cutting a helical slit into a metal-plated rod or by cutting a meandering line similar to a Rowland grating.

Instead of being immersed in an oil-filled container, the electrode-gaps may be covered with a thin layer of electric oil which may be protected by wrapping or hermetically sealing. Whether one type or the other is preferred depends on the various conditions of operation. It must be clearly understood that every colloidal resistor with a larger volume of free oil is more or less microphonic, whereas the sensitivity to vibration vanishes in all cases where only a thin layer of the oil is supported by an insulator.

The possibility of matching the power dissipation as well as the voltage sensitivity to any desired range is of great practical significance. Whereas the power dissipation is determined largely by the cross section or by the current density—if necessary with air or water cooling —the voltage sensitivity or non-linearity, respectively, depends for a given suspension only on the oil gap. Accordingly, the two electrode arrangements shown in Fig. 2 allow encompassing a wide range of non-linearity as well as resistivity.

In addition to the preceding considerations, the colloidal resistor may be compared to the previously mentioned magnetically controlled resistor because both devices have in common the fluctuating transition resistances between individual particles. An important difference, however, is that the electric oil leads to a steadily increasing transition or controllability whereas the magnetic fluid relay operates, so to speak, only in "black-and-white," i.e., its resistance fluctuates only between infinity and zero. Furthermore, the electric oil requires no artificial reduction to its initial state, in contrast to the fluid relay. Only when the electric oil is overloaded do its particles burn and fuse together, and then they must be broken up by stirring, or by strong vibrations.

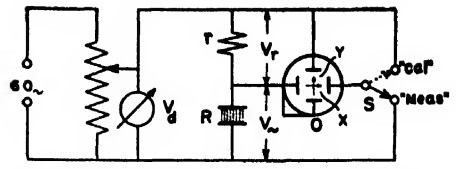

FIG. 4. Simple device for oscillographing non-linear I–V characteristics.

3. NON-LINEAR CHARACTERISTICS

(a) Static Measurements

For obtaining a preliminary insight into the non-linear properties of colloidal resistors, numerous types were investigated at static conditions. In these experiments, the resistors were merely fed by a variable direct voltage V and the passing currents I were observed. Some typical examples of simple I-V characteristics are shown in Fig. 3 in the form:

$$I=f(V)=V/R=G\cdot V, \qquad (1a)$$

where R and G are the non-linear resistance and the non-linear conductance, respectively.

A detailed study of the characteristics yields the following results: At the beginning of the measurements, the electric oil is in its virgin state. Because no chains are present, current cannot flow. As soon as the impressed voltage reaches a certain threshold value V_{th}, the chains become active and produce a semiconductive connection between the electrodes. From then on the current rises rapidly with the voltage and follows the steep virgin curve (a) thereby revealing the progressive strengthening of the chains by the increasing forces of electrostatic attraction. When the chains, under the influence of a certain polarization, have attained a certain state, they keep this assumed state, at least to a certain degree, even though the voltage is decreased. In this particular example not enough time has elapsed at the extreme maximum voltage to permit the chains to become fully developed. Consequently, the first I–V characteristics (b) and (c) do not coincide but circumscribe the shaded area.

In order to describe the static picture as completely as possible, it must be emphasized that only a relatively small range can be measured. As noted before, the electric oil becomes unstable at higher current densities because the graphite particles burn and fuse together so that the original colloidal character is completely destroyed.

Quite obviously, the phenomenon of the chain formation has a certain analogy to hysteresis, with the important difference being that the chain formation has a certain inertia. As a result, the chain hysteresis disappears, even at low frequencies, because the chains assume an average state of polarization.

In regard to this time lag and, therefore, to the previous history, the static step-by-step method is somewhat delicate and laborious. A steady state is

reached only after a sufficient time has elapsed before the next step. Accordingly, only after a sufficiently strong polarization has taken place, preferably connection with some reversals of the polarizing field, the fairly stable I–V characteristic (d) in Fig. 3 was measured.

This final characteristic may be considered in greater detail. It passes the zero point of inflection according to the dashed tangent with the slope $\tan\alpha_0$ indicating a zero resistance R_0 or a zero conductance G_0. At higher fields the electrostatic attraction causes the currents to rise over this initial tangent thus indicating a decrease in resistance or an increase in conductivity. This preliminary analysis picture will be completed later.

(b) Oscillograms

Because of the aforementioned phenomena, the static step-by-step method is somewhat inaccurate. An oscillographic representation is much more advantageous because it discloses not only the dynamic behavior of the electric oil in question, but, at the same time, assures greater stability because the chains assume an average state of polarization.

The simplest device for oscillographing non-linear I–V characteristics is indicated in Fig. 4. The colloidal resistor R is fed via the fixed preresistor r by the alternating voltage V_d of 60 cycles with variable amplitude. The cathode ray of the oscilloscope O—which, for the sake of simplicity, is shown without its amplifiers—is deflected horizontally by the voltage V_- across R, if the switch S is in "measuring" position, and vertically by the voltage drop $V_r = I \cdot r$.

Figure 5 shows a typical example of a non-linear I–V oscillogram (a). The straight calibration line (b) was obtained with the switch S in "calibration" position so that both inputs of the oscilloscope are in parallel. If Y and X are the deflecting sensitivities in

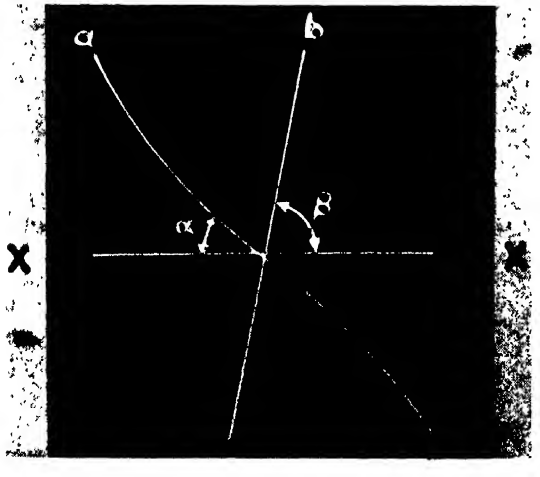

Fig. 5. Oscillographic I–V characteristic (a) with calibration line (b).

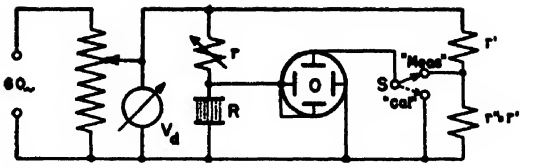

Fig. 6. Alternating current bridge for obtaining oscillographic bridge characteristics.

both axes, then their ratio is determined by the angle β: $Y/X = \tan\beta$. On the other hand, any angle α of an arbitrary chord connecting the point of any voltage V with the zero point or two arbitrary points at any voltages $\pm V$, whose tangent is proportional to the corresponding conductance $G = 1/R$, is given by the ratio of the horizontal deflection:

$$D_x = X \cdot V_d/(1+r/R)$$

and the vertical:

$$D_y = Y \cdot V_d/(1+R/r)$$

as:

$$\tan\alpha = D_y/D_x = (r/R)\tan\beta = r \cdot G \cdot \tan\beta. \qquad (2)$$

By means of this relation, R, G, or $\sigma = e/F \cdot R$ (F = surface of the electrodes) can be plotted *versus* V provided the horizontal deflection sensitivity (X) is determined by a simple voltage calibration.

A more sensitive device for oscillographing the non-linearity of a colloidal resistor is an alternating current bridge whose schematic is indicated in Fig. 6. It differs from Fig. 4 only in that the non-linear attenuator $r \cdots R$ is supplemented by the resistive attenuator $r' \cdots r''$, which balances the fundamental voltage drop across R so that only the non-linear deviations produce the vertical deflection.

A simple analysis as before yields:

$$\tan\alpha = \tan\beta \frac{(r'r/r''R)-1}{(r'/r'')+1}. \qquad (3a)$$

Naturally the bridge has its highest sensitivity when $r' = r''$ so that Eq. (3a) simplifies into:

$$\tan\alpha = \tfrac{1}{2}\tan\beta[(r/R)-1]. \qquad (3b)$$

The bridge operates at its maximum sensitivity if it is in balance at very low momentary voltages. This means that r must always be adjusted in such a manner that the middle portion of the oscillogram remains horizontal. Such an example is shown in Fig. 7 together with the calibration line (b) which is obtained as before with the switch "S" in "calibration" position.

In analogy to Fig. 3 the gradual formation of the chains can be demonstrated by increasing the alternating driving voltage V_d. Such an oscillogram is shown in Fig. 8 whose individual characteristics differ by driving voltages progressing in increments of five volts. As long as the colloidal resistor is in its virgin state, R is approximately infinite and a little deflection line

appears with the slope:

$$\tan\gamma \sim \tfrac{1}{2}\tan\beta.$$

As soon as the threshold field is reached, the oscillogram becomes non-linear and, after having passed a horizontal middle portion at $R=r$, simultaneously becomes erect and expands.

This turning, especially the middle portion, reveals a decrease of the zero resistance R_0. On the other hand, the bridge can easily be kept in balance by always adjusting r in such a manner that the turning-up is neutralized or that the non-linear bridge characteristic keeps a horizontal zero passage. The measuring points shown in Fig. 9 were obtained in this manner and will be explained in greater detail in Section 5.

(c) Analytical Characteristics

A complete analysis of the complex behavior of the colloidal resistors is not possible, at least not at the present time, because too many parameters are unknown and not computable. However, an analytical representation of the experimental I–V characteristics yields a better insight into the philosophy of the electric oil and electrical performance of any colloidal suspension. Further investigations may disclose the complex relations by which the individual parameters, i.e., the dielectric constant and conductivity of the particles and the carrier fluid, the form and size of the particles and their surface properties, the mixture ratio, and last but not least, the previous history are related.

The following analysis is based on numerous measurements of a graphite-oil suspension. The solid curve in Fig. 10 shows an example which has been averaged from numerous measuring points at a certain prepolarization and limited to a permissible current density. The characteristic is deduced by plotting the current density i per cm^2 instead of the entire current I, and the field strengths E, instead of the impressed measuring voltage V. Hence, Eq. (1a) is presented by the reduced form:

$$i=I/F=\sigma E=\sigma V/e \qquad (1b)$$

where F is the electrode area in cm^2, σ the conductivity in mhos per cm, and E the electric field strength in volts per cm. This reduction has an advantage in that the characteristic is referred directly to the conductivity as well as to the electric fields which are responsible for the dielectric chain formation and the resulting non-linearity.

It has been mentioned in Section 3(a) that the I–V characteristic passes its inflection point under the slope of the lower tangent:

$$\tan\alpha_0=(i_0/E_0)\tan\beta=\sigma_0\tan\beta. \qquad (4a)$$

The fact that σ_0 depends to a very large degree on the previous history, i.e., on the momentary polarization, makes any pre-calculation very difficult if not impossible.

The deviation of the solid curve from the initial zero tangent can be represented by a cubical parabola, at least at low polarizing fields, in the vicinity of the zero point. Hence, the lower portion of the actual i–E characteristic may be described by:

$$\begin{aligned} i&=\sigma_0E+\sigma_0KE^3 \\ &=\sigma_0E[1+KE^2]. \end{aligned} \qquad (5a)$$

The so-called "field coefficient" K characterizes the non-linearity in first-order approximation.

As soon as the polarizing field becomes increasingly stronger the characteristic remains below the simple parabola. This deviation can be perceived by diminishing K in relation to E:

$$K'=K/(1+PE^2), \qquad (6)$$

where P is an additional quantity which characterizes the non-linearity of the extended characteristic. Hence, Eq. (5a) assumes the more accurate form:

$$i=\sigma_0E[1+KE^2/(1+PE^2)]. \qquad (5b)$$

The evaluation of the measured characteristic in Fig. 10 gives $\sigma_0=2\cdot10^{-7}$ mhos per cm, $K=1.2\cdot10^{-5}$, and $P=9\cdot10^{-7}$.

By means of this analytical representation the condition can be extended to field strengths far above the permissible measuring range. Equation (5b), with the

FIG. 7. (a) Non-linear bridge oscillogram with (b) calibration line.

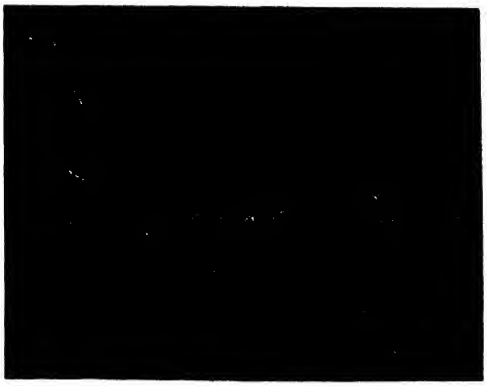

FIG. 8. Non-linear bridge oscillogram at successively increasing driving voltages.

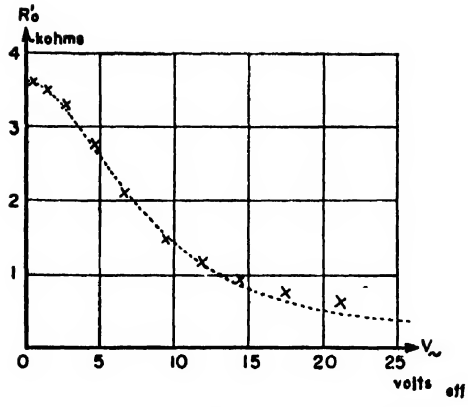

FIG. 9. The zero resistance R_0' in relation to the alternating voltage $V_\sim$ across the colloidal resistor.

experimentally determined values, yields the dashed characteristic shown in Fig. 10. Of special interest is the condition arising when it approaches the upper tangent whose slope follows when $E\rightarrow\infty$ as:

$$\sigma_{sat}=\sigma_0[1+K/P]. \tag{4b}$$

This saturation conductivity is the only quantity which can be understood very simply as characterizing the phenomenon that all semiconductive particles are compressed by infinitely powerful forces of electrostatic attraction in the form of a solid block. In other words, the saturation conductivity (in the present example 13 times the zero conductivity) must be identical with the conductivity of solid graphite, or, for example, coal, multiplied by the mixture ratio of the suspension, because the cube of unity is filled only in part by the graphite, while the rest is filled by the insulating carrier oil.

4. CONDUCTIVITY AND RESISTANCE CHARACTERISTICS

(a) Non-Linear Conductivity

The change in the relative direct current conductivity referred to zero conductivity can be computed easily

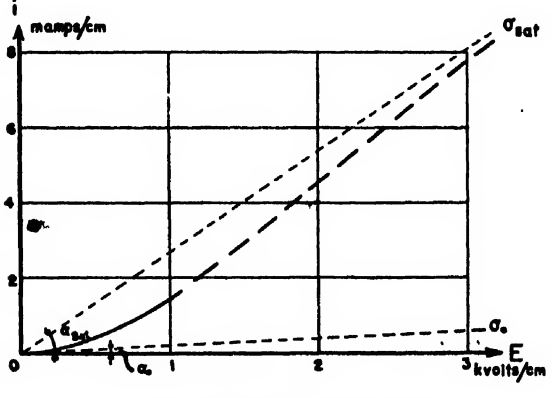

FIG. 10. Analytical I–E characteristic.

from Eq. (5b):

$$\Delta\sigma/\sigma_0=\sigma/\sigma_0-1=K\cdot E^2/(1+P\cdot E^2). \tag{7a}$$

Using the values given above for K and P, this quantity is plotted *versus* E as the solid curve in Fig. 11. Since $P<K$ the curve, in the vicinity of the zero point, is a simple parabola:

$$\Delta\sigma/\sigma_0=K\cdot E^2. \tag{7b}$$

At the field strength:

$$E_i=1/(3P)^{\frac{1}{2}}, \tag{7c}$$

in the present example at 610 v per cm, a point of inflection appears around which the relative direct current conductivity changes linearly with E. At very high field strengths, the relative change in conductivity approaches, asymptotically, a saturation value:

$$(\Delta\sigma/\sigma_0)_{sat}=K/P, \tag{7d}$$

i.e., in the present example, 13.4.

If the conductivity characteristic should be computed from the non-linear bridge oscillogram, it can be done by means of the simple formula:

$$\Delta\sigma/\sigma_0=2\tan\alpha/\tan\beta.$$

Apart from the direct current conductivity, a differential or alternating current conductivity which is proportional to the slope of the I–E characteristic at any arbitrary operating point or at any arbitrary bias field E_B must be included. Differentiation of Eq. (5b) yields the relative differential conductivity, i.e., $\sigma_\sim$ referred to σ_0:

$$\sigma_\sim/\sigma_0=1+KE_B^2\frac{3+PE_B^2}{(1+PE_B^2)^2}. \tag{8a}$$

The dashed curve in Fig. 11 illustrates this relation between the differential conductivity and the polarizing field E_B. In contrast to the solid curve, the latter starts at 1, passes a flat maximum of constant conductivity,

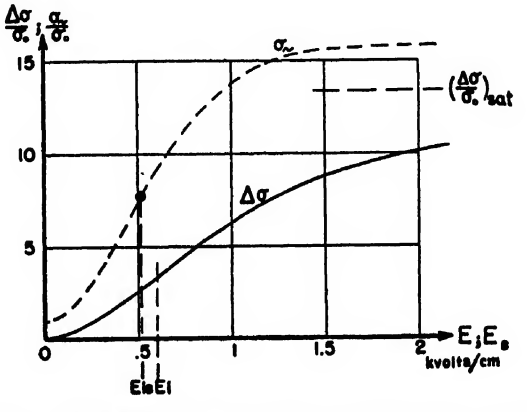

FIG. 11. The relative direct current conductivity $\Delta\sigma/\sigma_0$ and the alternating current conductivity $\sigma_\sim/\sigma_0$ *versus* the polarizing field strength E or E_B.

and approaches asymptotically the same saturation value as before.

At relatively low fields, in the vicinity of the zero point, Eq. (8a) simplifies to:

$$\sigma_\sim/\sigma_0=1+3KE_B^2 \tag{8b}$$

revealing a non-linearity three times greater than in $\Delta\sigma$.

This, at the same time, causes the inflection point to shift to:

$$E_{iB}\sim 1/2(P)^{\frac{1}{2}}, \tag{8c}$$

where the relative differential conductivity

$$(\sigma_\sim/\sigma_0)_i=3KE_\sim/2(P)^{\frac{1}{2}}, \tag{8d}$$

again is proportional to any fluctuations of E superimposed upon the bias field E_{iB}.

(b) Resistance Characteristics

The non-linear conductivity yields the corresponding resistance characteristics. For reasons which will become more apparent later, it is convenient to introduce the differential resistance $R_\sim$ which follows from Eq. (8a) as:

$$R_\sim=\frac{R_0}{1+KE^2[(3+PE^2)/(1+PE^2)^2]}. \tag{9a}$$

If it is considered in relation to the bias voltage V_B, the equation assumes the form:

$$R_\sim=\frac{R_0}{1+KV^2[(3+PV^2)/(e+(P/e)V^2)^2]} \tag{9b}$$

or, if restricted to the permissible range of relatively low voltages:

$$R_\sim=\frac{R_0}{1+3KV^2/(e^2+2PV^2)}. \tag{9c}$$

Examination of this equation reveals that the voltage sensitivity of any colloidal resistor becomes higher the

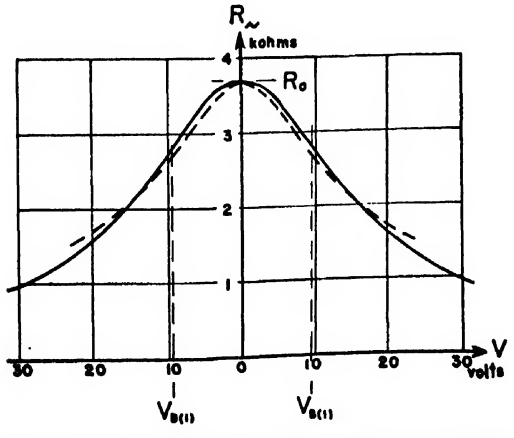

FIG. 12. Non-linear resistance characteristic of a colloidal test resistor with 1-mm electrode separation.

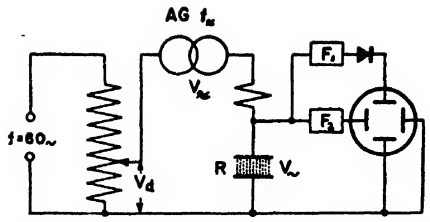

FIG. 13. Arrangement for obtaining oscillograms of differential resistance characteristics with the aid of an auxiliary-frequency $f_\simeq$ superimposed upon the oscillographing voltage $V_\sim$ of 60 cycles.

smaller the oil-gap, or, in first-order approximation, proportional to the second power of e.

As an example, the solid curve in Fig. 12 illustrates the non-linear characteristic of a colloidal test resistor with $R_0=3.7$ kohms and $e=0.1$ cm.

For the following experiments it is convenient to consider only two particular portions of the entire characteristic. First, the maximum portions around R_0 at zero bias which is simply described by:

$$R_{\sim(2)}=\frac{R_0}{1+3(K/e^2)V_\sim^2}. \tag{10a}$$

Second, the linear portions of both side branches around the bias voltage:

$$V_{B(1)}=e/3(K)^{\frac{1}{2}} \tag{10b}$$

in the present example 9.6 volts, at which operating point:

$$R_{\sim(1)}=-1.12R_0eV_\sim(K-P/3)/K^{\frac{1}{2}}$$
$$\sim -1.12R_0V_\sim(K)^{\frac{1}{2}}/e. \tag{10c}$$

The negative sign does not indicate a negative alternating current resistance but signifies only that the resistance decreases if the momentary control voltage $V_\sim$ has the same polarity as the bias voltage.

Naturally, the advantage of a direct oscillography holds also for the resistance characteristics. In order to obtain such characteristics, the arrangement diagrammed in Fig. 13 has been developed to operate as follows.

The basic schematic resembles the previous Fig. 4 with the following modifications: The auxiliary-frequency generator AG superimposes an auxiliary-frequency voltage $V_\simeq$ of some kc upon V_d. The auxiliary-frequency drop across R, after being separated from the 60 cycles by means of the high pass filter F_1 and after rectification between the vertical amplifier output and its deflecting plate, deflects the cathode ray in the Y axis. On the other hand, the horizontal deflection is produced, similarly as before, by the 60-cycle voltage drop $V_\sim$ after the auxiliary-frequency is filtered out by the low pass filter F_2. In this manner the oscilloscope indicates the differential resistance $R_\sim$ in relation to the momentary voltage across R instead of the direct current resistance R. Note that $V_\simeq < V_\sim$ so that only a very short portion of the I–V characteristic is controlled by the auxiliary-frequency.

An example of the differential resistance characteristic of a colloidal test resistor with one mm electrode separation is shown in Fig. 14. Replacing the colloidal resistor with various constant resistors introduces horizontal calibration lines, whereas the sensitivity of the X-deflection was calibrated by means of a known 60-cycle voltage. In this way the resistance oscillogram is completely calibrated. It is redrawn as the dashed curve into Fig. 12, indicating remarkable agreement

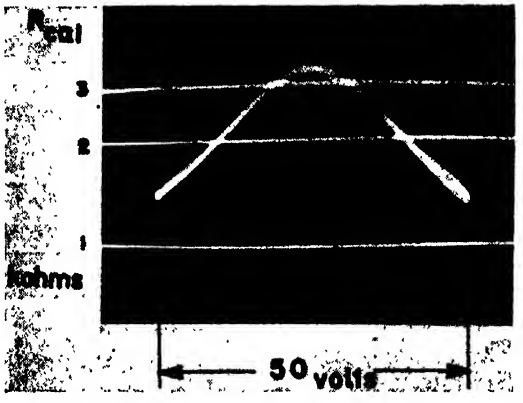

FIG. 14. Oscillographic characteristic of the differential resistance obtained at an auxiliary-frequency of 13 kc, with calibration lines.

with the analytical curve. As a preliminary result of these investigations it can be seen that the colloidal resistor has no drop in sensitivity with the auxiliary-frequency of 13 kc.

5. RECTIFICATION

(a) Pseudo Rectification

The aforementioned turning of the I–V characteristic under the influence of variable alternating voltages finds illustrative expression in the resistance characteristics. This is shown in Fig. 15 where three resistance characteristics are photographed successively at driving voltages $V_\sim$ increasing in increments of three volts. In analogy to Fig. 8 the resistance characteristics, at increasing $V_\sim$, shift downward.

According to these observations R_0 cannot be regarded as constant if the colloidal resistor operates under various voltage amplitudes but depends in turn on the state of polarization and, therefore, on the polarizing alternating field. This peculiar phenomenon can be included in the analysis in two different ways. Assuming that the dashed transfer characteristic in Fig. 16 is controlled by the alternating field $E_\sim = E_0 \cos\omega t$. Then, an average polarization takes place according to the effective field strength, i.e., proportional $E_{eff} = E_0/2^{\frac{1}{2}}$. As a result the initial tangent, whose slope characterizes σ_0, turns into the dotted chord which extends between the effective fields $\pm E_{eff}$ and whose slope indicates a new zero conductivity $\sigma_0' > \sigma_0$.

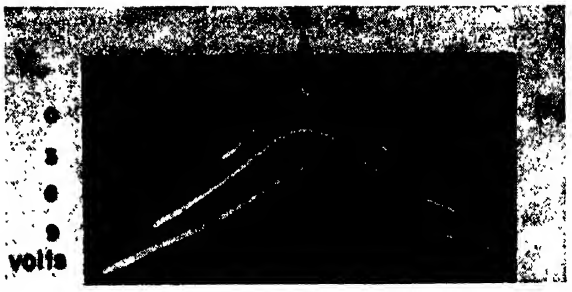

FIG. 15. Non-linear resistance oscillograms at various driving voltages $V_\sim$.

If for the sake of simplicity the simple Eq. (5a) is used, an analytical treatment of this average polarizing effect yields:

$$\sigma_0' = \sigma_0(1+(K/2)E_0^2) = \sigma_0(1+KE_{eff}^2), \qquad (11)$$

where σ_0 denotes the freely adjusting threshold conductivity just above the threshold field.

A more comprehensive explanation of the average polarization is given by considering the non-linear conductivity—or resistance—characteristic being controlled by a large voltage $V_\sim = V_0 \cos\omega t$. This is illustrated in Fig. 17. Here the fluctuating polarization causes a "pseudo-rectification," as shown on the right side of the figure. Because the chain formation is too inert to follow the alternating field itself, R_0 is diminished by the average value ΔR and, therefore, assumes the lower value $R_0' = R_0 - \Delta R$ where R_0 denotes, as before, the threshold resistance just above the threshold voltage. The analytical treatment of this resistive rectification yields, naturally, the same Eq. (11).

An exact example of the relation between R_0' and V_{eff} has already been shown in Fig. 9. There the dotted curve is computed by means of Eq. (11) in the form:

$$R_0' = 3.63/(1+1.51 \cdot V_{eff}^2 \cdot 10^{-2})$$

and is in agreement with the measuring points as well as could be expected.

(b) True Rectification

In addition to the resistive rectification which deals only with an average state of prepolarization, the curved I–V characteristic produces a true rectification. This is explained in greater detail by means of Fig. 18 where the non-linear diode characteristic is controlled by the alternating field $E_0 \cos\omega t$ at various operating points or at various bias fields E_B, respectively. Introducing $E = E_B + E_0 \cos\omega t$ into Eq. (5b) one obtains a rectified current density:

$$i_{rect} = \sigma_0 E_B \frac{1+(K+P)(E_B^2+E_0^2/2)}{1+P(E_B^2+E_0^2/2)}. \qquad (12a)$$

The dashed curves in Fig. 18 represent the true rectifi-

cation at two field amplitudes E_0. Obviously, the diode characteristic becomes erect as in Fig. 8 when subjected to an alternating control field. At very high fields $E_0 \gg E_B$, Eq. (12a) simplifies into:

$$i_{rect} = \sigma_0 E_B (1 + K/P). \qquad (12b)$$

As a result, the rectified diode characteristics straighten and finally approach the dotted line.

In order to prove this result by experiment, the non-linear bridge shown in Fig. 6 is supplemented, as illustrated in Fig. 19. The new arrangement differs from the simple bridge, in that an additional high frequency voltage $V_{\sim}$ of, e.g., 5 mc, is impressed upon the colloidal resistor. This high frequency is supplied by the signal generator "*SG*," whereby *R–F* chokes "*ch*" and capacitors *C'* prevent the high frequency energy from penetrating the bridge. Quite obviously the 60-cycle field $E_{\sim}$ takes the place of the steady bias field E_B which produces, in connection with $E_{\sim}$, the "rectified diode characteristics" shown in Fig. 20.

Whether the true rectification is combined with the previously mentioned pseudo rectification or not, is open to conjecture. Be that as it may, the fact that the diode characteristic indicates no change in frequency up to the 50 mc presently attained, reveals a remarkably good frequency response. The frequency stability marks the colloidal resistor as a useful detector whose versatility will be revealed in greater detail by means of a subsequent paper.

6. NON-LINEAR LISSAJOUS-FIGURES, AND HARMONICS

Up to the present, all oscillograms have been considered only in reference to the characteristic of the colloidal resistor itself. The following section deals with the analysis of the electrical properties of a non-linear

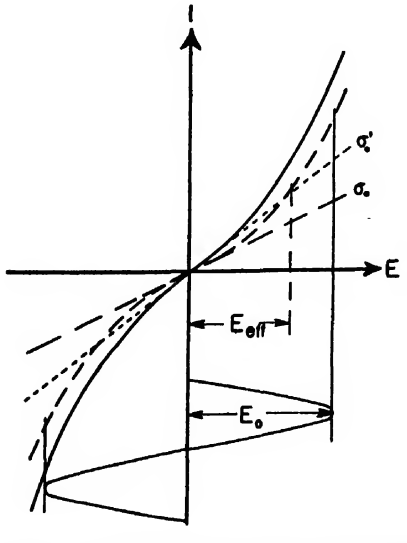

FIG. 16. Average polarization when under the influence of an alternating control field with the amplitude E_0.

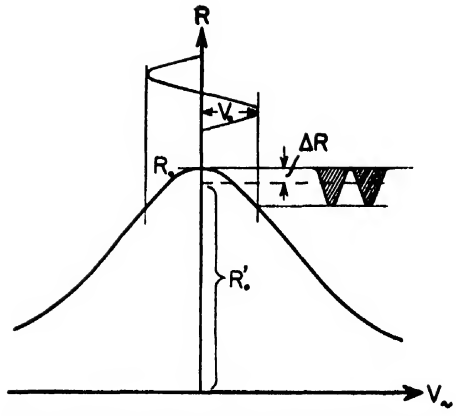

FIG. 17. Illustration of the pseudo rectification.

attenuator when the colloidal resistor operates in series with a constant resistor. For investigation from an electrical point of view, the non-linear bridge already shown in Fig. 6 is obtained, when combined with a linear attenuator.

The foregoing bridge circuit, according to Fig. 21, is modified in that the horizontal input of the oscilloscope is reversed. The *X*-deflection is sinusoidal:

$$D_x = X V_d/2,$$

whereas the diagonal voltage across the middle branch of the bridge is:

$$V_{dg} = V_{\sim} - V_d/2$$
$$= (V_d/2)\{[2/(1+RG)]-1\}.$$

Furthermore, an adjustable bias voltage V_B is added, insuring various operating points of the colloidal resistor.

For the sake of simplicity, the following analysis is restricted to two specific cases: First, the colloidal resistor operates under first-order non-linearity on linear branches of its conductance characteristic at a certain

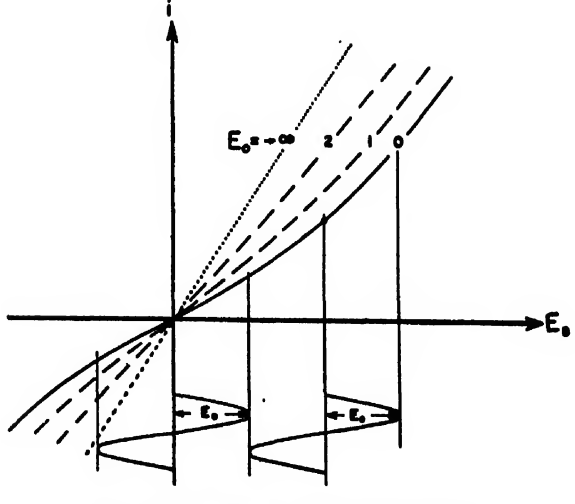

FIG. 18. "Rectified" diode characteristics.

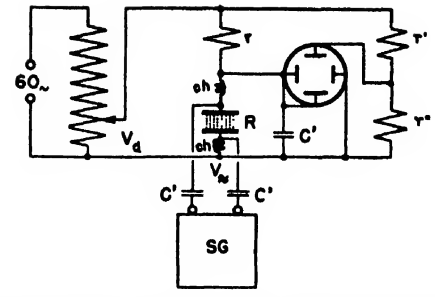

FIG. 19. Schematic of the non-linear bridge with superimposed high frequency voltages for oscillographing rectified diode characteristics.

bias voltage V_{Bi}; second, it operates under the non-linearity of second order, i.e., on the parabolic middle branch without bias.

In case one, the conductance characteristic is linear, following Eq. (7c) at the bias:

$$V_{Bi}=e/(3P)^{\frac{1}{2}}$$

with the slope:

$$G_B/V_d=\pm 3G_B eK/2(P)^{\frac{1}{2}}$$

so that the actual conductance at V_B becomes:

$$G_{\sim}=G_B[1\pm 3eKV_{\sim}/2(P)^{\frac{1}{2}}]$$

where G_B is the direct current conductance at the bias V_{Bi}. Introducing this expression into Eq. (13) and, if the bridge is balanced by means of $rG_B=1$, then:

$$V_{dg}=\frac{V_d}{2}\left[\frac{1}{1\pm eKV_{\sim}/3(P)^{\frac{1}{2}}}-1\right]. \qquad (14a)$$

A simple solution is possible only at very low driving voltages. Then the distortions of the voltage $V_{\sim}$ across R compared to the fundamental amplitude can be neglected. More accurately it means that only distortions of the first order should be considered as distortions caused by the fundamental voltage $V_{\sim}$ alone, and not distortions of the higher order caused by a cross-modulation. According to this simplification $V_{\sim}=V_d/2$. With this value, Eq. (14a) in first-order approximation becomes:

$$V_{dg}=eKV_d/12(P)^{\frac{1}{2}}$$

or furthermore, if V_d is introduced in the form $V_0 \sin\omega t$:

$$V_{dg}=eKV_0^2/24(P)^{\frac{1}{2}}\pm eKV_0^2/24(P)^{\frac{1}{2}}\cos 2\omega t$$
$$=\Delta V_{dg}\pm V_{dg\sim}. \qquad (14b)$$

Apart from a direct voltage ΔV_{dg}, corresponding to the aforementioned rectification, a second harmonic appears whose phase reverses with the polarity of the bias.

Plotting V_{dg} *versus* V_d produces a non-linear Lissajous-figure as shown in Fig. 22(a). If the polarity of the bias is reversed, the oscillogram inverts and assumes the shape (b) illustrating and thus proving the reversal of phase.

The Lissajous-figures are pure parabolas only if taken at low driving voltages. In the present examples, however, the driving voltage was relatively high, so that the parabolas are distorted, partly because the linear portions of the conductivity characteristic are overcontrolled, and partly because of the cross-modulation. The linear-time oscillogram shown in Fig. 22(c) reveals the additional distortion of the original second harmonic and indicates a full series of higher order harmonics predominantly of even order.

The second example of second-order non-linearity at zero bias yields, after introducing:

$$G_{\sim}=G_0(1+K(V_{\sim}/e)^2)$$

into Eq. (13), when limited again to low voltages, with $V_d=V_0 \sin\omega t$, and $V_{\sim}=V_d/2$:

$$V_{dg}=-3KV_0^3[\sin\omega t-(\sin 3\omega t)/3]/64e^2. \qquad (15)$$

Obviously the second-order non-linearity, characterized by the second power of the control voltage, causes a fundamental voltage to appear—because of true rectification—together with a harmonic of the second-plus-one, i.e., the third-order harmonic. Plotting V_{dg} *versus* V_d produces a Lissajous-figure similar to the non-linear bridge characteristic shown in Fig. 7. The fundamental can be suppressed by rebalancing the bridge by means of a slightly diminished r. At this rebalanced condition, only the third harmonic remains and the Lissajous-

figure lies symmetrically on the X axis as shown in Fig. 23(a).

Here again, the oscillogram has been taken at relatively high driving voltages so that the validity of the developed formulas is exceeded. Consequently, the cross-modulation produces higher harmonics of an odd order as can be seen in the linear time oscillogram (b).

CONCLUSIONS

The concept of the formation of purely dielectric or of additionally semiconductive chains and the resulting non-linearities of dielectric constant or conductivity, respectively, may be important for understanding the philosophy of Seignette-electricity and some peculiarities of semiconductors.

On the other hand, the operational characteristics of the colloidal resistors assure certain interesting applications, as, for instance, new types of detectors, frequency converters and mixers, stabilizers and limiters for d.c. and a.c. voltages, linearizers for vacuum tube amplifiers, etc., where their large range of voltage sensitivity and power dissipation reveals entirely new possibilities. Furthermore, the sensitivity of the dielectric-semiconductive chains to mechanical or quasi-mechanical influences makes it possible to design sensitive conversion elements and transducers. In addition, when the dielectric-semiconductive particles are also ferromagnetic, magnetic forces of attraction can be superimposed upon the electrostatic attractions so that the resistance

(a)

(b)

FIG. 23. Non-linear Lissajous figures at zero bias.

of such a ferromagnetic resistor can be controlled in a manner similar to Hull's first magnetron. It remains for further experiments to prove whether or not it is possible to substitute the magnetic control field by an electric field and to develop liquid-filled amplifier and oscillator devices similar to the transistor.

During the preparation of this paper, it was possible to change from the liquid-filled colloidal resistors to dry types (the so-called polar resistors or "*Polaristors*") displaying basically all the properties mentioned before. All of these problems are under study and results of the investigations will be published in the near future.

Internal Friction of Metals at Very High Temperatures*

T'ING-SUI KÊ
Institute for the Study of Metals, University of Chicago, Chicago, Illinois
(Received October 10, 1949)

In connection with the study of the internal friction peak (*versus* temperature) associated with the viscous behavior of grain boundaries in metals, some other effects were observed at higher temperatures causing an additional internal friction in superposition with the high temperature branch of this internal friction peak. This additional internal friction at high temperatures was found to have its origins in some effects of cold-working introduced in the interior of the grains which remains even after the complete recrystallization of the cold-worked specimens. It increases with the amount of cold-work the specimen was subjected to before and after recrystallization; it decreases with annealing at successively higher temperatures until a stable value is reached; and it increases with the precipitated impurity content in the specimen. This high temperature internal friction was found to be very high in an aged specimen of high purity aluminum alloyed with 4 percent of copper. These observations are consistent with the viewpoint that this internal friction is caused by the presence of dislocations in the interior of the specimen although the mechanism of giving rise to the internal friction is unknown. It is pointed out that a study of high temperature creep under very low stress may be conveniently carried out through the internal friction measurements described.

INTRODUCTION

IN the study of the high temperature internal friction of annealed polycrystalline aluminum, a peak has been observed when the internal friction is plotted as a function of temperature of measurement.[1] Such a peak was not observed in single crystal aluminum under similar conditions. Extensive study has shown that the internal friction peak is associated with the viscous behavior of the grain boundaries in metals. However, it has also been observed that the high temperature branch of this internal friction peak did not drop as rapidly as expected if this peak is entirely due to the viscous behavior of grain boundaries (Fig. 2 of reference 1). Apparently, some other effects occur at higher temperatures causing an additional internal friction in superposition with the high temperature branch of the grain boundary internal friction peak. The physical origin of this additional internal friction at very high temperatures is not understood.

The purpose of this paper is to report the results of a study on the factors influencing this additional internal friction. The physical origin of this internal friction will be discussed. All the internal friction measurements were made using a torsion pendulum as previously described.[1] The frequency of vibration was about one cycle per second. The applied stress was sufficiently small so that the magnitude of internal friction is independent of stress level at each temperature range concerned.

The additional internal friction at high temperatures has been observed in a number of metals in addition to aluminum. Figure 1 shows the internal friction peaks associated with the viscous behavior of grain boundaries for Mg,[1] Al,[1] Cu,[2] alpha-brass,[3] and Fe.[4] They were all measured in torsional vibration with a frequency of about one cycle per second. In each case it is seen that the internal friction increases again at temperatures higher than the optimum temperature of the grain boundary internal friction peak. Such a feature has also been observed by Köster in transverse vibration for Cu and Ag.[5] The frequency of vibration he used was 795 cycles per second for Cu and 642 cycles per second for Ag. It seems thus the occurrence of additional internal friction at high temperatures is independent of the mode of vibration and is a common feature of all metals.

This high temperature internal friction cannot be caused by the strain amplitude effect of the applied stress since, as we have mentioned above, the applied stress has been always kept small enough for each temperature so that the internal friction is independent of stress level. In making internal friction measurements with a torsion pendulum, a small load including the

inertia arm was applied longitudinally to the specimen. The effect of this longitudinal load has been tested for each metal. Figure 2 shows the internal friction for the case of iron when two different longitudinal loads were used in the measurement. It is seen that the whole curve is similar in both cases although one longitudinal load was seven times heavier than the other. Consequently, the additional internal friction at elevated temperatures is not attributable to the longitudinal load.

INFLUENCE OF COLD-WORK

We have mentioned previously that the high temperature internal friction is quite sensitive to the amount of cold-work the specimen was subjected to before recrystallization. Figure 3 shows the internal friction curves of specimens of recrystallized 99.991 aluminum: Curve I for the case when the specimen was subjected to a cold-work of 70 percent reduction in area and Curve II a cold-work of 95 percent reduction in area. Both specimens were recrystallized after being annealed at 450°C for five hours and the grain sizes of both were found to be similar. It is seen that the high temperature branch of the curve is lower in the case of the specimen subjected to a smaller amount of cold-work prior to recrystallization. This indicates that a smaller amount of prior cold-work causes a smaller addititional internal friction at high temperatures.† Curve III shows the internal friction curve of a specimen which was subjected to a small amount of cold-work after recrystallization. This cold-work has modified considerably the high temperature branch of the internal friction peak. It is apparent, thus, that cold-working both prior to and after recrystallization has the effect of raising the additional internal friction at elevated temperatures.

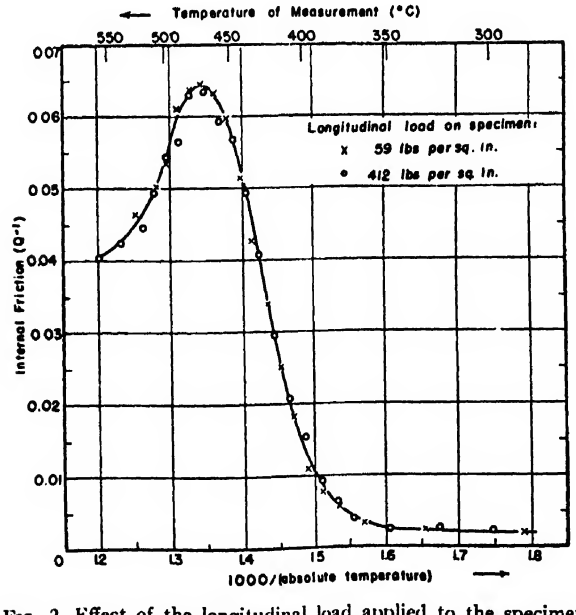

FIG. 2. Effect of the longitudinal load applied to the specimen upon the high temperature internal friction.

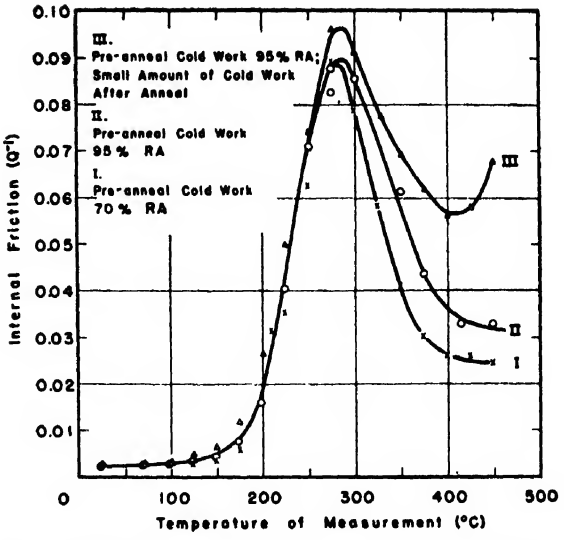

FIG. 3. Influence of the cold-work performed on the specimen before and after recrystallization.

This additional internal friction has been found to decrease as the annealing temperature goes successively higher. Figure 4 shows the effect of annealing on 99.991 aluminum subjected to a prior cold-work of 70 percent reduction in area. Figure 5 shows the case of aluminum of commercial purity (Al 2S) subjected to a prior cold-work of 96 percent reduction in area. It is to be pointed out that such a decrease of internal friction with an increase of annealing temperature reaches eventually a steady state which tendency can be seen by comparing the 400°C and 500°C annealing curves in Fig. 5.

ORIGIN OF THE HIGH TEMPERATURE INTERNAL FRICTION

The high temperature internal friction described above has also been observed in single crystal aluminum (99.6 percent purity) as shown by Curve IV in Fig. 6. The internal friction peak associated with the viscous behavior of the grain boundaries is absent in this case. However, the internal friction is seen to rise at very high temperatures. Curves I–III of Fig. 6 are the internal friction curves of several similar aluminum single crystal wires which were subjected, respectively, to the amount of cold-work shown and were then annealed at 450°C for one hour. The high temperature internal friction is seen to increase with the amount of cold-working. This indicates that this internal friction had originated from some effects of cold-working introduced inside the grains.

† In the present case the position of the grain boundary internal friction peak did not shift with the different amount of prior cold-work (70 percent and 90 percent reduction). The situation is different when the amount of prior cold-work involved is smaller (see Fig. 2 of reference 2).

INFLUENCE OF IMPURITIES

A careful study of the internal friction curves shown in Fig. 1 revealed one interesting feature: The rise of internal friction at elevated temperatures is relatively higher when the grain boundary internal friction peak is relatively lower. Thus, in the case of aluminum, the grain boundary peak is the highest and the relative rise of the high temperature internal friction is the lowest. Previous experiments have shown that the viscous slip along grain boundaries can be partly or completely blocked by the presence of impurities at the grain boundaries. A lower grain boundary internal friction peak thus indicates a higher impurity content

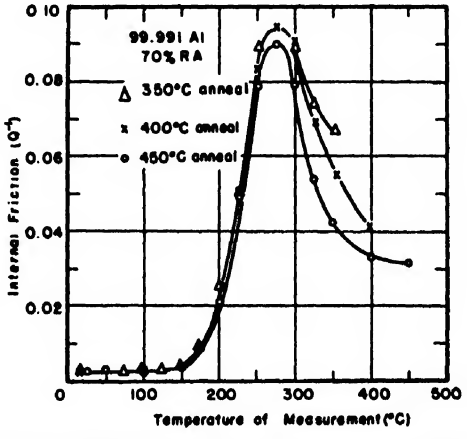

FIG. 4. Influence of annealing at successively higher temperatures (99.991 Al).

at the grain boundaries. The observation that the high temperature internal friction is larger whenever the grain boundary internal friction is smaller suggests that the former is connected with, or at least is influenced by, the presence of impurities.

Figure 7 shows the internal friction curves of polycrystalline aluminum of varying impurity content. Curve I is for high purity 99.991 percent aluminum; Curve II for aluminum 2S (containing as impurities 0.14 percent Cu, 0.48 percent Fe, 0.11 percent Si); Curve III for high purity aluminum alloyed with four percent of high purity copper. The prior cold-work and the subsequent annealing were similar in all cases. The grain sizes of the three specimens are also similar. The differences in these curves shown in Fig. 7 are thus attributable to the different amounts of impurity content. It is seen that in the case of aluminum containing 4 percent of copper, the grain boundary peak has been completely eliminated while the internal friction at 450°C is almost three times larger than the case when no copper was added.

STUDY OF AL-CU ALLOYS

In order to find out how the impurity content influences the internal friction at elevated temperatures, a detailed study has been made for the case of high

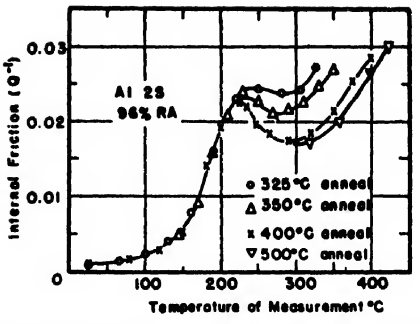

FIG. 5. Influence of annealing at successively higher temperatures (aluminum 2S).

purity aluminum alloyed with four percent of copper. In this case the impurity responsible for the effect concerned is undoubtedly copper. Figure 8 illustrates how the internal friction changes with heat treatment. The specimen was first solution-treated at 525°C for one hour and was then cooled slowly from 525°C so that the copper precipitates out in some form from the solid solution. It is seen that, after this treatment, the internal friction peak associated with the viscous behavior of the grain boundaries was eliminated while the additional internal friction at elevated temperatures is unusually high. The elimination of the grain boundary peak is supposedly due to the precipitation of copper in some form at the grain boundaries. As we have shown in the last section that the high temperature internal friction is not attributable to the grain boundaries, the rise of this internal friction is probably connected with the general precipitation of copper in aluminum, that is, the precipitation at the interior of the grains. The curve marked with (1) shows the case when the specimen was quenched from 525°C into water at room temperature. Under this treatment the

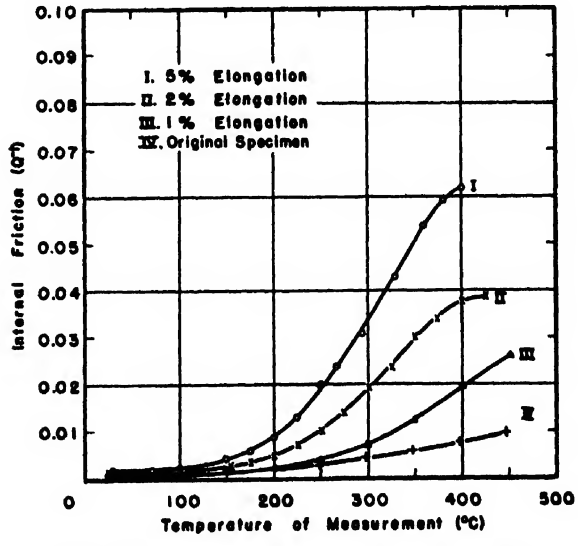

FIG. 6. High temperature internal friction of single crystal aluminum.

copper remains in solid solution in a supersaturated form. However, as the specimen is tempered at a higher temperature, the precipitation of copper will proceed at an increasing rate. The portion of curve marked (1) gives the grain boundary internal friction peak around 200°C which was measured by heating the specimen rapidly from room temperature to 200°C. This peak is fairly high although it is much lower than that for high purity aluminum without copper. This indicates that during the heating period some precipitation has taken place at the grain boundaries to block partly the viscous intercrystalline slip. When the specimen was heated rapidly from 200°C to 450°C, the internal friction at

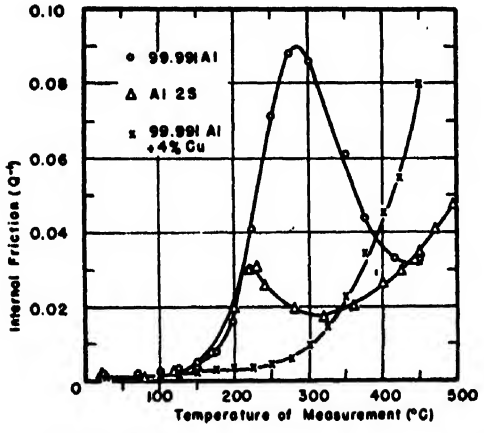

FIG. 7. Influence of impurity content upon the high temperature internal friction of aluminum.

450°C was measured and is given by (1). This internal friction was found to increase with time and its magnitude is shown by the time sequence of (1), (2), (3). This increase seems to be due to the fact that more copper was precipitated out from solid solution by tempering at 450°C. After the time sequence (3), the specimen was rapidly cooled from 450°C to 200°C. The internal friction at 200°C as given by (4) is much smaller than the original curve marked (1), indicating that more precipitation had been taking place at the grain boundaries during the tempering at 450°C. As the grain boundary precipitation is accompanied by general precipitation especially when the specimen is tempered at elevated temperatures, it is natural to assume that the rise of internal friction at 450°C by tempering is associated with the general precipitation of copper.

When the specimen was cooled slowly from 525°C, the solution treatment temperature, to 450°C, the precipitation of copper has probably been completed and the amount of copper left in solid solution is determined by the solubility of copper in aluminum at 450°C which is 2.60 percent by weight.[6] Under this condition the

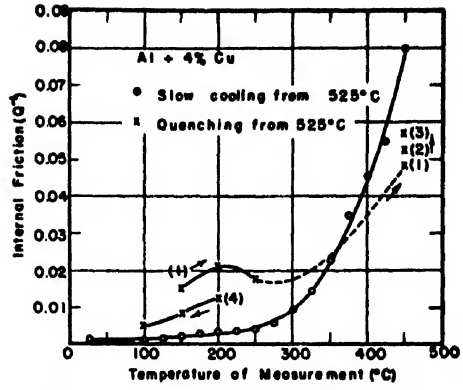

FIG. 8. Influence of heat treatment and the state of precipitation upon the high temperature internal friction of Al containing 4 percent of Cu.

internal friction at 450°C was found to be the highest as shown in Fig. 8. This indicates that the internal friction is the highest when the copper is in the precipitated state of some form.

The internal friction at elevated temperatures has been found to be independent of the impurities in dissolved form. Figure 9 shows the internal friction curves of high purity aluminum and of high purity aluminum alloyed with ½ percent of high purity copper. At 300°C the solubility of copper in aluminum is 0.45 percent.[6] The ½ percent copper in the specimen is thus in dissolved form at temperatures a little over 300°C. It is seen that the portions of the two curves over 300°C are almost identical, indicating that the ½ percent Cu in dissolved form has nothing to do with the internal friction at elevated temperatures. At temperatures lower than 300°C, the internal friction curve for the specimen containing ½ percent of copper is lower. This is evidently because of the blocking of grain boundary slip by copper precipitated in some form at the grain boundaries at temperatures lower than 300°C.

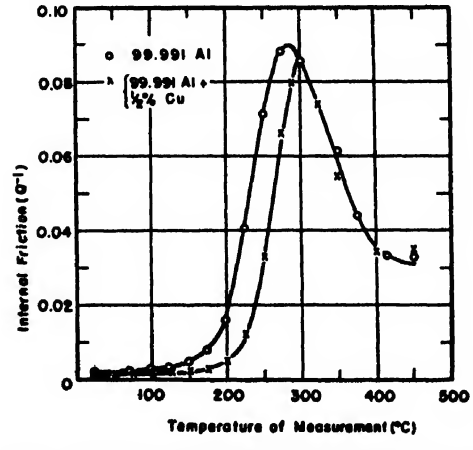

FIG. 9. Influence of dissolved impurity upon the high temperature internal friction.

Mg	0.003		

STUDY OF TERNARY ALUMINUM ALLOYS

In describing the effect of impurity upon the internal friction at elevated temperatures, we have mentioned in connection with Fig. 7 that the high temperature internal friction of aluminum increases with the amount of copper contained in the specimen. Thus aluminum 2S containing 0.14 percent of copper has a higher internal friction than that of high purity aluminum but a lower internal friction than that of high purity aluminum alloyed with 4 percent of copper. A closer examination indicates that in the case of aluminum 2S, the situation is not so simple as the solubility of copper in aluminum at 450°C is 2.60 percent. The 0.14 percent of copper in the specimen should be in solid solution at 450°C and the high temperature internal friction should be small at this temperature. Figure 9 shows this is the case for high purity aluminum alloyed with $\frac{1}{2}$ percent of copper. The anomalous condition in aluminum 2S indicates that a ternary or more complicated system is involved. The situation is more puzzling in the case of chemically pure aluminum containing 0.13 percent of copper, which gives an internal friction at 450°C as high as 0.11 (for a prior cold-work of 77 percent reduction in area. See Fig. 3 of reference 2). This internal friction is even higher than that of aluminum alloyed with 4 percent of copper at the same temperature. Table I gives the impurity content of the high purity aluminum and other samples.

It is seen that the copper content in aluminum 2S and in the chemically pure Al is about the same. The other impurities are chiefly iron and silicon. An insoluble Al-Cu-Fe phase or Al-Fe-Si phase may be formed and precipitates out from the solid solution although the copper and silicon, if present alone, will go into solid solution at the temperature range concerned. If this is the case, then the rise of the high temperature internal friction may be attributed to the presence of these ternary phases.

However, this still cannot explain why the internal friction of the chemically pure Al at 450°C is much higher than that of aluminum 2S. Figure 10 shows that at 450°C the internal friction of the former is higher than that of the latter although the previous cold-work in the former is only 42 percent reduction in area while it is 96 percent in the latter. It is not understood whether this difference can be attributed to the difference of the iron content in the two specimens (see Table I) or to some other unknown factors such as the past history of the specimens.

DISCUSSION OF RESULTS

In summary, we have found that the additional internal friction which dominates at elevated temperatures has the following features:

1. It occurs in polycrystalline and single crystal metals.
2. It increases with the amount of cold-work the specimen was subjected to before and after recrystallization.
3. It decreases with annealing at successively higher temperatures until a stable value is reached.
4. It increases with the precipitated impurity content in the specimen.

Let us examine now what are the underlying mechanisms of this high temperature internal friction.

A glance at Fig. 1 shows that the internal friction at elevated temperatures always occurs after the grain boundary relaxation has been completed. As the shear stress is relaxed along the grain boundaries, a concentration of stress will be built up at the grain corners.[7] Under proper conditions the local stress concentration may be large enough to initiate slip at the grain corners.[8] If this does happen it will certainly cause a considerable increase of internal friction. As a matter of fact, Hanson and Wheeler[9] have observed the macroscopic movement of grain boundaries at elevated temperatures. However, this was the case only when the applied stress is large. In our present case the applied stress is small, so the stress concentration at the grain corners is probably not large enough to initiate slip. This seems to be true as the curves in Fig. 7 show that the internal friction at 450°C is high in spite of the fact that the grain boundary relaxation was blocked by the presence of impurities.

If slip at grain corners has been initiated during measurements at 450°C, the internal friction should be sensitive to the stress amplitude. On the contrary, the internal friction has been found to be independent of stress levels under the experimental conditions.

In his study of amorphous plasticity, Orowan has pointed out that a disordered arrangement of atoms leads to a viscous type of flow if the temperature is

sufficiently high.[10] "Atomic disorder can be found not only at grain boundaries, but also inside the crystals if these have been plastically distorted, and particularly during recrystallization and phase transformations when the atoms leave one lattice and join another."[11] Along this line of thought this author has recently described a grain boundary model in which the transition region at the boundary was considered as consisting of numerous disordered groups of atoms or diffused holes.[2] The viscous intercrystalline slip was considered to occur through the atomic rearrangement by thermal agitation within each "disordered group" by a shear process involving as units of flow only a few atoms. Such a grain boundary model and slip mechanism are consistent with experimental facts. Among others, such a viscous intercrystalline slip will give rise to internal friction.

We have also pointed out that the "disordered groups" of atoms may conceivably exist also in the interior of the grains, except that they are much smaller in number than those existing at the grain boundaries. However, it can be shown that such disordered groups of atoms, when existing isolated in the interior of grains, cannot cause appreciable stress relaxation to account for the high internal friction observed at high temperatures as shown in Fig. 7 in which the internal friction of Al+4 percent of Cu is shown to be as high as 0.08 at 450°C. In the language of dislocation theory, we can say that numerous dislocations were introduced in the specimen during the cold-working and some dislocations remain therein even after the complete recrystallization of the specimen. The stress-induced movement of the dislocations can give rise to internal friction although the exact mechanism involved is not known.

The number of dislocations introduced in the specimen increases with the amount of cold-work. It is conceivable that the number of dislocations remaining in the specimen after recrystallization is larger in the case of a larger prior cold-work. The number of survival can be further reduced by annealing at a higher temperature until an equilibrium state is reached. In each case the internal friction increases with the number of dislocations existing in the specimen.

The effect of undissolved impurities on the observed internal friction may be primarily due to their retarding effect upon the removal of dislocations by annealing. This explains the observed facts that the high temperature internal friction is raised by undissolved impurities. However, additional consideration must be given to the complicated influences of impurities upon the stress-induced movement of dislocations.

CONCLUDING REMARKS AND CORRELATION WITH CREEP MEASUREMENTS

The foregoing discussions indicate that the experimental observations are consistent with the viewpoint that the internal friction at elevated temperatures under small stresses (of non-grain boundary origin) is caused by the presence of dislocations in the interior of the specimen. Accordingly, any factor that influences the number and the movement of dislocations in the specimen will result in a change of this internal friction. Such factors consist of the past thermal and mechanical treatments on the specimen, the impurity content, and the state of the impurities in the specimen.

Since a rise of internal friction has been shown to correspond to a rise of the rate of anelastic creep under low stress,[1,7] the additional internal friction at elevated temperatures may be correlated with the anelastic creep of metals at elevated temperatures in the same manner as the grain boundary internal friction was correlated with the anelastic creep of metals originating from the viscous behavior of grain boundaries (grain boundary creep).[1] Consequently, the discussions concerning the physical aspects and origin of the high temperature internal friction hold equally well for the case of anelastic creep under very small stress.

In conventional creep experiments the load applied to the specimen is usually large. This complicates the situation since the applied stress introduces additional creep properties to the specimen under test. To understand the physical aspects of the creep of the original specimen, the creep experiments must be done under sufficiently small stress so that the applied stress furnishes only a directive effect. A step toward this direction has been made by Chalmers in his study of the effect of applied stress upon the micro-creep of tin.[12] The study of creep through measurements of internal friction at low stress, as described in this paper, may prove to be both expedient and capable of giving unambiguous results for theoretical analysis.

The Orientation Dependence of the Rate of Grain Boundary Migration*

PAUL A. BECK, PHILIP R. SPERRY, AND HSUN HU
Department of Metallurgy, University of Notre Dame, Notre Dame, Indiana
(Received November 14, 1949)

Very small recrystallized grains of a large variety of orientations were produced locally in lightly rolled high purity aluminum crystals. The rate of growth of these small grains varied greatly, depending on their relative orientation with respect to the matrix crystal. Grains with an orientation corresponding to a [111] rotation of about 40° showed by far the highest rate of growth. These results indicate that recrystallization textures developing in the spontaneous recrystallization of deformed single crystals can be accounted for by the orientation dependence of the rate of growth.

THE large grains growing in an essentially strain-free fine-grained matrix of single orientation texture (coarsening) have quite definite orientation relationships with the matrix. In face-centered cubic metals, such as aluminum,[1] copper,[2,3] and nickel-iron,[4] the orientation relationship most frequently found corresponds to a rotation of about 30–45° around a [111] axis.

It was recently observed[1] that for the essentially strain-free grains growing in a highly oriented cold-worked matrix (rolled or compressed single crystal of aluminum), where the driving force of grain boundary migration is the strain energy stored in the cold-worked metal (recrystallization), the orientation relationship with the matrix is the same as for coarsening.[5] The identity of the orientation relationships in the two processes is all the more remarkable as the driving energy for recrystallization after large deformations is estimated to about 100 or 1000 times that for coarsening.

FIG. 1. Strain induced boundary migration in high purity aluminum. Area swept by boundary while moving from 1 to 2, during last anneal, is essentially strain-free, has same orientation as cold-worked grain *A*. Oblique illumination. Magnification 75×.

The understanding of these reorientation phenomena depends largely on the question whether the orientation relationship is determined by the availability of nuclei in definite orientations only, or whether it is determined by the dependence of the rate of growth on the orientation. Oriented nucleation was proposed by Burgers and Louwerse[6] for recrystallization and by Burgers[7] and recently by Kronberg and Wilson[3] for coarsening. Oriented growth in coarsening was suggested by van Arkel.[8] The possibility of interpreting the reorientation in recrystallization on the basis of an oriented growth theory, was pointed out by Barrett.[9] Recent work by three independent groups of investigators,[1,3,4] with three different metals, furnished overwhelming evidence to the effect that in coarsening "nucleated" by small grains, formed amidst the highly oriented matrix in a large variety of orientations by recrystallization after inhomogeneous local deformation (sawing or shearing of the edges, ball indentation, needle scratch), the grains growing to large size have the same orientation relationship to the matrix as the coarse grains formed spontaneously (without artificial nucleation). These experiments prove that the rate of growth in coarsening does depend on the orientation and that the orientations favored in spontaneous coarsening are actually ac-

counted for by their high rate of growth.† It is significant that no observation was so far reported by any investigator that could not be readily based on oriented growth. Finally, Dunn reported[10] the variation of the rate of growth with orientation for coarsening in silicon ferrite. There has been, however, no similarly direct evidence available to prove that in recrystallization, too, the rate of growth does in fact depend on the orientation of the growing grain with regard to the matrix.

The chief difficulty in carrying out a recrystallization experiment, analogous to that described above for coarsening, has been the supposed impossibility of preventing spontaneous recrystallization. If the spontaneous formation of recrystallization nuclei could be prevented, even though nuclei artificially provided in various orientations were capable of growing, then the possible dependence of the rate of growth of these nuclei on their orientation could be studied.

It was recently found[11] that in high purity aluminum the spontaneous formation of recrystallization nuclei is rather rare up to deformations as high as 40 to 50 percent by rolling. Instead, essentially strain-free material is formed by migration of certain grain boundaries already present in the cold-worked material (Fig. 1). Starting with a relatively large initial grain size in order to minimize the effect of these boundary migrations, in the present experiments large grain-areas were made available for artificial nucleation. Artificial nucleation was effected by inscribing with a sharp needle one or two scratches into the surface of each large grain of the electrolytically polished portion of high purity aluminum specimens, which had been previously rolled 12 percent. After scratching, the specimens were annealed in salt bath for 1 hour at 350°C, and electrolytically etched to produce a thin oriented oxide layer, revealing variations in grain orientation.[12] Typical results are shown in Fig. 2. It is clear that in the immediate vicinity of the scratches many small grains were formed by recrystallization caused by the high local deformation. Of these small grains some served as nuclei for larger grains growing at the expense of the lightly (12 percent) deformed original grains. The relative orientation of the largest recrystallized grains with respect to the deformed matrix crystal was determined

FIG. 2. Many small recrystallized grains of various orientations at the immediate vicinity of the two scratches. Selective growth of those recrystallized grains with suitable orientation with respect to the cold-worked matrix grain. High purity aluminum initially annealed 4 hr. at 650°C, rolled 12 percent, electrolytically polished and scratched, annealed 1 hr. at 350°C. Repolished and anodically etched. The two scratches were partially removed by repolishing in order to make the numerous small grains more clearly visible. Polarized light, Biot-Klein quartz plate. Magnification 25×.

by the etch pit and optical goniometer method to an estimated accuracy of about ±1°. The results for 19 recrystallized grains found in 6 deformed matrix grains are shown in Fig. 3, with all matrix poles rotated to the same position, the "active" [111] axis being in each case in the center of the pole figure. The direction of rotation was reversed for some crystals so as to correspond in Fig. 3 to that of the other crystals. In all cases the relative orientation of the large recrystallized grains with respect to the matrix corresponded approximately to a [111] rotation of 40°. In some matrix grains two or even three [111] axes were found to be active. In Fig. 3 these are all separately rotated to the center of the pole figure.[13]

† This conclusion was reached in references 1 and 4. Kronberg and Wilson (see reference 3) attempted to explain their results in terms of oriented nucleation.

[13] The fairly well-defined orientation relationship found here with artificial nucleation (Fig. 3) is in sharp contrast to the large scattering of orientations found by Burgers [W. G. Burgers and J. C. M. Basart, "Rekristallisation von Aluminium-Einkristallen I.," Zeits. f. Physik 51, 545 (1928)] for the recrystallized grains in slightly deformed aluminum single crystals, without artificial nucleation. In accordance with a suggestion by F. C. Frank, the University of Bristol, England, it is very likely that the scatter of orientations in Burgers' experiments was a result of lack of nuclei in orientations most favorable for growth. Such a condition could have resulted from the small extent of the deformation used. In the present experiments nuclei of a sufficient variety of orientations were produced artificially. In the recrystallization experiment with copper, described by Kronberg and Wilson (see reference 3), the lightly deformed matrix was polycrystalline, with a cube texture. The sharp recrystallization texture found by these investigators was probably a result of the availability of a large variety of nucleus orientations, due to inhomogeneous deformation at grain boundaries.

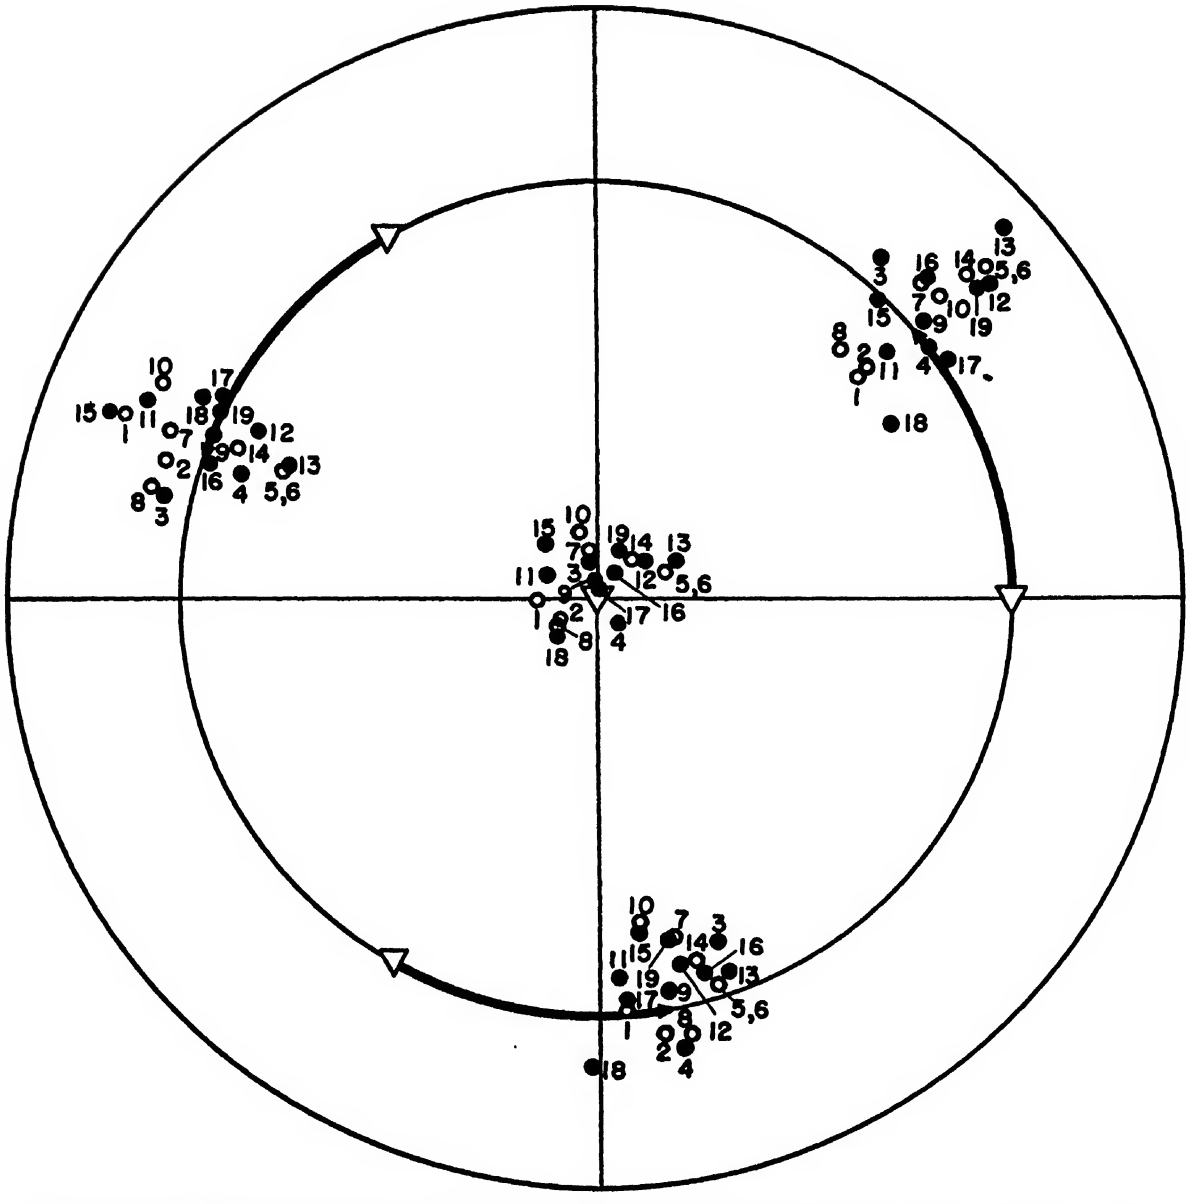

FIG. 3. (111) pole figure showing relative orientation of matrix grains △ (with the active [111] axis in the center) and of 19 largest recrystallized grains (circles). Arrow shows [111] rotation of 40°. Direction of rotation was reversed (by using mirror image of poles) for poles marked ●.

From the results shown it is evident that for recrystallization, as found previously for coarsening, the rate of growth of the artificially nucleated growing grains is highly dependent on their orientation relative to the matrix. In the recrystallization of high purity aluminum the crystal orientation which develops the highest rate of growth corresponds to a [111] rotation of about 40°–45° with respect to the matrix, as previously found for coarsening.[1] Since the same orientations were found[1] to predominate in recrystallization with spontaneous nucleation, it follows that the textures obtained in ordinary recrystallization (as well as in coarsening) can be accounted for by oriented growth, without recourse to oriented nucleation. It is interesting to note the high degree of independence of the orientation relationship between the fast-growing recrystallized grains and their matrices (Fig. 3) from variations in the orientation of the deformed matrix-grains with respect to the main directions of the rolling operation (Fig. 4). Another interesting observation may be made by inspection of Fig. 2. In certain directions the new grains grow much faster than in others; the rate of growth of the recrystallized grains is quite anisotropic. It appears that (111) faces tend to develop, suggesting that the rate of migration of such faces is lower than that of others.

Considering the controlling importance of the orien-

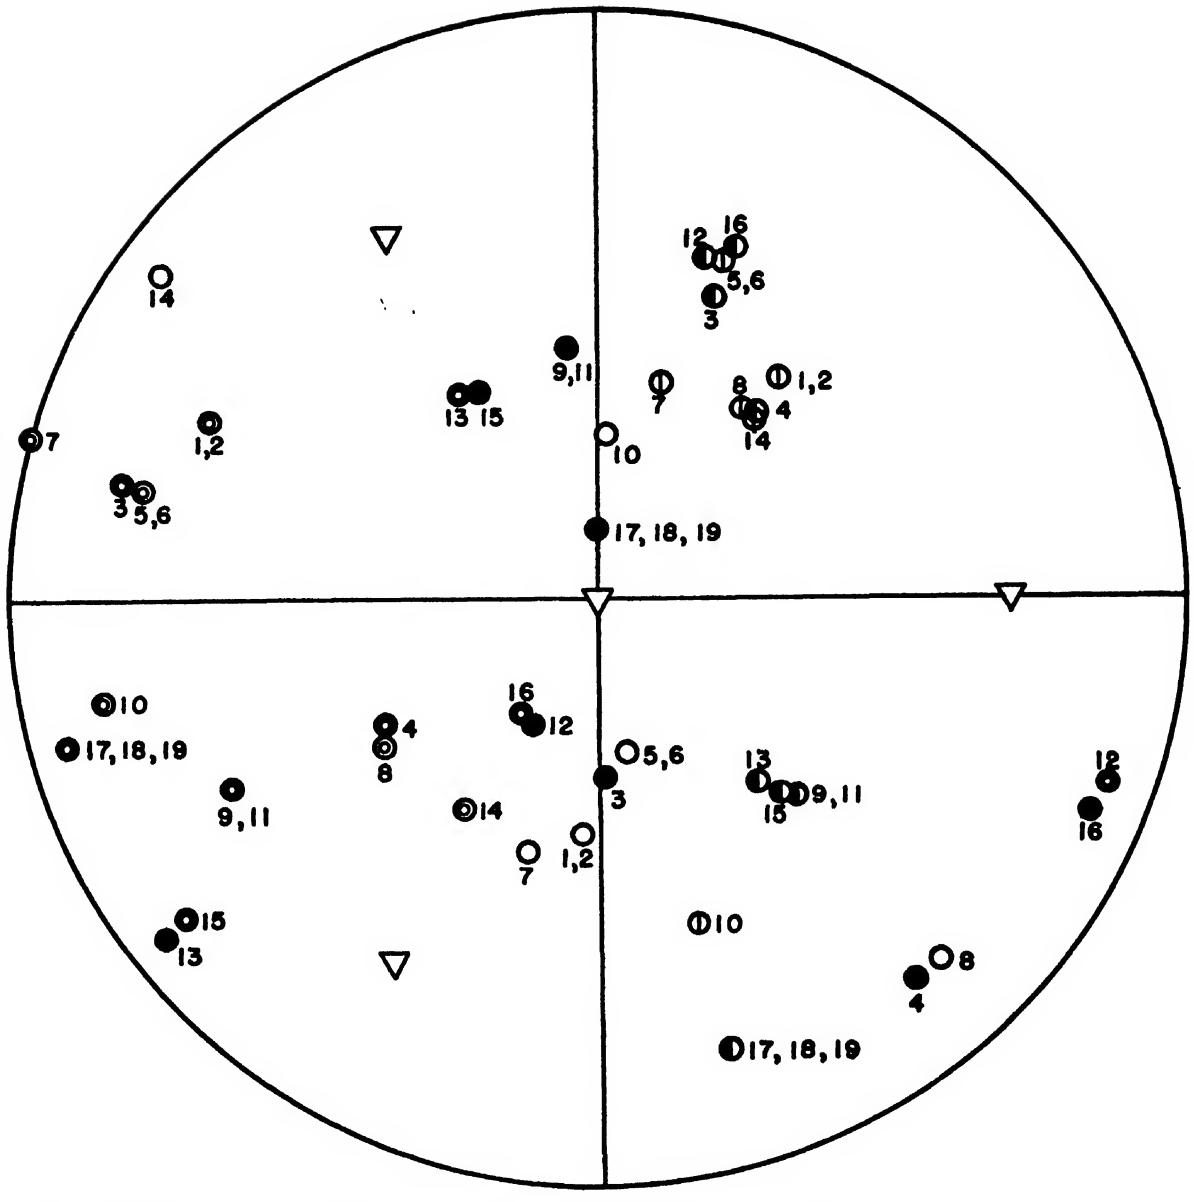

FIG. 4. Pole figure showing orientation of matrix grains △, with respect to the direction of rolling ○, the normal direction ● and the cross direction ⊕ (active [111] axis in the center). The direction of rotation was reversed where circles are partially or completely filled.

tation-dependence of the rate of grain boundary migration, one would like to form a picture of this effect in terms of fundamental physical processes. In this connection, it is worth noting that the strain-free grains formed in cold-worked and annealed high purity aluminum in the manner shown in Fig. 1, are always growing at the expense of a strained grain of different orientation.[11] In observing a large number of such grains, they were *never found to grow at the expense of the strained grains of nearly the same orientation* with which they are in contact.[14] That the absence of migration of the boundary between a strained and a strain-free grain of nearly the same orientation is not due to

[14] It is interesting that, on the other hand, the sub-boundaries observed by P. Lacombe and L. Beaujard ["Les imperfections de structure des cristaux uniques d'aluminium pur," Revue de Metallurgie 45, 317 (1948)] in polygonized aluminum are apparently highly mobile [A. Guinier and P. Lacombe, "L'état polygonisé, du cristal metallique," Métaux et Corrosion (1948), No. 212], even though they are located between lattice regions of nearly the same orientation. Possibly, this high mobility is connected with the fact that such a sub-boundary may be considered as a set of parallel line dislocations; the mechanism of boundary migration here is probably the one proposed by W. G. Burgers ["Recovery and recrystallization viewed as processes of dissolution and movement of dislocations," Proc. Koninklÿke Nederlandsche Akademie van Wetenschappen, 50, 452 (1947)]. On the other hand, in the more general case, where two sets of intersecting edge dislocations are necessary to describe the boundary, it is more

FIG. 5. Strain induced boundary migration between grains *C* and *B* and between grains *A* and *B*. Boundary positions before and after the last anneal are marked 1 and 2. Strain-free area swept by moving boundary between *C* and *B* has orientation of *B*; it is growing into *C*. Strain-free area swept by migrating boundary between *A* and *B* has same orientation as *A*, and it is growing into *B*. High purity aluminum annealed at 650°C for 4 hr., rolled 12 percent, electrolytically polished, annealed 4 hr. at 350°C and 1 min. at 400°C, repolished mechanically and electrolytically and etched anodically. Oblique illumination. Magnification 75×.

a lack of driving energy[15] is obvious from the fact that the same strained grain is often seen being absorbed by a strain-free grain of a different orientation (Fig. 5). The surface energy connected with the migrating boundary (between two grains of different orientation) is undoubtedly larger than that connected with the stationary boundary (between two grains of practically the same orientation). Hence the energy required to increase the surface area of the boundary actually migrating is larger than the energy that would be required to expand the boundary which is in fact stationary; it so happens that strain induced boundary migration occurs just where the surface energy conditions are unfavorable for it. Clearly, then, the deciding factor must be something other than surface energy. It has been pointed out by Kronberg and Wilson[3] that the experimentally found relative orientations are near ones at which a certain percentage (such as 7 percent) of the atomic positions in the two lattices (that of the growing crystal and of the matrix) coincide, whereas generally in other orientations such coincidences are very rare. That an orientation relationship involving a large number of coincidences is not necessarily favorable for fast boundary movement is clear from the fact described above, that with nearly 100 percent coincidence the boundary is practically immobile. The fact that twin boundaries are particularly stable also points in the same direction. An exceptionally convincing demonstration of the lack of mobility of twin boundaries in the face of considerable driving forces was recently given by C. S. Smith.[16]

The experimental facts may be summarized by stating that with relative lattice orientations corresponding to a [111] rotation of 0° or 60° (twin orientation) the mobility of the grain boundaries is very low, and that with relative lattice orientations between these two, corresponding to [111] rotations of about 30°–45°, the mobility is the highest. Let us assume that grain boundary migration is a result of atoms leaving unfavorable positions in one crystal lattice, diffusing along the grain boundary and finally attaching themselves at some particularly favorable location to the crystal on the other side of the boundary. The necessity of *self-diffusion along the boundary* is an essential feature of the assumed mechanism of grain boundary migration. The effect of the relative orientation of the two crystals on the "mobility" of the boundary between them must be a result of its influence on the rate of transfer of atoms across the boundary. In view of the above mechanism of boundary migration, the most probable assumption as to the manner in which such an influence may be exercised is that the relative lattice orientation has a strong effect on the rate of self-diffusion along the grain boundary. It can be readily visualized for instance that at the boundary between two crystals of nearly the same orientation, or at a twin boundary, there is relatively little disturbance; the atoms are more tightly held in their positions, hence the rate of their diffusion is lower than along a boundary with more disorientation. Such an effect has apparently not as yet been found in diffusion studies, but its existence could be relatively easily ascertained by comparing the rate of self-diffusion along grain boundaries in a specimen of a single-orientation texture with that in a specimen of random orientation, other factors, such as grain size, being held constant.

CONCLUSION

(1) Evidence is presented to show that in slightly deformed high purity aluminum crystals the rate of growth of recrystallized grains of various orientations varies over wide limits.

(2) Those recrystallized grains which grow at the

likely that grain boundary migration takes place by individual atomic migration, as described further below.

[15] The fact that in fine grained high purity aluminum gradual grain growth is impeded in the presence of a strong single orientation texture [P. A. Beck and P. R. Sperry, "Effect of recrystallization texture on grain growth," Trans. A.I.M.E. 185, 240 (1949)] is probably closely related to the described effect. However, in this case the situation is not nearly as clear-cut as in the phenomenon just discussed, since the driving energy (in this case grain boundary surface energy) as well as the mobility becomes very small. The same applies to the remarkable stability of a sharply defined "cube texture" in copper (see reference 3), and probably also to the small "insular" grains left unabsorbed by a surrounding recrystallized grain of nearly the same orientation [P. Lacombe and Aurel Berghazen, "Relations d'orientation entre monocristaux métallique de recristallization et petits cristaux inclus," Métaux et Corrosion (1949), No. 281].

[16] Discussion by C. S. Smith of the paper by Hibbard, Liu, and Reiter, "Annealing twins in copper and 70–30 alpha-brass," Trans. A.I.M.E. 185, 635 (1949).

highest rate have relative orientations with respect to the matrix corresponding approximately to a 40° rotation around a common [111] axis.

(3) Since the orientation with the highest rate of growth closely approximates that found previously for the recrystallization texture of 70 to 80 percent rolled or compressed aluminum single crystals, it is concluded that the recrystallization texture can be accounted for by the orientation dependence of the rate of grain boundary migration. (Similar conclusion was reached earlier (see reference 1) regarding the coarsening texture.)

(4) The hypothesis is advanced that the orientation dependence of the rate of grain boundary migration is brought about by the dependence of the rate of self-diffusion along grain boundaries upon the relative orientation of the two grains meeting at the boundary. The assumed diffusion effect could be tested independently from its connection with grain boundary migration.

Measurement of the Thermal Diffusivity of a Soil by the Use of a Heat Pump

E. B. PENROD
Department of Mechanical Engineering, University of Kentucky, Lexington, Kentucky
(Received October 13, 1949)

An earth heat pump was set in operation to abstract heat from soil assumed to be in thermal equilibrium. Temperature-time graphs of the antifreeze and of the soil at distances of six, twelve, and eighteen inches below the center of the antifreeze line were plotted from experimental data. From these graphs data are obtained from which the thermal diffusivity of the soil is calculated. The soil was analyzed and found to fall in the general Casagrande classification of lean clay (*CL*) with low plasticity.

INTRODUCTION

IN designing the ground coil or earth heat exchanger for a heat pump system that uses the earth as its source of heat, the thermal properties of the soil and its general classification should be known.* When the earth heat pump[1] is operating on the heating cycle, for example, heat is absorbed from the soil by the cold fluid circulating through the earth heat exchanger. The time rate of heat flow through the earth depends partly on its moisture content which in turn depends on the grain size of the soil.

An original method is used to determine the thermal diffusivity of soils which may be applicable to geological and geophysical studies. The soil was analyzed and classified in addition to measuring its thermal diffusivity.

THE METHOD

After the earth heat exchanger had been buried in the soil a transient temperature distribution was created in the ground. This was accomplished by circulating a cold antifreeze solution continuously through the earth heat exchanger (Fig. 1) and the evaporator coils of the heat pump system. A section of the earth heat exchanger at station 3 (Fig. 2) was considered as an infinite line heat source when the heat pump was operating on the heating cycle.

It was assumed that the initial temperature of the soil is a function $f(r)$ of the distance from the antifreeze line and that the temperature at any time τ is a function $t(r, \tau)$. The differential equation for transient heat flow[2] in cylindrical coordinates is

$$\frac{\partial t}{\partial \tau}=\alpha\left(\frac{\partial^2 t}{\partial r^2}+\frac{1}{r}\frac{\partial t}{\partial r}\right). \tag{1}$$

Using finite differences[3] instead of differentials, Eq. (1) transforms to

$$\alpha=\frac{\Delta t/\Delta \tau}{(\Delta^2 t/\Delta r^2)+(1/r)(\Delta t/\Delta r)}, \tag{2}$$

where α is the thermal diffusivity of the soil.

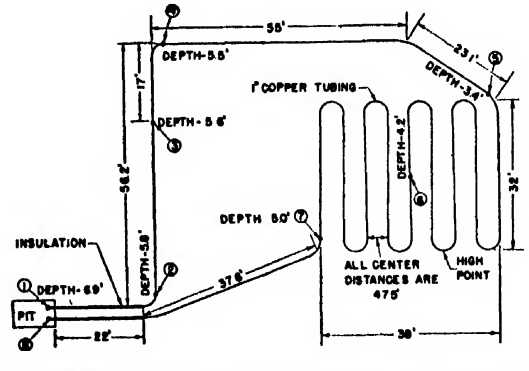

FIG. 1. Schematic diagram of the earth heat exchanger. The portion at station 3 was considered as an infinite line heat source.

* The Kentucky Utilities made the research possible by giving a Marvair heat pump and financial grant-in-aid to the University of Kentucky which supplemented the funds allocated by the Engineering Experiment Station of the University.

TABLE I. Data for calculating $\Delta t/\Delta\tau$ and $\Delta t/\Delta r$.

Curve	Distance below center of antifreeze line, r ft.	Thermo-couple No.	Temperatures at noon, March 19, 1949, °F	Change in temperature from March 16 to 22, 1949, Δt°F	Time interval, $\Delta\tau$ hours
A	0.0	3	30.6	− 9.7	144
B	0.5	12	44.5	−10.9	144
C	1.0	13	48.6	− 9.0	144
D	1.5	14	50.1	− 5.0	144

The experiment was started on March 16, 1949 when temperatures of the antifreeze and soil were recorded at regular intervals for two days before the heat pump was put in operation. At 9:00 A.M., March 18, the plant was set in operation so that heat was absorbed from the soil as the antifreeze was circulated through the earth heat exchanger. While the heat pump was in operation temperatures were taken at regular intervals in the center of the antifreeze line (Fig. 2) at station 3 and in the soil below it at distances of six, twelve, and eighteen inches respectively. These data are shown graphically in Fig. 3.

Data for calculating the slope, $\Delta t/\Delta\tau$, of curves *A*, *B*, *C*, *D* at distances $r=0.0$, 0.5, 1.0, and 1.5 feet below the center of the antifreeze line are given in the last two columns in Table I. Curve *I* (Fig. 4) shows the variation of the slope with respect to distance below the center of the antifreeze line.

The temperature gradients, or first differences, were calculated from the data given in the fourth column of

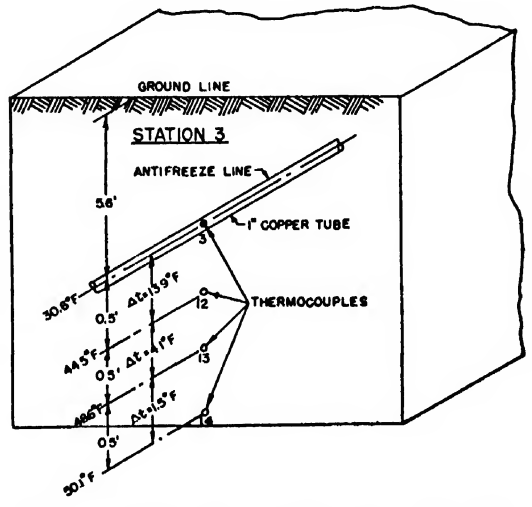

FIG. 2. Schematic diagram showing the location of the thermocouple beads at station 3.

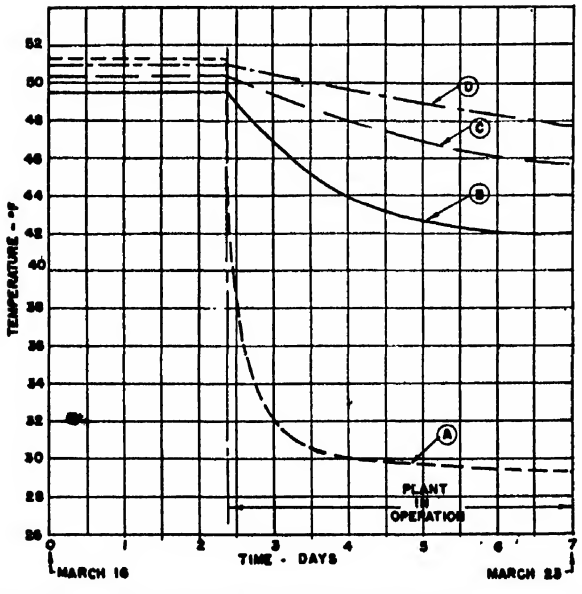

FIG. 3. Graphs showing the variation of temperature with respect to time at station 3.

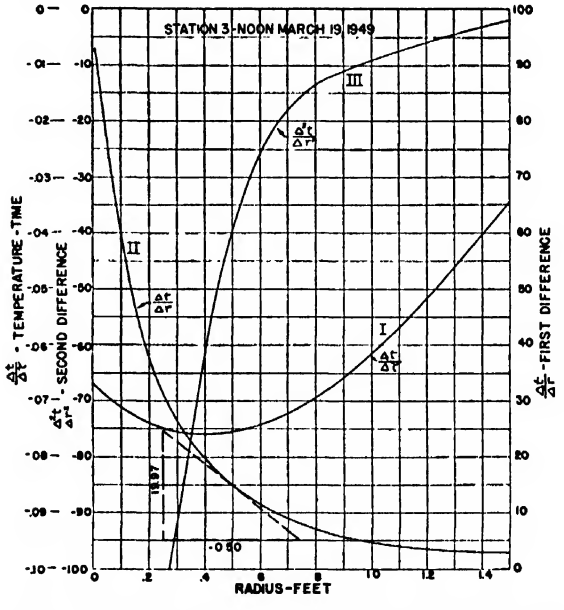

FIG. 4. Graphs used to determine the thermal diffusivity of the soil at station 3. Curve *I* was obtained from curves *A*, *B*, *C*, and *D* of Fig. 3 for noon, March 19. Curves *II* and *III* show the variation of the first and second differences with respect to the distance below the center of the antifreeze line.

Table I, and are listed in the third column of Table II. Curve *II* (Fig. 4) was obtained by coordinating values of the temperature gradient and distance from the center of the antifreeze line. The second differences, $(\Delta^2 t/\Delta r^2)$, were obtained by finding the slopes of curve *II* (Fig. 4) at various distances from the center of the antifreeze line. These results are given in the fourth column of Table II.

By substituting data given in Table II, in Eq. (2) values of the thermal diffiusivity of the soil were obtained.

SOIL CLASSIFICATION

It is necessary to know the thermal properties of the soil as well as its general classification before an efficient

earth heat exchanger can be designed. In order to determine the characteristics of the soil in which the earth heat exchanger was buried, a sample of the soil was taken at a depth of about 5 feet and 6 inches in the vicinity of station 3 at the time of the trench excavation.† Table III contains physical test data on the sample of soil, while results of the test for grain size distribution and plasticity characteristics are shown in Figs. 5 and 6. About 60 percent of its grains are in the size generally termed clay, and less than 30 percent of the sample is silt. The liquid limit of the sample is 43.4 percent and its corresponding plasticity index is 16.1 percent. The sample of soil falls in the general Casagrande classification of lean clay (*CL*) with low plasticity characteristics.[4]

By core sampling, the density of the soil in the vicinity of station 3 was found to be 120 pounds per cubic foot as received and 103.4 pounds per cubic foot after being dried to constant weight.

CONCLUSIONS

The average value of the thermal diffusivity of the soil was found to be 0.019 ft.² hr.$^{-1}$ (0.0049 cm² sec.$^{-1}$) for the soil at a density of 120 pounds per cubic foot. The soil falls in the general Casagrande classification of lean clay (*CL*) with a low plasticity.

† The soil was analyzed by Messrs. L. E. Gregg and N. B. Drake of the Highway Materials Research Laboratory, Department of Highways of the Commonwealth of Kentucky.

I. Indoor Measurement of Microwave Antenna Radiation Patterns by Means of a Metal Lens

G. A. Woonton, R. B. Borts, and J. A. Carruthers
Department of Physics, McGill University, Montreal, P.Q.
(Received October 19, 1949)

The *E*-plane radiation patterns of two horn radiators have been measured in the laboratory with a metal lens by the same method that is used in optical diffraction pattern measurements. Comparison of patterns measured outdoors, by standard methods, with the lens measurements shows little deterioration in precision over the angular interval between ±15 degrees, for horns of aperture width 32 cm, measured by a lens of aperture 110 cm, at a wave-length of 3.2 cm. It was found that a stepped lens was unsatisfactory for this purpose, possibly because of diffraction caused by the steps.

INTRODUCTION

THE radiation pattern of an antenna is a statement of the power that the antenna abstracts from a plane electromagnetic field, expressed as a function of its angular position in the field. The pattern usually takes the form of a graph between power, relative to maximum received power, and angle of rotation measured from the point of maximum reception. Microwave antenna patterns are measured by rotating the antenna on a turntable, in a field set up by a transmitter some tens, hundreds or thousands of feet away. It has been shown by Cutler, King, and Kock[1] that the pattern produced in this way, approximates the true pattern to the extent that the spherical wave front from the transmitter approximates a plane wave in both phase and amplitude. It follows from Eq. (11) of their paper that, as the wave-length is decreased, it becomes increasingly more difficult to find a suitable, clear site for antenna pattern measurements, or conversely, that for a given site there is a wave-length limit below which the precision of measurement deteriorates.

Experiments have shown that, under favorable conditions, antenna patterns can be measured in the laboratory, with the help of a lens, by the same method as that used in optical diffraction measurements. Since both the precision and the convenience of making measurements of this type may be expected to increase with decreasing wave-length, it appears, that in these optical-type measurements there may be found a technique which will supplement standard radio methods in the wave-length range where a small outdoor site tends to become useless. The method is as follows: The spherical wave front from a point source is made plane for pattern measurement, by a metal lens, to an approximation that is determined by incidental diffraction from the aperture of the lens. Subject to restrictions on wave-length, on the sizes of the antenna and the lens, and on the angle of rotation, errors in the laboratory measurement due to incidental diffraction can be calculated and the calculations can be used to correct the measured pattern to the true plane wave pattern. The theory of these calculations, for linear radiators, has been discussed by G. A. Woonton.[2]

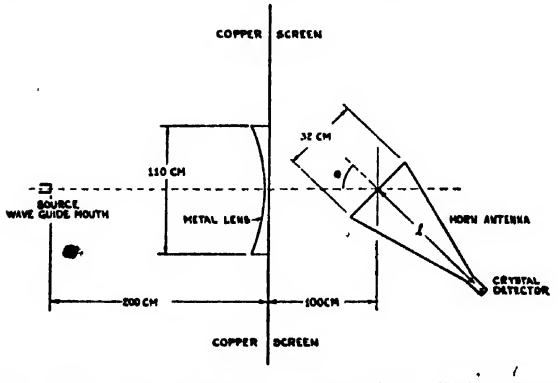

FIG. 1. Plan view of laboratory set-up for radiation pattern measurements at a wave-length of 3.2 cm.

EXPERIMENTAL METHODS AND RESULTS

Figure 1 is a schematic plan view of the measuring apparatus. Figure 2 is a photograph giving some of the details of the equipment. All measurements were made at a wave-length of 3.2 cm.

The source of radiation was the open end of a piece of 1 in.×½ in. wave guide which had been terminated with a plane flange. The open end was fed with 3.2 cm energy, through a wave meter and a calibrated antenuator section, from a Type 723A/B Klystron. The open end of the guide was placed about five feet above the laboratory floor, in line with the center point of the metal lens and at the focal point which was 200 cm behind the back surface of the lens.

Two metal lenses were used in these experiments, both of which were designed, from formulas given by Kock,[3] to have a focal length of 200 cm. The plate spacing for both lenses was chosen to be 2 cm which resulted in an effective refractive index of 0.6, at a wave-length of 3.2 cm. The first of these was a stepped lens of square aperture, 114 cm to the side, and was designed to focus in all planes. The plate spacing was maintained by five columns of metal spacers. It was found that antenna patterns, measured with this lens, exhibited unpredictable divergences from the true

[3] W. E. Kock, Proc. I.R.E. 34, 828 (1946).

radiation pattern and, after a series of modifications, the lens was discarded. The evidence is not conclusive, but it is believed that the final failure of this lens is associated with diffraction from its steps. During the tests with this lens it was found that the metal plate-spacers, which were $\frac{3}{16}$-in. metal cylinders, contributed unwanted diffraction, as did substitute Bakelite spacers. This trouble was eliminated by spacing the plates with acetate foam blocks. The performance of the lens was critically sensitive to the transverse position of the source. The condition was remedied by shielding most of the lens aperture so that the radiation passed through a rectangular slit 110 cm long by 22 cm high, with its long dimension in the plane of measurement.

The second lens was designed for the measurement of linear radiators only, and has been found satisfactory; the measurements which appear in Figs. 3, 4, and 5 were made with it. The lens contour is an elliptic cylinder which focuses in the *E*-plane. The aperture is a rectangle 114 cm in the *E*-plane by 20.6 cm in the *H*-plane. The plates are spaced by slabs of Styrofoam which completely fill the inter-plate space. The lens was mounted in a wooden frame with its center plate parallel to and five feet above the floor. Energy from the source was prevented from reaching the antenna, by paths other than through the lens, by means of a copper screen approximately nine feet square around the lens. The front, uncurved surface of the lens fitted snugly against the edge of an aperture (110 cm by 20.6 cm) which was cut in this screen; the edges of the aperture were given sharp definition by soldering the copper screen around a frame made of formed brass rod.

The correct position of the lens and source and the general adequacy of the set-up were determined by comparing the measured field in front of the aperture with the predicted diffraction field; simple optical theory, applied to the case of a plane wave, of length 3.2 cm incident on an aperture 110 cm by 20.6 cm was used in the calculation. Figure 3 shows that, by careful adjustment, the measured field can be made to approximate the predicted field. In the course of these measurements, it was learned that strong reflections from the windows and the walls could be minimized by setting the lens at an angle to the reflecting surface. The field measurements were made with a dipole and crystal detector mounted on an optical bench. The auxilliary apparatus was the same as that used for antenna measurements.

The *E*-plane patterns of the two horn radiators have been measured by this lens method; Figs. 4 and 5 give the results of these measurements. The field in which the horns were measured was square-wave modulated at six hundred cycles per second by modulating the reflector voltage of the klystron. A crystal detector attached to the apex of the horn converted the modulated received field into an audio voltage, which was amplified by a tuned audio amplifier and measured by a diode and direct current microammeter. The system was calibrated, before the measurements, by plotting the direct current output from the diode against the attenuation setting of a precision, calibrated, vane-type attenuator, which had been interposed between the klystron and the wave guide mouth. The antenna pattern was constructed by recording relative power in decibels (as determined by the microammeter and this graph) against the angular position of the horn in the field.

The copper horns on which experimental measurements were made were flared linearly in both the *E*- and *H*-planes from the end of a piece of standard, laboratory, *X*-band wave guide to a square aperture 32 cm to the side. Figure 4 presents pattern data on one of these horns, which was approximately 50 cm long; Fig. 5 presents data on the other which was about 100 cm long. Results from three different experiments are compared on each of these graphs: the solid line is the horn pattern, measured at an outdoor site, over a measuring path of about 225 feet, following standard procedure; it is considered to be a close approximation to the true antenna pattern. The dashed line is the mutilated distant pattern; a rectangular aperture, of the same dimensions and orientation as that used in the laboratory with the lens, was cut in the center of a large copper screen. The screen and its aperture were erected, at the outdoor site, one meter in front of the horn, between the horn and the distant measuring point 225 feet away. The horn pattern was then measured, following standard procedure. The pattern of the horn, as measured in the lens field in the laboratory, is indicated by crosses.

CONCLUSION

The radiation pattern of a linear antenna can be measured in the laboratory by optical methods, to a precision that is set only by incidental diffraction from the aperture of the lens. If the lens aperture is several times larger than the antenna aperture, the contribution

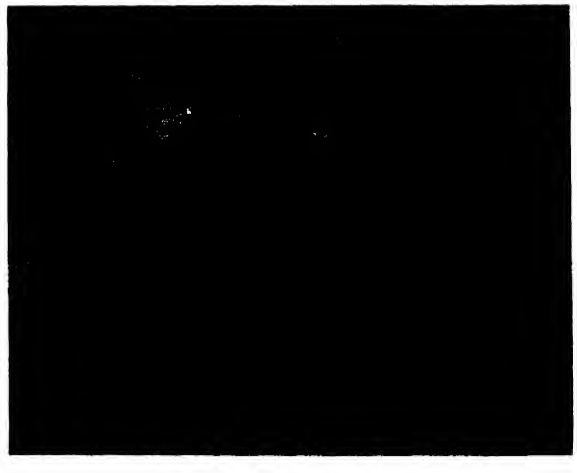

FIG. 2. Equipment used in laboratory measurement of antenna patterns.

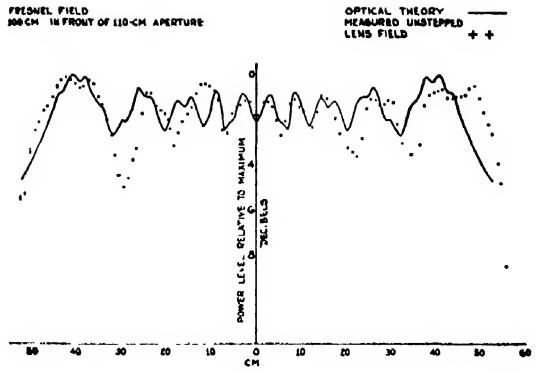

FIG. 3. Comparison of measured and predicted Fresnel field at a distance of 100 cm in front of the lens.

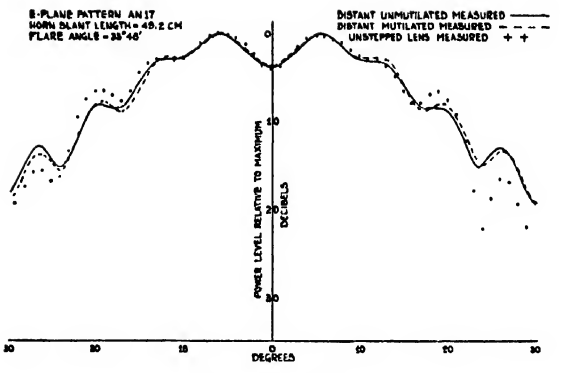

FIG. 4. Comparison of the true radiation pattern, the mutilated distant radiation pattern, and the radiation pattern measured through the lens for the *E*-plane of the 50-cm horn.

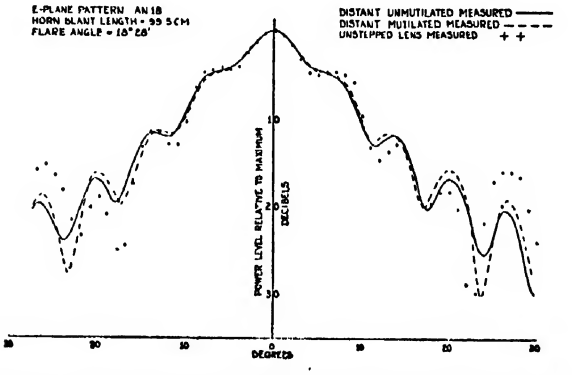

FIG. 5. Comparison of the true radiation pattern, the mutilated distant radiation pattern and the radiation pattern measured through the lens for the *E*-plane of the 100-cm horn.

of incidental diffraction to the center region of the pattern is negligible. Good agreement between patterns measured by the lens method and by the standard outdoor technique was obtained over the angular interval $-15° \leq \alpha \leq 15°$ for a lens aperture of 110 cm, an antenna aperture of 32 cm, and at a wave-length of 3.2 cm; beyond $\pm 15°$ the measured positions of the side lobes are approximately correct, but the relative amplitudes depart from those found by outdoor measurements. The effect of room reflections on these measurements can be minimized by proper location of the apparatus and when so minimized, reflections are not a serious source of error. A stepped lens has been found to be unsatisfactory in this application, probably because of diffraction caused by the steps and in general it has been found necessary to take more care in the design and construction of a lens for measuring purposes than has seemed essential with those to be used as antennas. Although it was found necessary to limit these measurements to the *E*-plane of the horn radiators, it is believed that there is no reason, other than physical size, why the method cannot be applied to all planes of an antenna of any kind.

ACKNOWLEDGMENT

This research was made possible by a grant from the Defence Research Board of the Department of National Defence, Ottawa, Canada. The stepped lens was built and some of the first experiments on it were performed by Messrs. J. H. Blackwell and H. M. Dutton with the senior writer, at the University of Western Ontario. Funds for the construction of the stepped lens and other apparatus used at that time were supplied from a grant made by the National Research Council, Ottawa, Canada. One of us (R.B.B.) is indebted to the National Research Council for a Bursary during the winter term of 1948–49.

Load Induced X-Ray Line Broadening in Nylon Filaments

JOHN KAUFFMAN* AND WALLER GEORGE*
Naval Research Laboratory, Washington, D. C.
(Received October 21, 1949)

The load induced microscopic structural changes in highly oriented Nylon filaments were followed by changes in the x-ray fiber diffraction pattern as a function of the resulting strain. Observations made included (1) changes in the dimensions of the fiber spots, and (2) a decrease in ratio of the intensity of amorphous to crystalline x-ray scattering. These new results for Type 200 du Pont Nylon indicate a change in the micro deformation mechanism at a strain corresponding to the inflection of the load-strain diagram (14 percent elongation). The mechanism for smaller plastic strains appears to involve a rotation of the crystallized domains into alignment with the fiber axis, accompanied by a small over-all additional crystallization. For strains larger than the inflectional strain, the mechanism seems to involve a progressive reduction in the domain size, and a reduction in alignment with the fiber axis. Both effects appear to saturate in the vicinity of the rupture strain. These results are discussed in terms of load induced effects found in metal single and polycrystals. It is suggested that the qualitative features observed may be representative of a wide class of load or strain induced micro deformation reactions in the solid state.

INTRODUCTION

THIS paper** describes a portion of a general research directed toward an understanding of the micro mechanisms of plastic flowing in crystalline high polymers. X-ray diffraction was the tool used for the study, and the material chosen was a strong, highly oriented, crystalline Nylon fiber obtained from E. I. du Pont de Nemours, Inc., denoted as Type 200. The fibers were received as 100 denier monofilaments.

The fine structure of oriented Nylon approaches the state found in polycrystalline metals, but in the case of crystallized polyamides, the crystallites are composed of long, complex molecules instead of atoms. These linear molecules exhibit a high degree of geometric organization within the region of the crystallite. The boundaries between crystallites, while imperfect and ill-defined, consist of what is essentially an "amorphous" material composed of molecules in a disordered state, which may be pictured as coiled and interlaced without geometric simplicity.

The microstructural state of 100 denier filaments of Type 200 is indicated by the x-ray fiber patterns as shown in Fig. 1. They are qualitatively similar to those obtained from polyamide fibers by others.[1] These were obtained using Ni filtered Cu$K\alpha$-radiation at room temperature with film specimen distance of 6 cm. The spots and arcs in the pattern result from periodicities in the crystalline material which scatter the radiation coherently. The disordered intercrystalline material produces the poorly defined amorphous halo at about the reflecting angle of the two very prominent equatorial spots. It is possible to obtain an estimate of the ratio of amorphous to crystalline material present in the specimen by comparing the intensity of the crystalline scattering to the amorphous scattering.[2]

EXPERIMENTAL PROCEDURE

The structure of the material as it is indicated by diffraction patterns was followed as a function of the amount of plastic strain from the initial condition of the specimen through tensile strains up to the rupture point, for strains resulting from a constant time rate of load application of 2.6 grams/denier/minute.

The specimens were in the form of a bundle of 25 monofilaments, and were deformed in tension in a commercial Scott IP-4 inclined plane testing machine.

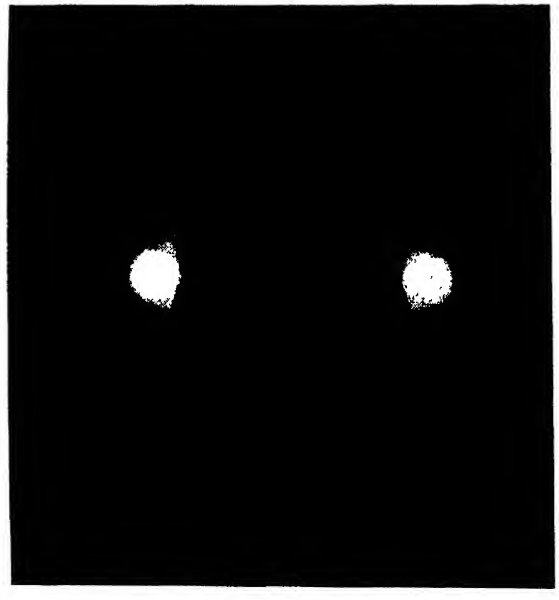

FIG. 1. Typical fiber pattern from Nylon bundle as received. Exposure *ca.* 1 hour. Film-specimen distance 4 cm Cu$K\alpha$-radiation.

** The new results reported in this paper comprise a portion of a thesis submitted by John W. Kauffman to the graduate faculty of the University of Maryland in partial fulfillment of the requirements for the M.S. degree (June, 1949). In abbreviated form, the results were discussed at the Cambridge meeting of the American Physical Society [Phys. Rev. 76, 467 (1949)].

[1] I. Fankuchen and H. Mark, J. App. Phys. 15, 364 (1944).

[2] W. Weidinger and P. H. Hermans, J. App. Phys. 19, 491 (1948).

The machine used was equipped with "drum"-type specimen clamps which had been highly polished to reduce the friction at the fiber-drum interface. As the specimens reached various strains, the loading was abruptly terminated, the specimen clamped at a constant strain, removed from the testing machine, and the diffraction pattern immediately taken. In order to detect effects which might have an appreciable time dependence, additional patterns were taken after the specimen had been under a constant strain for several days; however, no such effects were observed for these times. Hence, one may consider long-time relaxation effects to be negligible for these experiments and therefore it is possible to relate the structural changes shown by the diffraction pattern to the points on the load-elongation curve at which the loading of the specimen was terminated. The time elapsed from the termination of the loading cycle until the beginning of radiation was approximately thirty minutes and held essentially constant for all experiments. This time interval apparently is sufficiently long to allow completion of short-time relaxation processes in all cases. This latter point is demonstrated in Figs. 2a and 2b, which show patterns obtained within one hour after the termination of the loading epoch and forty-eight hours, respectively. The strain used in this case was almost the strain at rupture, 26 percent.

Photometer traces were taken of the spots, arcs and halo of the diffraction patterns. A full interpretation of these patterns involves tedious and laborious procedures. The present paper is concerned with their more direct and obvious features which are pertinent to a plastic deformation study. In all cases attention was confined to relative changes in the diffraction patterns which could be considered to result from plastic flowing.

RESULTS

With deformation it was observed that the diffraction pattern showed (1) changes in the dimensions of the fiber spots and (2) a decrease in the intensity of the amorphous relative to crystalline scattering.

Dimensional changes were observed in the two most prominent equatorial spots and these were of two types, which are designated as angular and radial broadening. The annular width at half-maximum intensity in a direction radially from the center of the pattern was taken as the radial broadness. It has been used by many investigators[3] for determining particle size or for detecting inhomogeneous lattice strains. One can show that the radial broadness of a diffraction spot may result from one or both of two sources: (1) Diffraction from small crystallographically ordered domains which is a function of the domain size, and (2) Diffraction from lattice planes with irregularly varying parameter possibly associated with the existence of internal strains which vary from point to point in the lattice. Simple theories of both types of radial broadness effects are essentially the same, and lead to relations for the dependence of the broadness on the Bragg angle and wave-length of the incident radiation which are identical to a multiplicative constant.[4] However, it will be seen that the data reported below lend themselves more readily to the particle size interpretation.

The angular broadness is defined as the width of the diffraction spot or line at half-maximum intensity taken in a direction at right angles to the radial broadness measurement; that is, the photometer trace is made around the pattern at a constant radius from the center. The angular broadness is taken as a measure of the degree of preferred orientation of the crystallites

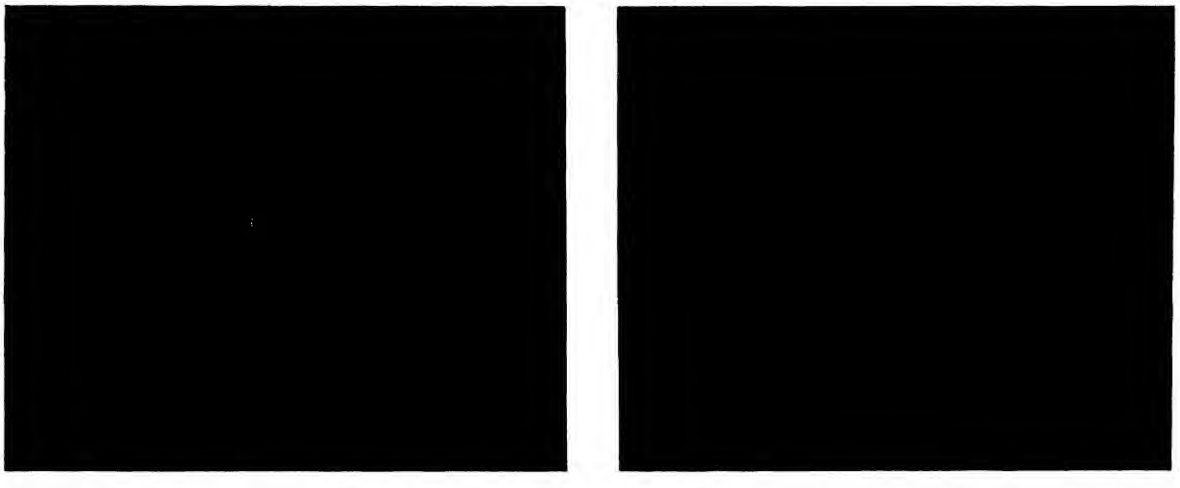

FIG. 2. Fiber patterns after relaxation at constant strain (*ca.* 26 percent). (a) Within 1 hour after termination of straining; (b) 48 hours later.

[3] S. D. Gehman and J. E. Field, J. App. Phys. 15, 371 (1944).
[4] W. L. Bragg, Proc. Camb. Phil. Soc. 45, 125 (1949).

in the fibers. If the orientation of the crystallites is broken down by heating or wetting of the fiber specimen, then the spots will diverge into more complete and uniform rings. As orientation or fibering takes place, the arcs converge into spots of smaller and smaller angular width. The interpretation of this broadness as a measure of the degree of orientation is clear and unambiguous.

Figure 3 shows a typical load-elongation curve for the Nylon used, when loaded at a constant time rate. After a small initial elastic rise followed by a somewhat rounded "yield point," the curve consists of two large portions; a concave upward region terminating in

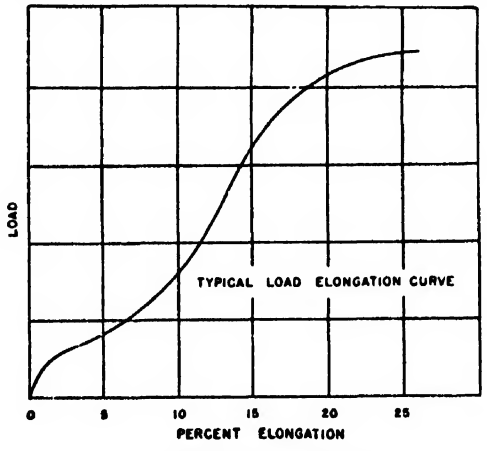

FIG. 3. Typical load elongation for Type 200 Nylon (constant r of load application). Load units arbitrary.

an inflection point at about 14 percent elongation, and a following portion concave to the strain axis which terminates at the rupture point.

Figure 4 is a plot of the results of the angular broadness measurement; they are plotted against the same strain ordinate as in the previous diagram. The broadness decreases up to strains at the inflection point of the load-elongation curve, at which there appears to be a cusp, followed by an increasing broadness to the rupture point. From the interpretation of angular broadness cited above, this plot suggests, for strains up to the inflection point of the load-elongation curve, that the crystallites rotate toward positions parallel to the fiber axis. Further, these data suggest that this process terminates at the inflection point and is replaced by a disordering process. This interpretation is supported by the data shown in Fig. 5. Here the radial broadness is plotted as a function of the elongation. For strains up to the inflection point of the load-elongation curve, the broadness remains approximately constant but rises rapidly for larger strains. From the shape of this curve and from Fig. 3, it seems rather difficult to attribute this radial broadening to tessellated elastic strains, existing throughout the irradiated volume, which would be expected to rise monotonically throughout the straining epoch. On the other hand, it appears logical to associate this with a reduction in particle size, that is, crystallite break-up. Analogous measurements of radial broadening associated with macroscopic plastic torsional strains have been made for metals by Patterson and Orowan.[5] In both the magnitude of the broadness change and in shape, their results are similar to those broadness values shown in Fig. 5 which are associated with strains greater than the inflection point of the Nylon load-strain curve, 14 percent. The view of these authors varies as to the details of interpretation of this result.

The intensity of the amorphous scattering was compared to the crystalline scattering and was found to decrease with strain up to the inflection point of the load-elongation curve, and to remain approximately constant thereafter. Since this measure was difficult to make accurately, we offer at present only the qualitative result.

DISCUSSION

The experimental result and its apparent interpretation which were obtained above can be used together with other known observations concerning plastic flowing in metallic solids to infer a very interesting and probably general characteristic of the reaction of reasonably well-ordered solids to large load applications.

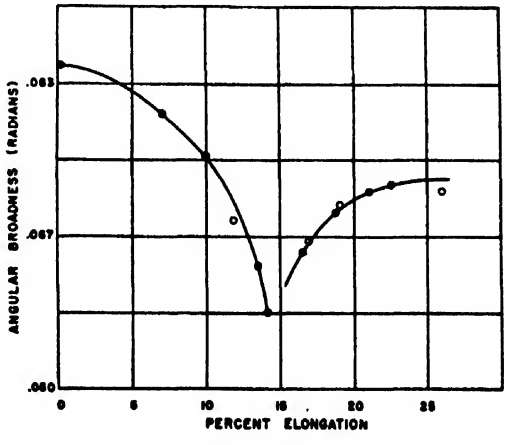

FIG. 4. Angular broadness *vs.* the elongation (%). Type 200 Nylon.

Recently, Koehler and Blewitt,[6] from studies of the changes in electrical resistivity with applied load, have inferred the existence of a sharp change in the micro deformation mechanisms at small plastic strains in ordered $AuCu_3$ single crystals. They have further pointed out that a similar inference can be obtained from: (1) a study of the curvature of "resolved" stress-strain relations of single crystals of $AuCu_3$, Cu, Ag, and Au, (2) x-ray line broadness changes with cold work in polycrystalline Cu, and (3) in other less direct ways. In view of the Nylon result reported above, the

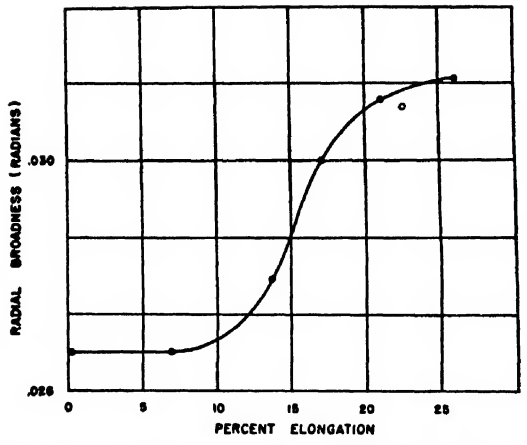

FIG. 5. Radial broadness *vs.* elongation (%). Type 200 Nylon.

Koehler-Blewitt generalization might be revised to the following. For any well-ordered solid, one will likely find in the region of true plastic flowing a narrow region of plastic strain through which there occurs a relatively sharp transition in the micro mechanisms of reaction to applied loads.

Recently, many theoretical papers have appeared which attempt to explain plastic flowing, and apparently related phenomena in metallic solids in terms of elementary units of crystallographic disorder termed "dislocations."[7,8] In view of the relatively high degree of order in the Nylon used for the work reported in this paper, one might seek an explanation of the results presented in terms of the dislocation concept. It should be noted, however, that the broadness measure reported here does not constitute evidence for the existence of particular dislocation arrays or, in fact, any array within a domain, but rather the existence of domains characterized by a linear dimension which is inversely proportional to the broadness. This dimension is the quantity which changes with the applied load. The domain viewpoint focuses, then, one's attention on the physically observed, whereas an explanation of the Nylon effects in terms of a generalized dislocation concept would stress entities which were not observed in the experiments. It is recognized that some type of disorder must exist between domains leading to x-ray line broadness, but it is felt that until experimental techniques are perfected which allow its study, explanations of general mechanical behavior in terms of disorder concepts should be avoided.

The suggestion that there is generally a transition in the microscopic mechanisms of plastic flowing in solids will, if verified, pose important theoretical problems. Currently, theoretical discussions of work hardening, e.g., in terms of dislocations often assume what is essentially an "exhaustion" hypothesis. Given amounts of the disorder are thought to initially exist. These theories explain the effects associated with continued plastic flowing in terms of the diminution of the number of elementary disordered regions with increased strain or time. Such exhaustion theories will surely require modifications if they are to account for the possibility of a transition in the micro reactions to gross flowing. The physical nature of flowing in solids, whatever it is, is surely extremely complex, even in what might be termed "simple" cases.

CONCLUSIONS

The new data for highly oriented Nylon fibers presented indicate a change in the nature of plastic flowing, which occurs in the straining cycle at the point of inflection of the load-elongation curve (approximately 14 percent elongation). In the initial portion of the curve, the mechanism of flowing appears to involve rotation of the crystallites toward positions parallel to the fiber axis accompanied by an additional crystallization at the expense of the amorphous material initially present. The latter follows directly from the variations noted in the ratio of the intensity of the amorphous halo to that of the diffraction spots. This process terminates at the inflection point and is replaced by a mechanism of crystallite break-up, and disorientation.

The x-ray line broadness effects in Nylon, coupled with less direct effects observed in metallic solids which appear to be related to plastic straining all point to the existence in these solids of at least two types of microscopic reactions resulting from the load application. The experimental evidence, while not as direct as might be desired in some cases, seems to point to the existence of domains of nearly perfect atomic order, the motions and sizes of which are altered by the macroscopic flowing. Finally, from the domain viewpoint, it would appear that there are more general similarities between the micro reactions of well-ordered solids to applied loads than is commonly accepted. Obviously, domain structure on the atomic scale varies with materials, but it may be that this scale of structure is unimportant in describing at least some of the qualitative features of microscopic plastic flowing reactions.

Aluminum Oxide Replicas for Electron Microscopy Produced by a Two-Step Process

G. Hass and M. E. McFarland
Engineer Research and Development Laboratories, Fort Belvoir, Virginia
(Received October 26, 1949)

A two-step method is described for preparing aluminum oxide replicas of aluminum and non-aluminum specimens. In this method a thick layer of aluminum is evaporated onto the surface to be studied and pulled off the surface with Scotch Tape or cement covered glass. Aluminum oxide is formed on the side of the aluminum film which has been in contact with the specimen by anodizing in 3 percent ammonium tartrate at about 40 volts. The aluminum oxide film, which represents a positive replica of the specimen surface, is released from its substrate in dilute hydrochloric acid, washed with distilled water, and mounted for the electron microscope investigation. The applicability of the described method is demonstrated with electron micrographs of various specimens. The aluminum oxide films produced in ammonium tartrate are free of pores and grain structure. Films only 100 to 150A in thickness can be prepared and are suitable as temperature resistant supporting membranes for electron microscope and electron diffraction investigations.

ALUMINUM oxide coatings produced anodically in a suitable electrolyte have proved to be particularly useful as replica films for electron microscope studies.[1] Originally, however, the application of this method was restricted to aluminum and aluminum alloys on which anodic films can be formed directly. Only recently there was reported a modification of this method, a two-step process, applicable to studies of the surfaces of some non-aluminum materials.[2] In this process a piece of electrolytically polished pure aluminum is pressed against the surface to be studied; thus an aluminum replica is produced. On this aluminum replica a thin anodic film is produced and then removed chemically for examination in the electron microscope. Evidently this "engraving method" is only applicable to studies of extremely hard surfaces which are not damaged or changed by the high pressure required to press the aluminum against them.

By using a double replica method similar to the silver-collodion one first suggested by Zworykin and Ramberg,[3] a more general application of anodic aluminum oxide as replica film can be obtained. The specimen to be investigated is placed in a vacuum chamber and a thick film of aluminum ($t > 1\mu$) and a thin layer of magnesium ($t < 0.1\mu$) is evaporated onto its surface. The specimen is removed from the vacuum chamber and the magnesium-aluminum film is pulled off the surface with Scotch Tape or a cement covered glass slide. If the aluminum is sufficiently thick, the magnesium-aluminum layer can readily be removed from most specimens without damaging their surfaces. Aluminum oxide is now formed on the

side of the aluminum film which has been in contact with the specimen by anodizing with 30–40 volts for 20–30 sec. The electrolyte used for the anodic oxidation is a solution of 3 percent tartaric acid with ammonium hydroxide added to make the *p*H about 5.5. The thin magnesium film placed between the aluminum and the Scotch Tape or cement makes the separation of the aluminum oxide replica easier and faster than it would be with aluminum only. If the film now consisting of aluminum oxide, aluminum, and magnesium on Scotch Tape is immersed in dilute hydrochloric acid the magnesium dissolves rapidly and the aluminum film with the oxide replica on top rises to the surface in less than a minute. There the aluminum also dissolves in a few minutes and the aluminum oxide replica film is left floating on the surface. After being washed in distilled water, the replica film can be mounted on a support screen for the electron microscope investigation. Replicas produced by the above method can be shadow cast to increase the contrast of surface details. Germanium has been used for shadowing because it evaporates easily and forms films with glass-like structure when condensed onto unheated bases.[4,5] Figures 1 and 2 are unshadowed and germanium-shadowed aluminum oxide replicas of a 30,000 lines/inch grating obtained by the aluminum-aluminum oxide method. The replicas were made from a reflection grating ruled on an evaporated aluminum mirror. It is remarkable that a thick film of aluminum evaporated onto the aluminum grating can be removed without damaging the grating. Aluminum-aluminum oxide replicas have been made from the original grating more than 30 times without changing its appearance. The unshadowed grating replicas (Fig. 1) show sharp dark lines and are therefore especially suitable for calibrating the magnification of electron microscopes and for measuring particle sizes exactly. The fact that anodic aluminum oxide films are of uniform thickness and of temperature resistant material makes the replicas withstand electron bombardment of high intensity. The germanium shadowed replica (Fig. 2) shows more contrast and detail and allows a better study of the grating surface. Figures 3 and 4 demonstrate the general applicability of the two-step replica method described above. Figure 3 shows an electron micrograph of a Plexiglass surface scratched by careful cleaning with cotton and Fig. 4 represents the surface of a KRS-5 crystal (TlBr-TlI) on which KRS-5 has been condensed slowly at high temperature.
